Plants and algae can take up sulfur and incorporate it into proteins, but bacteria and archaeons dominate the sulfur cycle by means of oxidation and reduction reactions that are linked to the carbon cycle. [page 528](#)

Some bacteria and archaeons can reduce nitrogen gas to ammonia in a process called nitrogen fixation. [page 529](#)

The nitrogen cycle also involves oxidation and reduction reactions by Bacteria and Archaea that are linked to the carbon cycle. [page 530](#)

**24.4 BACTERIAL DIVERSITY:** Genomic surveys of non-culturable bacteria reveal the extent of bacterial diversity.

Traditionally, bacterial groups were recognized by their morphology, physiology, and ability to take up specific stains in culture. [page 530](#)

Direct sequencing of genes, and now genomes, from organisms in soil and seawater samples has revealed new groups of bacteria. [page 530](#)

Proteobacteria are the most diverse group of bacteria; they are involved in many of the biogeochemical processes that are linked to the carbon cycle. [page 534](#)

Gram-positive bacteria include important disease-causing strains as well as species that are principal sources of antibiotics. [page 534](#)

Photosynthetic bacteria are not limited to a single branch of the bacterial tree. [page 534](#)

**24.5 ARCHAEAL DIVERSITY:** The diversity of Archaea has only recently been recognized.

Archaeons tend to thrive where energy available for growth is limited. [page 535](#)

Archaea are commonly divided into three major groups, called DPANN, TACK, and Euryarchaeota. [page 535](#)

Archaeons that branch from the earliest nodes are hyperthermophiles, meaning that they grow only at high

temperatures. [page 536](#)

A number of archaeons grow in highly acidic waters, such as those associated with acid mine drainage. [page 537](#)

Some archaeons (but no bacteria or eukaryotes) generate methane as a by-product of their energy metabolism, thereby making important contributions to climate and the carbon cycle. [page 537](#)

Haloarchaea are archaeons that can live only in extremely salty environments. [page 537](#)

Thaumarchaeotes are among the most abundant cells in the oceans. [page 537](#)

## **24.6 THE EVOLUTIONARY HISTORY OF PROKARYOTES:**

The earliest forms of life on Earth were Bacteria and Archaea

Evidence for the early history of life comes from microfossils, fossilized structures called stromatolites, and the isotopic composition of rocks and organic matter. [page 539](#)

Fossils indicate that life on Earth originated more than 3.5 billion years ago. [page 539](#)

The early atmosphere and ocean contained little or no free oxygen. [page 540](#)

Oxygen began to accumulate in the atmosphere and oceans approximately 2.4 billion years ago as a result of the success of cyanobacteria utilizing oxygenic photosynthesis. [page 540](#)

Prokaryotic metabolisms were essential in the early history of Earth

and remain vital today, as many forms of life depend on biogeochemical cycles and metabolisms unique to Bacteria and Archaea. [page 540](#)

Most animals, including humans, live in intimate association with bacteria, which in turn affect health. [page 541](#)

## CHAPTER 25 Eukaryotic Cells Origins and Diversity

Lebendkulturen.de/Shutterstock

---

## CORE CONCEPTS

**25.1 A REVIEW OF THE EUKARYOTIC CELL:** Eukaryotic cells are defined by the presence of a nucleus, but features such as a dynamic cytoskeleton and membrane system explain their evolutionary success.

**25.2 EUKARYOTIC ORIGINS:** The endosymbiotic hypothesis proposes that the chloroplasts and mitochondria of eukaryotic cells were originally free-living bacteria.

**25.3 EUKARYOTIC DIVERSITY:** Eukaryotes were formerly divided into four kingdoms, but are now divided into at least seven superkingdoms.

**25.4 THE FOSSIL RECORD OF PROTISTS:** The fossil record provides perspectives on the timing and environmental context of eukaryotic evolution.

---

Eukaryotic cells have a nucleus, which serves as their defining characteristic. As we will see, however, it is quite another set of features that distinguishes eukaryotes in terms of their function and their capacity for evolutionary innovation. Eukaryotic diversity—the animals, plants, fungi, and protists we are familiar with—does not reflect exceptional versatility in energy metabolism. In fact, compared with Bacteria and Archaea, the Eukarya obtain carbon and energy in only a limited number of ways. For example, oxygenic photosynthesis and aerobic respiration are widespread among eukaryotes, but anoxygenic photosynthesis is unknown. Furthermore, anaerobic respiration has been reported in only a handful of species, while chemoautotrophy has not been documented in eukaryotes at all. Many

eukaryotes can ferment organic substrates, but with the exception of yeasts, which are particularly active fermenters, most use fermentation only as a supplementary metabolism.

Why then, have eukaryotes been so successful? The source of eukaryotic success lies in their remarkable capacity to form cells of diverse shapes and sizes and to produce multicellular structures in which multiple cell types act in concert. Together, these innovations opened up a range of possibilities for structure and function not found among Bacteria and Archaea. Eukaryotic diversity includes cells that can engulf other cells, as well as organisms as large as redwoods and as complex as humans.

# 25.1 A REVIEW OF THE EUKARYOTIC CELL

[Chapter 5](#) introduced the fundamental features of eukaryotic cells.

Here, we revisit those attributes ([Fig. 25.1](#)) and consider their consequences for function and diversity. How do eukaryotic cells differ from bacteria and archaeons, and how do these differences explain the roles that eukaryotes play in modern ecosystems?

# Internal protein scaffolding and dynamic membranes organize the eukaryotic cell.

All cells require a mechanism to maintain spatial order in the cytoplasm. As we saw in [Chapter 24](#), bacteria and archaeons rely primarily on walls that support the cell from the outside, along with a relatively rigid framework of proteins within the cytoplasm. Some eukaryotic cells have walls, but many others, including the cells in your body, do not. Eukaryotes rely mainly on an internal scaffolding of proteins to organize the cell, with most of those supports being microtubules composed of the protein tubulin and microfilaments of actin. This cytoskeleton, which is found in all eukaryotic cells, differs in one key property from the protein framework of bacteria: it can be remodeled quickly, enabling cells to change shape ([Chapter 10](#)).

Dynamic cytoskeletons require dynamic membranes that enable the cell to continue functioning even as it changes shape; eukaryotes maintain within their cells a remarkably dynamic network of membranes called the endomembrane system ([Chapter 5](#)). This network includes the nuclear envelope, an assembly of membranes that runs through the cytoplasm called the endoplasmic reticulum (ER) and Golgi apparatus, and a plasma membrane that surrounds the cytoplasm. All membranes of the endomembrane system are interconnected, either directly or by the movement of vesicles. Many are also capable of changing shape rapidly. In fact, the different membranes are interchangeable in the sense that material originally added to the endoplasmic reticulum may in time be transferred to the cell membrane

or nuclear membrane. Biologists like to say that the membranes of eukaryotic cells are in dynamic continuity. Membranes that are stable, as required for energy metabolism, occur only in the mitochondria and chloroplasts.

In combination, the dynamic cytoskeleton and the membrane system provide eukaryotes with new possibilities for movement. For example, amoebas extend finger-like projections that pull the rest of the cell forward. The cytoskeleton and membrane system also enable eukaryotic cells to engulf molecules or particles, including other cells, in a process called endocytosis; prokaryotic cells cannot perform this activity. Phagocytosis is a specific form of endocytosis in which eukaryotic cells surround food particles and package them in vesicles that bud off from the cell membrane ([Fig. 25.2](#)). When packaged in this way, the particles can be transported into the cell interior for digestion. The same process also works in reverse: in exocytosis, molecules or cytoplasmic waste formed within the cell are packaged in vesicles and moved to the cell surface for removal ([Chapter 5](#)).

Source: Valentina Mercanti et al. Selective membrane exclusion in phagocytic and macropinocytotic cups, *Journal of Cell Science* 119, 4079–4087. doi:10.1242/jcs.03190

**FIG. 25.2 Phagocytosis.** The flexibility of the eukaryotic cytoskeleton and membrane system enables eukaryotic cells to engulf food particles, including other

cells. This sequence shows an amoeba engulfing a yeast cell. Note how the cell membrane (green) folds inward locally to form a vesicle around the red food particle.

Intracellular vesicles and the molecules they carry are transported through the cytoplasm by means of molecular motors associated with the cytoskeleton ([Chapter 10](#)). In this way, both nutrients and signaling molecules move through the cell at speeds much greater than diffusion allows. A major consequence of this accelerated pace of transport is that eukaryotic cells can be much larger than most bacteria.

The cytoskeleton and membrane system are flexible in another way: a change in the expression of a few genes can change their shape and organization. This flexibility makes possible yet another hallmark of eukaryotic evolution—complex multicellularity ([Chapter 26](#)). In complex multicellular organisms, patterns of gene expression can differ from cell to cell. A change in gene expression can modify the cytoskeleton and membranes of individual cells, enabling cells to function in different ways.

## In eukaryotic cells, energy metabolism is localized in mitochondria and chloroplasts.

Relative to prokaryotic organisms, eukaryotes are fairly limited in the ways they obtain carbon and energy. Moreover, the metabolic processes that power eukaryotic cells take place only in specific organelles. Specifically, aerobic respiration occurs in the mitochondrion ([Chapter 7](#)), and photosynthesis in the chloroplast

([Chapter 8](#)). Only limited anaerobic processing of food molecules takes place within the cytoplasm.

As noted earlier, many eukaryotic cells engulf food particles and package them inside a vesicle, which is then transported into the cytoplasm. Within the cytoplasm, enzymes break down the particles into molecules that can be processed by the mitochondria. Many single-celled eukaryotes feed on bacteria or other eukaryotic cells. Animals, in turn, ingest larger foodstuffs, including other animals and plants. As a consequence, eukaryotes can exploit sources of food that are not readily available to bacterial heterotrophs, which feed on individual molecules. This ability opened up the great new ecological possibility of predation, which vastly increased the complexity of interactions among organisms.

The structural flexibility of eukaryotic cells also allows photosynthetic eukaryotes to interact with their environment in ways that photosynthetic bacteria cannot. Unicellular algae (which are eukaryotes) can move effectively through surface waters vertically as well as horizontally and, therefore, can seek and exploit local patches of nutrients. Diatoms, discussed shortly, go one step further: they store nutrients in large internal vacuoles for later use when nutrient levels in the environment become low. Plants have evolved multicellular bodies with many different cell types. For example, specialized cell types working together can provide leaves high in the canopy of trees with water and nutrients from the soil in which the plants are rooted. Thus supplied, leaves can capture sunlight many meters above the ground, giving plants a tremendous advantage on land.

## The organization of the eukaryotic genome also helps explain eukaryotic diversity.

Bacteria and Archaea absorb available nutrients quickly, and both rapid deployment of metabolic enzymes and rapid reproduction are key to exploiting patchily distributed nutrients. DNA replication needs to be fast for reproduction to also be fast. In bacteria, the speed of DNA replication is limited because the majority of the cell's DNA is organized in a single circular chromosome, and replication begins from only one site. As a result, selection favors those strains of Bacteria and Archaea that retain only the genetic material vital to the organism.

Eukaryotes have multiple linear chromosomes and can begin replication from many sites on each one. On this basis, eukaryotes are able to replicate multiple strands of DNA simultaneously and rapidly ([Chapter 12](#)). This ability relieves the evolutionary pressure for streamlining, allowing eukaryotic genomes to build up large amounts of DNA that do not code for proteins. Most of this additional DNA was originally considered to have no function; indeed, it was traditionally called “junk DNA.” That view has been modified in recent years, as the complete genome has become better understood ([Chapter 13](#)). Although eukaryotic genomes do appear to contain truly junky DNA, at least some of the DNA that does not code for proteins functions in gene regulation ([Chapter 18](#)). This regulatory DNA gives eukaryotes the fine control of gene expression required for both multicellular development and complex life cycles, two major features of eukaryotic diversity.

At this point, you can see that the evolutionary success of eukaryotes rests on a combination of features. The innovations of their dynamic cytoskeletal and membrane systems gave eukaryotes the structure required to support larger cells with complex shapes and the ability to ingest other cells. Thus, early unicellular eukaryotes did not gain a foothold in microbial ecosystems by outcompeting bacteria and archaeons, but rather succeeded by evolving novel functions such as the capacity to remodel cell shape. Along with these new functions, eukaryotes evolved complex patterns of gene regulation, which in turn enabled unicellular eukaryotes to evolve complex life cycles and multicellular eukaryotes to generate multiple, interacting cell types during growth and development. These abilities opened up still more possibilities for novel functions, which we explore in this and later chapters.

## Sex promotes genetic diversity in eukaryotes and gives rise to distinctive life cycles.

In [Chapter 24](#), we saw how Bacteria and Archaea generate genetic diversity by horizontal gene transfer. Horizontal gene transfer has been documented in eukaryotic species, though it is relatively uncommon. How, then, do eukaryotes generate and maintain genetic diversity within populations? The answer is quite simple: sex.

Sexual reproduction involves meiosis and the formation of gametes, and the subsequent fusion of gametes during fertilization ([Chapters 11](#) and [40](#)). Sex promotes genetic variation in two basic ways. First,

meiotic cell division results in gametes that are genetically unique. Each gamete has a combination of alleles different from the other gametes and from the parental cell as a result of recombination and independent assortment. Second, in fertilization, new combinations of genes are brought together by the fusion of gametes. Interestingly, a few eukaryotic groups have lost the capacity for sexual reproduction. The best studied of these eukaryotes are tiny animals called bdelloid rotifers. The genetic diversity of these organisms is actually quite high, as it is maintained by high rates of horizontal gene transfer.

Meiotic cell division results in **haploid** cells, which have one set of chromosomes. Sexual fusion brings two haploid ( $1n$ ) cells together to produce a **diploid** ( $2n$ ) cell that has two sets of chromosomes. The life cycle of sexually reproducing eukaryotes, then, necessarily alternates between haploid and diploid states.

Many single-celled eukaryotes normally exist in the haploid stage and reproduce asexually by mitotic cell division (**Fig. 25.3a**). The green alga *Chlamydomonas* is one such organism. Nevertheless, under the right conditions, such as starvation or other environmental stress, two cells may fuse, forming a diploid cell, or **zygote**. The zygote formed by these single-celled eukaryotes commonly functions as a resting cell. It covers itself with a protective wall and then lies dormant until environmental conditions improve. In time, further signals from the environment induce meiotic cell division, resulting in four genetically distinct haploid cells that emerge from their protective coating to complete the life cycle.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 25.3 Eukaryotic life cycles. (a and b) The life cycles of single-celled eukaryotes differ in the proportion of time spent as haploid ( $1n$ ) versus diploid ( $2n$ ) cells. (c) The life cycles of animals have many mitotic divisions between formation of the zygote and meiosis. (d) Vascular plants have two multicellular phases.

As shown in [Fig. 25.3b](#), some single-celled eukaryotes normally exist as diploid cells. An example is provided by the diatoms, single-celled eukaryotes commonly found in lakes, soils, and seawater. Most diatom cells are diploid and reproduce asexually by mitotic cell division to make more diploid cells. Because their external mineralized skeletons constrain their growth, diatoms become smaller with each asexual division. Once a critical size is reached, meiotic cell division is triggered, producing haploid gametes that fuse to regenerate the diploid state as a round, thick-walled cell. This cell eventually germinates to form an actively growing cell with a mineralized skeleton. In diatoms,

then, short-lived gametes constitute the only haploid phase of the life cycle.

The two life cycles just introduced, of *Chlamydomonas* and diatoms, are similar in many ways. In both, haploid cells fuse to form diploid cells, and diploid cells undergo meiotic cell division to generate haploid cells. Both life cycles also commonly include cells capable of persisting in a protected form when the environment becomes stressful. Why some single-celled eukaryotes usually occur as haploid cells and others usually occur as diploid cells remains unknown—a good question for continuing research.

Sexual reproduction has never been observed in some eukaryotes, but most species appear to be capable of sex, even if they reproduce asexually most of the time. Variations on the eukaryotic life cycle can be complex, especially in parasitic microorganisms that have multiple animal hosts. All, however, have the same fundamental components as the two life cycles described here.

In chapters that follow, we discuss multicellular organisms in detail. Here we note only that animals, plants, and other complex multicellular organisms have life cycles with the same features as those just discussed. The big difference is that in animals, the zygote divides many times to form a multicellular diploid body before a small subset of cells within the body undergoes meiotic cell division to form haploid gametes (eggs and sperm). During fertilization, the egg and sperm combine sexually to form a zygote ([Fig. 25.3c](#)). In animals, as in diatoms, the only haploid phase of the life cycle is the gamete. As we

will see in [Chapter 28](#), plants have two multicellular phases in their life cycle, one haploid and one diploid ([Fig. 25.3d](#)). Like single-celled eukaryotes, many plants and animals can reproduce asexually. Humans and other mammals are unusual in that we cannot reproduce asexually.

#### Self-Assessment Questions

1. Which features distinguish a eukaryotic cell from a prokaryotic cell?
2. Which forms of energy metabolism are found in eukaryotes?
3. How did the evolutionary expansion of eukaryotic organisms change the way carbon is cycled through biological communities?

## 25.2 EUKARYOTIC ORIGINS

In the preceding section, we reviewed the basic features of eukaryotic cells. The distinctive cellular organization of Eukarya differs markedly from the cells of Bacteria and Archaea. How did the complex cells of eukaryotes come to exist? In [Case 5: The Human Microbiome](#), we saw that symbioses are common, even in humans. Is the relationship between humans and bacteria unusual, or are symbioses so fundamental that they played key roles in the evolution of the eukaryotic cell?

### CASE 5 THE HUMAN MICROBIOME: DIVERSITY WITHIN

## What role did symbiosis play in the origin of chloroplasts?

The chloroplasts found in plant cells closely resemble certain photosynthetic bacteria, specifically cyanobacteria. The molecular workings of photosynthesis are nearly identical in the two, and internal membranes organize the photosynthetic machinery in similar ways ([Chapter 8](#)). The Russian botanist Konstantin Sergeevich Merezhkovsky recognized this similarity more than a century ago. He also realized that corals and some other organisms harbor algae within their tissues as symbionts that aid the growth of their host. A [symbiont](#) is an organism that lives in closely evolved association with another species. This association, called [symbiosis](#), is discussed in [Chapter 45](#).

Putting these two observations together, Merezkhovsky came up with a radical hypothesis. Chloroplasts, he argued, originated as symbiotic cyanobacteria that through time became permanently incorporated into their hosts. Such a symbiosis, in which one partner lives within the other, is called an [endosymbiosis](#). Merezkhovsky's hypothesis of chloroplast origin by endosymbiosis was difficult to test with the tools available in the early twentieth century, and his idea was dismissed, more neglected than disproved, by most biologists.

In 1967, American biologist Lynn Margulis resurrected the endosymbiotic hypothesis. She supported her arguments with new types of data made possible by the then-emerging techniques of cell and molecular biology ([Fig. 25.4](#)). Transmission electron microscopy revealed that the structural similarities between chloroplasts and cyanobacteria extend to the submicrometer level, such as in the organization of the photosynthetic membranes. It also became clear that the chloroplasts in red and green algae (and in land plants) are separated from the cytoplasm that surrounds them by two membranes. This arrangement would be expected if a cyanobacterial cell had been engulfed by a eukaryotic cell. The inner membrane corresponds to the cell membrane of the cyanobacterium, and the outer one is part of the engulfing cell's membrane system, as shown in [Fig. 25.2](#). In addition, the biochemistry of photosynthesis is essentially the same in cyanobacteria and chloroplasts. Both use two linked photosystems, including a common mechanism for extracting electrons from water, and both rely on the same reactions to reduce carbon dioxide (CO<sub>2</sub>) to form organic matter ([Chapter 8](#)).

HOW DO WE KNOW?

## FIG. 25.4

### What is the evolutionary origin of chloroplasts?

#### BACKGROUND

Transmission electron microscopy shows that cyanobacteria (top), red algal chloroplasts (middle), and plant chloroplasts (bottom) have very similar internal membranes. These structures, recognizable in the images as parallel laminae within cells or chloroplasts, organize the light reactions of photosynthesis. Other structural and biochemical features also indicate a strong similarity between cyanobacteria and the chloroplasts found in photosynthetic eukaryotes.

*Photos (top to bottom): Dr. Kari Lounatmaa/Science Source; Biology Pics/Getty Images; Dr. Jeremy Burgess/Science Source.*

### HYPOTHESIS

The similarities between cyanobacteria and chloroplasts reflect descent from a common ancestor: chloroplasts evolved from cyanobacteria living as endosymbionts within a eukaryotic cell.

### EXPERIMENT

Like cyanobacteria, chloroplasts have DNA organized in a single circular chromosome. Biologists sequenced genes for small-subunit rRNA in

chloroplasts and compared the sequences to those for small-subunit rRNA in the nuclei of various eukaryotes and in bacteria, including cyanobacteria. Phylogenies based on molecular sequence comparisons place chloroplasts unambiguously among the cyanobacteria.

#### CONCLUSION

Molecular and electron microscope data support the hypothesis that chloroplasts originated as endosymbiotic cyanobacteria.

SOURCE Giovannoni, S. J., et al. 1988. "Evolutionary Relationships among Cyanobacteria and Green Chloroplasts." *Journal of Bacteriology* 170:3584–3592.

Such observations kindled renewed interest in the endosymbiotic hypothesis, but the decisive tests were made possible by another, and unexpected, discovery. It turns out that chloroplasts have their own DNA, which is organized into a single circular chromosome, like that of bacteria. Because of this, investigators were able to use the tools of molecular sequence comparison ([Chapter 22](#)) to study chloroplast genes. The sequences of nucleotides in chloroplast genes closely match those of cyanobacterial genes but are strikingly different from the sequences of nucleotides in genes within the nuclei of photosynthetic eukaryotes. This finding provides strong support for the hypothesis of Merezhkovsky and Margulis. Chloroplasts are indeed the descendants of symbiotic cyanobacteria that lived within eukaryotic cells.

Eukaryotes were able to acquire the ability to perform photosynthesis because they could engulf and retain cyanobacterial cells. But engulfing another microorganism was just the beginning. The cyanobacteria most closely related to chloroplasts have 2000 to 3000 genes. In contrast, among photosynthetic eukaryotes, chloroplast

gene numbers vary from just 60 to 200. Where did the rest of the cyanobacterial genome go? Some genes may simply have been lost if similar nuclear genes could supply the chloroplast's requirements. Many others were transported to the nucleus when chloroplasts broke or by hitching a ride with viruses. As an example, the nuclear genome of the flowering plant *Arabidopsis* contains several thousand genes of cyanobacterial origin, some of which code for proteins destined for use within the chloroplast.

Although foreign to mammals and other vertebrate animals, symbiosis between a heterotrophic host and a photosynthetic partner is common throughout the eukaryotic domain. For example, reef corals harbor photosynthetic cells that live symbiotically within their tissues. Some corals have even lost the capacity to capture food from surrounding waters. Giant clams of the genus *Tridacna*, found in tropical Pacific waters, also obtain some or even most of their nutrition from symbiotic algae that live within their tissues.

Until recently, most biologists agreed that chloroplasts originated from endosymbiotic cyanobacteria only once, in a common ancestor of the green algae and red algae. Now, remarkably, a second case of cyanobacterial endosymbiosis has come to light. *Paulinella chromatophora* is a photosynthetic amoeba ([Fig. 25.5](#)). Gene sequence comparisons show that its chloroplast originated in a branch of the cyanobacteria different from the one that gave rise to chloroplasts in other photosynthetic eukaryotes. Approximately one-third to one-half of the ancestral genome remains in *P. chromatophora* chloroplasts, suggesting that in this organism chloroplast evolution is still in

progress.

Source: Courtesy of Hwan Su Yoon.

FIG. 25.5 A second example of chloroplast endosymbiosis. The photosynthetic amoeba *Paulinella chromatophora* acquired photosynthesis by endosymbiosis independently of, and more recently than, the endosymbiotic event that established chloroplasts in the algal ancestors of green plants.

## CASE 5 THE HUMAN MICROBIOME: DIVERSITY WITHIN

# What role did symbiosis play in the origin of mitochondria?

Like chloroplasts, mitochondria closely resemble free-living bacteria in organization and biochemistry. Also like chloroplasts, mitochondria contain DNA that confirms their close phylogenetic relationship to a form of bacteria—in this case, proteobacteria ([Chapter 24](#)). Like chloroplasts, then, mitochondria originated as endosymbiotic bacteria.

Mitochondria are also like chloroplasts in having a small genome. Indeed, the mitochondrial genome is dramatically reduced compared to

the ancestral proteobacterial genome; in most eukaryotes, it contains only a handful of functioning genes. Human mitochondria, for example, code for just 13 proteins and 24 RNAs. Once again, many genes from the original bacterial endosymbiont migrated to the nucleus, where they still reside.

Most eukaryotic cells contain mitochondria, but a few single-celled eukaryotic organisms found in oxygen-free environments do not. Biologists had originally hypothesized that these eukaryotes evolved before the endosymbiotic event that established mitochondria in cells having a nucleus, but that proposal was abandoned when it was recognized that genes migrated from the endosymbiont to the host's nucleus. In fact, every mitochondria-free eukaryote examined to date has relict mitochondrial genes in its nuclear genome. This finding provides support for a second hypothesis, that eukaryotic cells without mitochondria had them once but have lost them.

Many eukaryotes that lack mitochondria contain small organelles called hydrogenosomes that generate ATP by anaerobic processes ([Fig. 25.6](#)). These organelles have little or no DNA, but genes of mitochondrial origin are found in the cell's nuclei. These genes code for proteins that function in the hydrogenosome. Thus, hydrogenosomes appear to be highly altered mitochondria adapted to life in oxygen-poor environments.

Normal mitochondrion in *Euplotes*

Altered mitochondrion in *Nyctotherus* produces ATP and generates hydrogen. The small dark body in lower right is an endosymbiotic archaeon.

Source: Reprinted by permission from Macmillan Publishers Ltd: B. Boxma, et al., 2005, "An Anaerobic Mitochondrion That Produces Hydrogen," *Nature* 434:74–79. Copyright 2005.

FIG. 25.6 Transmission electron microscope images comparing mitochondria within the aerobic protist *Euplotes* (left) and *Nyctotherus*, a close relative that lives in oxygen-free environments (right). The organelle in *Nyctotherus* is halfway between a normal mitochondrion and a hydrogenosome, supporting the view that these two organelles are descended from a common ancestor.

Other anaerobic eukaryotes contain still smaller organelles called mitosomes that also appear to be remnant mitochondria. Interestingly, mitosomes have lost all capacity for metabolism, but they do retain genes needed for assembling the clusters of iron and sulfur found in many proteins. Why these genes are retained in a modified mitochondrion remains unknown.

## CASE 5 THE HUMAN MICROBIOME: DIVERSITY

WITHIN

# How did the eukaryotic cell originate?

If mitochondria originated as proteobacteria and chloroplasts as

cyanobacteria, where does the rest of the eukaryotic cell come from? Analysis of the nuclear genome alone provides no clear answer to this question, because genes of bacterial, archaeal, and purely eukaryotic origin are all present. As discussed, many nuclear genes originated with the mitochondria and chloroplasts acquired from specific bacteria. However, genes from other groups of bacteria also reside in the eukaryotic nucleus, recording multiple episodes of horizontal gene transfer through evolutionary history. In contrast, some genes are present only in eukaryotes and apparently evolved after the domain originated. Still others, including genes involved in DNA transcription and translation, are clearly related to the genes of Archaea.

For this reason, many biologists propose that Archaea-like microorganisms played a key role in the origin of the eukaryotic cell. Based on sequence comparisons of genes coding for the small subunit of ribosomal RNA, American biologists Carl Woese and George Fox hypothesized that the cells ancestral to the cytoplasm and nucleus of eukaryotes were once a distinct microbial lineage more closely related to Archaea than to Bacteria. Recent genome comparisons, however, increasingly place this ancestor within the Archaea, specifically alongside a recently discovered group called the Lokiarchaeota ([Chapter 24](#)). Studies of Lokiarchaeota living in hydrothermal vents beneath the Arctic Ocean reveal that the genome of these cells encodes actin-like proteins and other molecules fundamental to cell organization, vesicle trafficking, and phagocytosis in eukaryotes. Based on this information, it seems likely that some portion of the eukaryotic cell is archaeal.

Two starkly different hypotheses have been proposed to explain the origin of the eukaryotic cell. Some biologists believe that the host for mitochondrion-producing endosymbiosis was itself a true eukaryotic cell. This cell had a nucleus, cytoskeleton, and endomembrane system, but only limited ability to derive energy from organic molecules (hypothesis 1 in [Fig. 25.7](#)). According to this view, the Archaea-like component of the eukaryotic cell had already undergone massive changes in cell biology before it engulfed an endosymbiotic proteobacterium. As noted earlier, however, no one has ever found eukaryotes that do not have and never had mitochondria.

FIG. 25.7 Two hypotheses for the origin of the eukaryotic cell. Both hypotheses lead to the evolution of a mitochondrion-bearing protist.

An alternative hypothesis is that no eukaryotic cell existed before mitochondria emerged. Some biologists propose that the eukaryotic cell as a whole began as a symbiotic association between a

proteobacterium and an archaeon (hypothesis 2 in [Fig. 25.7](#)). The proteobacterium became the mitochondrion and provided many genes to the nuclear genome. The archaeon provided other genes, including those used to transcribe DNA and translate it into proteins.

Biologists continue to debate these alternatives. Both hypotheses explain the hybrid nature of the eukaryotic genome, but neither fully explains the origins and evolution of the nucleus, linear chromosomes, the eukaryotic cytoskeleton, or a cytoplasm subdivided by ever-changing membranes. There is no consensus on the origins of eukaryotes: it remains one of biology's deepest unanswered questions, awaiting novel observations by a new generation of biologists. Once a dynamic cytoskeleton became coupled to a flexible membrane system, however, the evolutionary possibilities of eukaryotic form were established.

## In the oceans, many single-celled eukaryotes harbor symbiotic bacteria.

The evolution of the eukaryotic cell is marked by intimate associations between formerly free-living organisms. We might view this kind of arrangement as unusual, but symbioses between eukaryotic cells and bacteria are all around us. For example, an unexpected symbiosis was recently discovered in the Santa Barbara Basin, a local depression in the seafloor off the coast of southern California. Sediments accumulating in this basin contain little oxygen but large amounts of hydrogen sulfide ( $\text{H}_2\text{S}$ ) generated by anaerobic bacteria within the sediments. We might predict that eukaryotic cells would be uncommon in these sediments. Not only is oxygen scarce, but in addition sulfide

actively inhibits respiration in mitochondria. It came as a surprise, then, when samples of sediment from the Santa Barbara Basin were found to contain large populations of single-celled eukaryotes.

Some of these cells have hydrogenosomes, mitochondria altered by evolution to generate energy where oxygen is absent. Others appear to thrive by supporting populations of symbiotic bacteria on or within their cells. In one case, rod-shaped bacteria cover the surface of their eukaryotic host ([Fig. 25.8](#)). Research has shown that the bacteria metabolize sulfide in the local environment, thereby protecting their host from this toxic substance. Scientists hypothesize that the bacteria benefit from this association as well because they get a free ride as their host moves through the sediments, enabling these chemoautotrophs to maximize growth by remaining near the boundary between waters that contain oxygen and those rich in sulfide.

Bernhard, 2011, "Identity of Epibiotic Bacteria on Symbiontid Euglenozoans in O<sub>2</sub>-Depleted Marine Sediments: Evidence for Symbiont and Host Co-evolution," *ISME Journal* 5:231–243. Copyright 2010. Courtesy of Naoji Yubuki.

FIG. 25.8 A modern bacteria–eukaryotic cell symbiosis. A scanning electron microscope image shows bacterial cells on the surface of a single-celled eukaryote found in oxygen-depleted sediments in the Santa Barbara Basin, off the coast of California. The bacteria are hypothesized to metabolize the H<sub>2</sub>S in this environment, thereby protecting the eukaryotes that they enclose.

The diversity of these eukaryotic–bacterial symbioses is remarkable, yet poorly studied. The evidence gathered to date shows that single-celled eukaryotes have evolved numerous symbiotic relationships with chemoautotrophic bacteria. The bacteria feed and protect the eukaryotes, enabling them to colonize habitats where most eukaryotes cannot live. Clearly, then, the types of symbioses that led to mitochondria and chloroplasts on the early Earth were not rare events, but basic associations between cells that continue to evolve today.

#### Self-Assessment Questions

4. What is the origin of the chloroplast and the mitochondrion?
  5. What are two hypotheses for the origin of the eukaryotic cell?
-

## 25.3 EUKARYOTIC DIVERSITY

Historically, the domain Eukarya was divided into four kingdoms: plants, animals, fungi, and protists. Plants, animals, and fungi received special consideration from biologists for the obvious reason that they include large and relatively easily studied species. All remaining eukaryotes were grouped together as **protists**. These were defined as organisms having a nucleus but lacking other features specific to plants, animals, or fungi. The term “protist” is frowned on by some biologists because it does not refer to a monophyletic grouping of species—that is, an ancestral form and all its descendants ([Chapter 22](#)). Nonetheless, as an informal term that draws attention to a group of organisms sharing particular characteristics, “protist” usefully describes the diverse world of microscopic eukaryotes and seaweeds.

Two other terms scorned by some biologists but embraced by ecologists are “algae” and “protozoa.” **Algae** are photosynthetic protists. They may be microscopic single-celled organisms or the highly visible, multicelled organisms we call seaweeds. **Protozoa** are heterotrophic protists, almost exclusively single-celled organisms. Although “algae” and “protozoa” may have little phylogenetic meaning, these simple and useful terms convey a great deal of information about the structure and function of these organisms.

Protist cells exhibit remarkable diversity. Some have cell walls, while others do not. Some are covered by skeletons of silica ( $\text{SiO}_2$ ) or calcium carbonate ( $\text{CaCO}_3$ ), while others are naked or live within **tests**,

or “houses,” constructed exclusively of organic molecules. Some are photosynthetic, others are heterotrophic, and still others are capable of both photosynthesis and heterotrophy. Some move by beating flagella; others, such as *Amoeba*, can extend fingers of cytoplasm, called pseudopodia, to move and capture food. Most are aerobic, but there are anaerobic protists as well. Surprisingly, most of these distinctive features have evolved multiple times and so do not define phylogenetically coherent groups. As a result, our understanding of evolutionary pattern in Eukarya had to wait for the molecular age.

**Fig. 25.9** shows a phylogenetic tree of eukaryotes as biologists currently understand it. As in the case of Bacteria, it is easier to identify major groups of Eukarya than to establish their evolutionary relationships to one another. Molecular sequence comparisons consistently recognize seven major groups, called **superkingdoms**. These groups are noted in bold black type in **Fig. 25.9**. Animals fall within one of these superkingdoms, the Opisthokonta, whereas plants fall within another, the Archaeplastida. Most, but not all, of these major eukaryotic branches and their respective species are strongly supported by data from genes and genomes. A few groups, notably the cryptophytes, haptophytes, and centrohelid heliozoans, seem to wander from position to position from one phylogenetic analysis to the next, sometimes moving together, sometimes separately. Whether the well-resolved superkingdoms constitute the only major limbs on the eukaryotic tree is less certain. Many microscopic protists remain unstudied, and we may yet be surprised by what they show.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 25.9 The eukaryotic tree of life showing major groups. Branches with photosynthetic species (shown in green) are distributed widely. Additional branches, including animals, foraminiferans, radiolarians, and ciliates, contain species that harbor photosynthetic symbionts. Dashed lines indicate a high degree of uncertainty.

In the following sections, we introduce the major features of eukaryotic diversity. The species numbers we present indicate only the

taxonomic diversity that is known to us; most protistan diversity remains undiscovered. Many biologists estimate that only about 1 in 10 protist species has been described so far. As this is also the case for animals and fungi (but perhaps not for land plants, because they are all visible to the naked eye), the relative numbers of species within different superkingdoms may reflect something like the actual distribution of biodiversity among eukaryotes.

## Our own group, the opisthokonts, is the most diverse eukaryotic superkingdom.

Over the past 250 years, biologists have described approximately 1.8 million species. Of these, 75% or so fall within the [Opisthokonta](#) ([Fig. 25.10a](#)), a group that encompasses animals, fungi, and some protists. The name for this superkingdom is derived from Greek words meaning “posterior pole.” The name calls attention to the fact that cell movement within this group is propelled by a single flagellum attached to the posterior end of the cell. Not all cells in this superkingdom move around. In humans, for example, the flagellum is limited to sperm. Opisthokonts are heterotrophic, although some species harbor photosynthetic symbionts.

FIG. 25.10 Opisthokonts. This superkingdom includes animals and fungi, as well as several protistan groups. The closest protistan relatives of animals are the choanoflagellates.

Animals are the most diverse and conspicuous opisthokonts. More than 1.3 million animal species, mostly insects and their relatives, have been described. Fungi are also diverse, with more than 75,000 described species, including the visually arresting mushrooms. Here, however, we focus on opisthokont protists, as these somewhat poorly known microorganisms hold clues to the origins of complex multicellularity in this superkingdom ([Chapter 26](#)).

Finding morphological characters that unite all opisthokonts is a challenge. One reason for this difficulty is that animals and fungi have diverged so strikingly from what must have been the ancestral condition of the group. However, as molecular sequence comparisons began to reshape our understanding of eukaryotic phylogeny, it soon became clear that fungi and animals are closely related.

Even more closely related to the animals are the [choanoflagellates](#). This group of mostly unicellular protists is characterized by a ring of microvilli, fingerlike projections that form a collar around the cell's single flagellum ([Fig. 25.10b](#)). About 150 choanoflagellate species have been described from marine and freshwater environments, where they prey on bacteria. As early as 1841, the close similarity between choanoflagellates and the collared feeding cells of sponges suggested that these minute organisms might be our closest protistan relatives. This view gained widespread popularity with the discovery in 1880 of *Proterospongia haeckeli*, a choanoflagellate that lives in colonies of cells joined by adhesive proteins.

Molecular sequence comparisons now confirm the close relationship between animals and choanoflagellates. For example, the complete genome of the choanoflagellate *Monosiga brevicollis* shows that a number of signaling molecules known to play a role in animal development are present in our choanoflagellate relatives, although their function in these single-celled organisms remains largely unknown. More generally, many genes once thought to be unique to animals have now been identified in choanoflagellates and other unicellular opisthokonts, underscoring the deep evolutionary roots of animal biology.

Microsporidia form another group of single-celled opisthokonts. Microsporidia are parasites that live inside animal cells. Only their spores survive in the external environment, where they await the opportunity to infect a host and complete their life cycle. Microsporidia infect all animal phyla, so the approximately 1000 known species

probably represent only the tip of the iceberg. More than a dozen species have been isolated from human intestinal tissues.

Microsporidia infections can be particularly devastating in patients with AIDS, who have compromised immune systems as a result of their disease.

Beyond their importance in human health, microsporidians have attracted the attention of biologists because of features they *lack*: microsporidian cells have no aerobically respiring mitochondria, no Golgi apparatus, and no flagella. Furthermore, they have a highly reduced metabolism and among the smallest genomes of any known eukaryote. The cellular simplicity of microsporidians does not mean that they are early-evolved organisms, however. In fact, molecular sequencing studies show that microsporidians are the descendants of more complex organisms. Their simplicity is actually an adaptation for life as an intracellular parasite. It is now widely accepted that microsporidians are closely related to the fungi.

Other protistan opisthokonts have been identified in recent years. These organisms are mostly bacteria-eating unicells or parasites of aquatic animals. Nevertheless, as with the choanoflagellates described earlier, their biology is beginning to illuminate the evolutionary path to complex multicellularity in animals and fungi.

## Amoebozoans include slime molds that produce multicellular structures.

Previously in this chapter, we learned one thing about amoebas: they move and feed by extending cytoplasmic fingers called pseudopodia.

As its name implies, the superkingdom **Amoebozoa** (**Fig. 25.11a**) is a group of eukaryotes with amoeba-like cells (illustrated by *Amoeba proteus* in **Fig. 25.11b**). More than 1000 amoebozoan species have been described. In some of them, large numbers of cells aggregate to form multicellular structures as part of their life cycle.

**FIG. 25.11 Amoebozoans.** This group includes protists with an amoeboid stage in their life cycle.

Although some amoeba-like cells are not members of the Amoebozoa superkingdom, all members of this group have cells similar to that of *Amoeba*, at least at some stage of their life cycle. Amoebozoans play an important role in soils as predators on other microorganisms. Some amoebozoans cause disease in humans. For example, *Entamoeba histolytica* (**Fig. 25.11c**), an anaerobic protist that causes amoebic dysentery, is responsible for 50,000 to 100,000 deaths every year.

Beyond considerations of human health, the amoebozoans of greatest biological interest are the slime molds. In plasmodial slime molds (**Fig. 25.12**), haploid cells fuse to form zygotes that subsequently undergo repeated rounds of mitosis but not cell division

to form colorful, often lacy structures visible to the naked eye ([Fig. 25.12a](#)). These structures, called plasmodia, are **coenocytic**, which means they contain many nuclei within one giant cell. The plasmodia can crawl along surfaces and so are able to seek out and feed on the bacteria and small fungi commonly found on bark or plant litter on the forest floor. Triggered by poorly understood environmental signals, plasmodia eventually differentiate to form stalked structures called sporangia that can be 1 to 2 mm high ([Fig. 25.12b](#)). Within the mature sporangium, cell walls form around the many nuclei, producing discrete cells. These cells undergo meiosis, generating haploid spores that disperse into the environment. Fusion of these spores to form a diploid amoeba-like cell begins the life cycle anew.

Sources: a. Matt Meadows/Science Source; b. Ray Simons/Getty Images.

FIG. 25.12 Plasmodial slime molds. (a) Plasmodia, such as this pretzel slime mold, are coenocytic structures containing many nuclei. (b) Plasmodia generate sporangia, stalked structures that produce spores for dispersal.

Cellular slime molds ([Fig. 25.13](#)) are a second type of slime mold. These slime molds spend most of their life cycle as solitary amoeboid cells feeding on bacteria in the soil. If the food supply runs out, however, the cells undergo a dramatic transformation. The starving

cells produce the chemical signal cyclic AMP ([Chapter 9](#)), which induces as many as 100,000 cells to aggregate into a large multicellular slug-like form ([Fig. 25.13a](#)). This “slug” can migrate by a coordinated movement of its cells governed by actin and myosin, the same proteins that control muscle movement in animals. Migrating “slugs” forage for food, leaving behind a trail of mucilage—which explains the “slime mold” name. Like plasmodial slime molds, the “slugs” of cellular slime molds eventually differentiate to form stalk-borne sporangia that produce the spores responsible for dispersal and for renewal of the life cycle ([Fig. 25.13b](#)).

FIG. 25.13 Cellular slime molds. (a) Starvation causes amoeboid feeding cells of cellular slime molds to aggregate into a multicellular “slug” that can migrate along surfaces, leaving behind a trail of slime. (b) “Slugs” differentiate to form stalked sporangia that produce spores.

Slime molds are not true intermediates in the evolution of multicellularity. In other words, they are not closely related to animals, fungi, or other groups in which complex multicellularity evolved. Nonetheless, biologists have studied the cellular slime mold

*Dictyostelium* as a model organism because it has much to teach us about fundamental eukaryotic processes of cell signaling and differentiation, cellular motility, and mitosis.

## Archaeplastids, which include land plants, are photosynthetic organisms.

After the opisthokonts, the most conspicuous and diverse eukaryotes fall within the superkingdom [Archaeplastida](#) ([Fig. 25.14](#)). This is where we find the land plants, whose 400,000 described species dominate eukaryotic biomass on this planet ([Chapter 31](#)). The archaeplastids comprise three major groups, and with the exception of a few parasitic and saprophytic (living on dead matter) species, all are photosynthetic ([Fig. 25.14a](#)). This ability indicates that the last common ancestor of living archaeplastids was itself photosynthetic. In fact, archaeplastids are the direct descendants of the protist that first evolved chloroplasts from endosymbiotic cyanobacteria. Some molecular analyses also place cryptophyte and haptophyte algae within this branch, but their location in the phylogenetic tree remains a topic of continuing research.

FIG. 25.14 Archaeplastids. (a) Archaeplastids are a photosynthetic group descended from the protist that acquired photosynthesis from an endosymbiotic cyanobacterium. They include the (b) glaucocystophytes, (c) red algae, and (d) green algae and their descendants, the land plants.

The least conspicuous archaeplastids are the glaucocystophytes (Fig. 25.14b), a small group of single-celled algae found in freshwater ponds and lakes. We might skip over them entirely, except for one illuminating observation: glaucocystophyte chloroplasts retain more features of the ancestral cyanobacterial endosymbiont than the chloroplasts of any other algae. Their chloroplasts have walls of peptidoglycan, the same molecule found in cyanobacterial walls, and their photosynthetic pigments include biliproteins, also found in

cyanobacteria.

More abundant and diverse is the second major archaeplastid group, the red algae ([Fig. 25.14c](#)). Approximately 5000 species of red algae are known, mostly from marine environments. Most are multicellular, and some have complex morphology that includes differentiated tissues such as sporangia and distinct surface and interior cell layers. Like other archaeplastids, most red algae have walls made of cellulose. The principal photosynthetic pigments in red algae are a form of chlorophyll called chlorophyll *a* and the biliproteins also found in glaucocystophytes and most cyanobacteria.

Red algae can be conspicuous as seaweeds on the shallow seafloor. One subgroup of red algae, known as the coralline algae, secretes skeletons of calcium carbonate ( $\text{CaCO}_3$ ) that deter predators and help the algae withstand the energy of waves in shallow marine environments. If you examine the margin of coral reefs, where waves crash into the reef, you will often see that it is coralline algae and not the corals themselves that resist breaking waves, thereby enabling the reefs to expand upward into wave-swept environments.

Red algae are important as food in certain cultures. For example, they are consumed as laver in the British Isles (particularly in Wales, in cakes similar to oatcakes) and as nori in Japan. Without knowing it, you often ingest carageenan, a polysaccharide synthesized by red algae. Carageenan molecules stabilize mixtures of biomolecules and promote gel formation, so they are used in products ranging from ice cream to toothpaste. Agar, another red algal polysaccharide, is found

universally in microbiology laboratories because the gel it forms at room temperature provides a nearly ideal substrate for bacterial growth.

The land plants and their algal relatives form Viridiplantae, the third branch of Archaeplastida. In this chapter, we are concerned with the protistan members of this group, the green algae ([Fig. 25.14d](#)). Green algae include a diverse assortment of species (about 10,000 have been described) that live in marine and, especially, freshwater environments. Green algae range from tiny single-celled flagellates to meter-scale seaweeds ([Fig. 25.15](#)). They all are united by two features: the presence of chlorophyll *a* and chlorophyll *b* in chloroplasts that have two membranes, and a unique attachment for flagella.

Sources: a. Charles J. O'Kelly, Ph.D.; b. DIOMEDIA/Eric Grave; c. Gerd Guenther/Science Source; d. Frank Fox/Science Source; e. Wolfgang Poelzer/Wa/AGE Fotostock.

FIG. 25.15 Diversity of green algae. (a) *Halosphaera minor*, a small flagellated unicell found in the surface ocean; (b) *Spirogyra*, a filament-forming freshwater green alga with distinctive helical chloroplasts; (c) a desmid, among the most

diverse and widespread of all unicellular green algae in fresh water; (d) *Volvox*, a simple multicellular organism; and (e) *Acetabularia*, a macroscopic (but single-celled!) green alga found in coastal marine waters in tropical climates.

Green algae likely originated as small flagellated cells. Indeed, today many still live as photosynthetic cells in marine or fresh waters, like their ancestors, at nodes near the base of the green algal tree ([Fig. 25.15a](#)). The larger diversity of green algae, however, is found on two branches that diverged from these flagellated ancestors. One branch, the chlorophytes, radiated mostly in the sea and includes the common seaweeds seen along the world's seashores. Chlorophyte green algae have also played a major role in laboratory studies of photosynthesis (*Chlamydomonas*) and multicellularity (*Volvox*, [Fig. 25.15d](#)).

For humans, the more important branch of the green algal tree is the one that diversified in freshwater and, eventually, on land. Called streptophytes, the species on this branch show a progression of form from unicells that branch from basal nodes through simple cell clusters and filaments on intermediate branches ([Figs. 25.15b](#) and [25.15c](#)), to multicellular algae that form some of the closest relatives of land plants ([Chapter 31](#)). As was true of choanoflagellates and animals, green algae display features of cell biology and genomics that tie them unequivocally to land plants.

## Stramenopiles, alveolates, and rhizarians dominate eukaryotic diversity in the oceans.

The phylogenetically related superkingdoms called the stramenopiles,

alveolates, and rhizarians may not be household names, but perhaps they should be. The surface ocean hosts three species belonging to these groups for every one marine animal species, and these protists also play important roles in the ecology of lakes, rivers, and soils.

The superkingdom **Stramenopila** (see [Fig. 25.9](#)) includes unicellular organisms and giant kelps, algae and protozoa, free-living cells and parasites. All have an unusual flagellum that bears two rows of stiff hairs ([Fig. 25.16](#)). Most also have a second, smooth flagellum.

FIG. 25.16 Stramenopiles. This electron micrograph of a unicellular stramenopile shows a flagellum with two rows of stiff hairs. Like this cell, most stramenopiles also have a second, smooth flagellum.

Despite the presence of heterotrophic species, most stramenopiles are photosynthetic. There are approximately a dozen groups of stramenopile algae, of which the brown algae and diatoms deserve special mention. Brown seaweeds are common along rocky shorelines across the world, and in the Sargasso Sea, huge masses of ropy brown algae (aptly named *Sargassum*) float at the surface. Easily the most impressive brown algae are the kelps, giant seaweeds that form forests above the seafloor ([Fig. 25.17](#)). Kelps not only develop functionally

distinct tissues, but also have evolved distinct organs specialized for attachment, photosynthesis, flotation, and reproduction.

*Source: Mark Conlin/Alamy.*

FIG. 25.17 Kelps. These complex multicellular brown algae can form “forests” tens of meters high in the ocean.

The most diverse stramenopiles are the diatoms ([Fig. 25.18](#)). Recognized by their distinctive external skeletons of silica, diatoms account for half of all photosynthesis in the sea (and, therefore, nearly one-fourth of all photosynthesis on Earth). The 10,000 known diatom species thrive in environments that range from wet soil to the open ocean.

Sources: a. and b. Steve Gschmeissner/Science Source; c. Andrew Syred/Science Source; d. Biophoto Associates/Science Source.

**FIG. 25.18 Diatoms.** Diatoms are the most diverse stramenopiles, and among the most diverse of all protists. Their shapes, outlined by their tiny skeletons made of silica ( $\text{SiO}_2$ ), can be (a) like a pill-box, (b) elongated, or (c) twisted around the long axis of the cell. Some diatom species form colonies, like those shown in (d).

Among heterotrophic stramenopiles, the oomycetes, or water molds, are particularly interesting. Originally classified as fungi, these multicellular pathogens cause a number of plant diseases, including the potato blight that devastated Ireland's major food crop and led to famine in that country during the 1840s ([Chapter 30](#)). Other species infect animals, including humans.

Like stramenopiles, the superkingdom **Alveolata** is a diverse group that includes both photosynthetic and heterotrophic species. Also like

stramenopiles and many other eukaryotic groups, alveolates are united by a feature observed only with careful electron microscopy: small vesicles called cortical alveoli are packed beneath the cell surface and, in some species at least, store calcium ions for use by the cell ([Fig. 25.19a](#)).

FIG. 25.19 Alveolates. (a) The arrows point to alveoli, flattened vesicles just beneath the surface of the cell that give alveolates their name. (b) Dinoflagellates have cell walls made of interlocking plates of cellulose. (c) A ciliate has many short flagella, or cilia, that line the cell.

Most photosynthetic alveolates belong to a large subgroup called dinoflagellates. Dinoflagellates are distinguished by two flagella that produce a rotary motion of the cell as it moves through its

environment; many also have a distinctive covering of organic plates ([Fig. 25.19b](#)). Approximately 4000 dinoflagellate species have been described, but recent genomic surveys of the oceans make it clear that they are much more diverse, by nearly an order of magnitude. In fact, recent studies indicate that dinoflagellates and their poorly known parasitic relatives are the most diverse eukaryotes in the world's sunlit oceans. About half of the known dinoflagellate species are photosynthetic, but most of these are also capable of heterotrophic growth. Notably, dinoflagellates affect humans when they form red tides, large and toxic blooms in coastal waters. Red tides occur when nutrients are supplied to coastal waters in large amounts, sometimes for natural reasons but commonly because of human activities such as sewage seeps or runoff from highly fertilized croplands.

The alveolates also include a second diverse (8000 described species) group of protists called ciliates ([Fig. 25.19c](#)). Ciliates are also distinct at the cellular level, with two nuclei in each cell and numerous short flagella called cilia. These heterotrophs feed on bacteria or other protists and so play key roles as both predators and prey in soil and water.

The third principal group of alveolates, the Apicomplexans, perhaps attracts the most scientific attention. The reason is simple: the apicomplexan *Plasmodium falciparum* and related species cause malaria, a lethal disease that sickened millions and killed more than 400,000 people in 2015 ([Case 4: Malaria](#)). Although *Plasmodium* cells are heterotrophic, they contain vestigial chloroplasts that suggest evolutionary loss of photosynthesis. Recently, this hypothesis has been

confirmed by the discovery in Sydney Harbour, Australia, of photosynthetic cells closely related to parasitic *Plasmodium*.

## Photosynthesis spread through eukaryotes by repeated endosymbioses involving eukaryotic algae.

A curious feature of the eukaryotic tree is that photosynthetic eukaryotes are distributed widely but discontinuously among its branches (see [Fig. 25.9](#)). How can we explain this pattern?

As explored in [Fig. 25.20](#), two hypotheses have been suggested: either photosynthesis was established early in eukaryotic evolution and then subsequently lost in some lineages, or eukaryotes acquired photosynthesis multiple times by repeated episodes of endosymbiosis. The second hypothesis, it turns out, is correct. The twist is that most of the symbionts involved in the spread of photosynthesis were photosynthetic eukaryotes, not cyanobacteria.

### HOW DO WE KNOW?

#### FIG. 25.20

### How did photosynthesis spread through the Eukarya?

#### BACKGROUND

Many different branches on the eukaryotic tree include photosynthetic species, commonly interspersed with non-photosynthetic lineages (named groups in [figure 25.20b](#)). Did eukaryotes gain photosynthesis once, by the incorporation of a cyanobacterium, and then lose this capacity multiple

times? Or is the history of photosynthetic endosymbioses more complicated? That is, did multiple events of symbiont capture and transformation occur?

#### HYPOTHESIS 1

Photosynthesis was established early in eukaryotic evolution by endosymbiosis and then lost in some lineages.

#### HYPOTHESIS 2

Eukaryotes acquired photosynthesis multiple times by repeated episodes of endosymbiosis.

#### PREDICTIONS

The two hypotheses make different predictions. If photosynthesis were acquired in a single common ancestor of all living photosynthetic eukaryotes and then lost in some lineages, we would expect chloroplast gene phylogenies and nuclear gene phylogenies to show the same pattern of branching. If photosynthesis were acquired multiple independent times, we would expect chloroplast phylogenies and nuclear phylogenies to show different patterns.

#### EXPERIMENT

Because chloroplasts have DNA, scientists developed a phylogenetic tree based on molecular sequence comparison of chloroplast genes ([Fig. 25.20a](#)). This chloroplast phylogeny was then compared with a second phylogeny, for all eukaryotes, based on molecular sequence comparison of nuclear genes ([Fig. 25.20b](#)).

a. Phylogenetic relationships based on chloroplast genes

Nuclear genes place brown algae and diatoms among the stramenopiles, dinoflagellates within the alveolates, and cryptophytes on their own poorly resolved branch. Chloroplast genes, however, relate them to red algae. These groups gained photosynthesis by incorporating red algal cells as endosymbionts.

Nuclear genes place chlorarachniophytes and euglenids among the rhizarians and excavates, respectively, but chloroplast genes relate them to green algae. Both groups gained photosynthesis by incorporating green algal cells as endosymbionts.

Chloroplasts form a monophyletic grouping nested within the cyanobacteria—a principal line of evidence supporting the endosymbiotic origin of chloroplasts.

For branches in black, chloroplast relationships match the phylogeny indicated by nuclear genes—these groups diverged from the ancestor in which endosymbiosis first gave rise to chloroplasts.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

b. Phylogenetic relationships based on nuclear genes

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

## RESULTS

The molecular sequence comparisons show that evolutionary relationships among chloroplasts do not mirror those based on nuclear genes. The

chlorarachniophyte algae and photosynthetic euglenids (shown in green) are classified into a monophyletic group with the green algae when chloroplast DNA is analyzed (see [figure 25.20a](#)). However, these groups lie far from green algae in the phylogeny based on nuclear genes ([figure 25.20b](#)). Similarly, brown algae, diatoms, most photosynthetic dinoflagellates, and cryptophyte algae (shown in red) form a monophyletic group with the red algae in the phylogeny based on chloroplast DNA ([figure 25.20a](#)), but analysis of nuclear genes places them in different groups ([figure 25.20b](#)).

#### CONCLUSION

The chloroplast and nuclear phylogenies show different patterns of branching, supporting the hypothesis that photosynthesis spread through the Eukarya by means of multiple endosymbioses involving eukaryotic endosymbionts.

SOURCE Hackett, J. D., et al. 2007. "Plastid Endosymbiosis: Sources and Timing of the Major Events." In *Evolution of Primary Producers in the Sea*, edited by P. G. Falkowski and A. H. Knoll, 109–132. Boston, MA: Elsevier Academic Press.

Once more, DNA sequence comparisons provide the decisive data. We can construct phylogenetic trees for photosynthetic eukaryotes using chloroplast genes and then repeat the exercise using nuclear genes. A comparison of the two trees, as shown in [Figure 25.20](#), reveals that two groups, chlorarachniophytes and euglenids, gained photosynthesis by establishing green algal cells as endosymbionts. (The algal cells contained chloroplasts derived from an earlier symbiotic assimilation of cyanobacteria.) Members of other groups (including brown algae, diatoms, most photosynthetic dinoflagellates, and cryptophyte algae) gained photosynthesis as well, but most likely by ingesting red algal cells.

Several features of cell biology support the view that eukaryotes acquired photosynthesis multiple times by repeated episodes of endosymbiosis. The chloroplasts of euglenids and chlorarachniophyte algae contain chlorophyll *a* and *b*, like green algae. In contrast, cryptophytes contain chlorophyll *a* and biliproteins, both of which are found in red algae, along with chlorophyll *c*, a form of chlorophyll not known from either red or green algae. (Diatoms, brown algae, and their relatives contain chlorophyll *a* and *c*, but not biliproteins.)

We noted earlier that chloroplasts in green and red algae are bounded by two membranes, but most of the algae shown in red and green in [Fig. 25.20](#) have chloroplasts bounded by four membranes. The presence of four membranes is expected under the hypothesis of eukaryotic endosymbionts: the inner two membranes are those that bounded the chloroplast in the green or red algal endosymbiont; the third membrane is derived from the outer cell membrane of the symbiont; and the fourth, outer membrane is part of the cell membrane of the host ([Fig. 25.21](#)).

FIG. 25.21 Successive endosymbiotic events that established photosynthesis in chlorarachniophyte algae.

Chlorarachniophyte algae retain another feature that supports the eukaryotic origin of their chloroplasts: a small organelle called a nucleomorph ([Fig. 25.21](#)). The nucleomorph in these algae is the remnant nucleus of a green algal symbiont. It retains only a few genes, but those show close affinity with genes in green algae. Nucleomorph genes in cryptophyte algae similarly provide evidence for a red algal symbiont.

How many endosymbiotic events are required to account for the diversity of photosynthetic eukaryotes? The primary endosymbiosis gave rise to green and red algae, two further events established chloroplasts derived from green algae in euglenids and chlorarachniophytes, and at least one to three events established chloroplasts derived from red algae in cryptophytes, haptophytes, and stramenopiles.

The dinoflagellates add a remarkable coda to this accounting. Like stramenopiles, most dinoflagellates have chloroplasts derived from red algae. Three dinoflagellate groups, however, have chloroplasts that are clearly derived from green, cryptophyte, and haptophyte algae. Include *Paulinella* in the mix, and at least 8 to 10 endosymbiotic events are required to explain eukaryotic photosynthesis. Eukaryotes never evolved oxygenic photosynthesis—only the cyanobacteria accomplished that feat. Instead, eukaryotes appropriated the biochemistry of cyanobacteria and spread it throughout the domain by the horizontal transfer of entire cells.

#### Self-Assessment Questions

6. What are the names of the seven superkingdoms of eukaryotes? Name an organism in each one.
7. Was the common ancestor of plants and animals unicellular or multicellular?
8. How do the molecular sequences of genes in chloroplasts show how photosynthesis spread throughout the eukaryotic domain?

## 25.4 THE FOSSIL RECORD OF PROTISTS

Not all algae and protozoa fossilize easily, but those that do provide a striking record of evolution that both predates and parallels the better-known fossil record of animals. Fossilized protists do not contain DNA, nor do they preserve the features of cell biology that define eukaryotes, such as nuclear membranes and organelles. Thus, for a fossil to be identified as eukaryotic, it must preserve other features of morphology found today in Eukarya, but not in Bacteria or Archaea. For this reason, fossils that can be identified with certainty as eukaryotic are limited to those left by eukaryotes that synthesized distinctive and preservable cell walls at some stage of their life cycle.

### Fossils show that eukaryotes existed at least 1800 million years ago.

Sedimentary rocks deposited in coastal marine environments 1800–1400 million years ago contain microscopic fossils (called [microfossils](#) for short) up to about 300  $\mu\text{m}$  in diameter. Many of these have complicated wall structures that identify them as eukaryotic.

Interlocking plates, long and branching arms, and complex internal layering have been imaged by both scanning and transmission electron microscopes ([Fig. 25.22a](#)). Comparison with living cells suggests that such fossils could be formed only by organisms with a cytoskeleton and endomembrane system, the hallmarks of eukaryotic biology.

FIG. 25.22 Eukaryotic fossils in Precambrian sedimentary rocks. (a) Simple protist in 1500-million-year-old rocks from Australia. (b) Simple multicellular red algae in 1050-million-year-old rocks from Canada. (c) Amoebozoan test in 730-million-year-old rocks from the Grand Canyon, Arizona.

At present, it appears that the eukaryotic domain first appeared no later than 1800 million years ago and possibly earlier, although the

record is difficult to trace in older rocks. None of these earliest eukaryotic microfossils can be placed with confidence into one of the living superkingdoms. Conceivably, at least some of the oldest protistan microfossils could predate the last common ancestor of living eukaryotes.

In sedimentary rocks dated at about 1050 million years old, we find the oldest fossils that can be linked clearly to a living group of eukaryotes ([Fig. 25.22b](#)). These fossils preserve features found today only in the red algae. Thus, by a billion years ago, Archaeplastida had already diverged from other eukaryotic superkingdoms. More generally, photosynthesis had become established in eukaryotes and simple multicellularity had already evolved within the domain.

Much more eukaryotic diversity is recorded in rocks 800–700 million years old, including green algae and the remains of test-forming amoebozoans ([Fig. 25.22c](#)). Molecular fossils further indicate that algae were expanding to become major photosynthesizers in the oceans. How can we explain this diversification? One hypothesis is that 800–700 million years ago, protists first evolved (or expanded) the ability to eat other protists rather than preying only on Bacteria and Archaea. The appearance of this ability initiated an evolutionary arms race that favored divergent means of preying on other organisms and avoiding predation. During this time interval, for reasons that are currently debated, nutrient levels of surface seawater also began to increase, providing conditions for the expansion of eukaryotic algae in the oceans. Both fossils and molecular clocks support these ecological hypotheses for eukaryotic diversification, perhaps assisted by a small

increase in the oxygen content of seawater.

## Protists have continued to diversify during the age of animals.

Modern protistan diversity took shape alongside evolving animals during the Phanerozoic Eon, 541 million years ago to the present. Two examples of these more recently emerging protist groups are foraminiferans and radiolarians, marine protozoans with shells of calcium carbonate and silica, respectively. These protist groups appear for the first time in rocks deposited near the beginning of the Phanerozoic Eon and have continued to diversify since that time ([Fig. 25.23](#)). Some seaweeds also evolved skeletons of calcium carbonate at this time, and diversified along with animals in Phanerozoic oceans. These mineralized skeletons presumably protect the organisms that form them from being eaten.

Sources: a. Astrid & Hanns-Frieder Michler/Science Source; b. M. I. Walker/Science Source.

FIG. 25.23 (a) Foraminifera and (b) Radiolaria, showing skeletons of calcium carbonate and silica, respectively.

Marine protists underwent a new round of radiation during the Mesozoic Era, 252–66 million years ago. The most significant changes

occurred among photosynthesizers. During the preceding Paleozoic Era, green algae and cyanobacteria were the primary photosynthesizers in the oceans. As the Mesozoic Era began, however, new groups of photosynthetic algae expanded, first dinoflagellates and coccolithophorid algae, followed by diatoms. Today, these three groups dominate photosynthesis in many parts of the sea.

Within the oceans, diatom and coccolithophorid evolution had another important consequence. The silica skeletons of diatoms are now the principal means by which  $\text{SiO}_2$  is transferred from seawater to sediments. Similarly, the  $\text{CaCO}_3$  scales made by coccolithophorids and the skeletons of planktonic foraminiferans are a primary source of carbonate sediments on the seafloor ([Fig. 25.24](#)). In this way, the ongoing evolution of protists in the age of animals has continued to transform marine ecosystems.

FIG. 25.24 Coccolithophorids. (a) Coccolithophorid algae, like *Emiliania huxleyi*, form tiny scales of calcium carbonate. (b) A satellite image captures a coccolithophorid bloom off the southwestern coast of England visible as light blue streamers of calcium carbonate in the otherwise dark blue ocean.

Today, microscopic eukaryotes dominate photosynthetic production in many parts of the oceans and play a major role in biogeochemical cycles. And for thousands of protists, plants and animals are simply habitats, ripe for colonization. For proof of this relationship, we need look no further than the many eukaryotic vectors of human disease. The key conclusion is that a remarkable, and still largely undocumented, diversity of eukaryotic organisms has evolved through time to form an integral part of ecosystems across our planet, shaping the world in which we live in ways both positive and negative.

#### Self-Assessment Questions

9. When did the first eukaryotic cell evolve?
10. What kind of evidence is used to date the timing of the first eukaryotic cell?

## CORE CONCEPTS SUMMARY

**25.1 A REVIEW OF THE EUKARYOTIC CELL:** Eukaryotic cells are defined by the presence of a nucleus, but features such as a dynamic cytoskeleton and membrane system explain their evolutionary success.

Eukaryotic cells have a network of proteins inside the cell that allow them to change shape, move, and transfer substances in and out of the cell. [page 545](#)

Eukaryotic cells have dynamic membranes that provide new possibilities for movement and feeding. [page 545](#)

Eukaryotic cells compartmentalize their machinery for energy metabolism into mitochondria and chloroplasts, freeing the cell to interact with the environment in novel ways not available to prokaryotes. [page 547](#)

Eukaryotes have larger genomes than those of prokaryotes, as well as novel mechanisms of gene regulation. [page 547](#)

Sexual reproduction promotes genetic diversity in eukaryotic populations. [page 547](#)

**25.2 EUKARYOTIC ORIGINS:** The endosymbiotic hypothesis proposes that the chloroplasts and mitochondria of eukaryotic cells were originally free-living bacteria.

The endosymbiotic hypothesis is based on physical, biochemical, and genetic similarities between chloroplasts and cyanobacteria, and between mitochondria and proteobacteria. [page 549](#)

Chloroplasts and mitochondria have their own genomes, but their genomes are small relative to those of the free-living bacteria to which they are closely related, in part because of gene migration to the nuclear genome. [page 550](#)

Symbiosis between a heterotrophic host and a photosynthetic partner is common throughout the eukaryotic domain; reef-forming corals are an example. [page 550](#)

Most eukaryotic cells have mitochondria, but a few do not. Evidence suggests that cells lacking mitochondria once had them but subsequently lost them. [page 551](#)

The eukaryotic nuclear genome contains genes unique to Eukarya, but also genes related to Bacteria and Archaea. This suggests that the ancestor of the modern eukaryotic cell was either a primitive eukaryote descended from archaeal ancestors or an archaeon that engulfed a bacterium. [page 552](#)

**25.3 EUKARYOTIC DIVERSITY:** Eukaryotes were formerly divided into four kingdoms, but are now divided into at least seven superkingdoms.

The terms “protist,” “algae,” and “protozoa” are useful, but do not describe monophyletic groups. [page 554](#)

Protists are eukaryotes that do not have features of animals, plants, and fungi; algae are photosynthetic protists; and protozoa are heterotrophic protists. [page 554](#)

The seven superkingdoms of eukaryotes are Opisthokonta,

Amoebozoa, Archaeplastida, Stramenopila, Alveolata, Rhizaria, and Excavata. [page 555](#)

Opisthokonts are the most diverse eukaryotic superkingdom. They include animals and fungi, as well as choanoflagellates (our closest protistan relatives). [page 555](#)

Amoebozoans produce multicellular structures by the aggregation of amoeba-like cells, and include organisms that cause human disease and those important in biological research. [page 556](#)

The archaeplastids, which include land plants, are photosynthetic, and are divided into three major groups. [page 558](#)

The related superkingdoms called the stramenopiles, alveolates, and rhizarians dominate eukaryotic diversity in the oceans. [page 559](#)

Photosynthesis spread through Eukarya by means of multiple independent events involving a protozoan host and a eukaryotic endosymbiont. [page 562](#)

**25.4 THE FOSSIL RECORD OF PROTISTS:** The fossil record provides perspectives on the timing and environmental context of eukaryotic evolution.

Fossils in sedimentary rocks as old as 1800 million years have unmistakable signs of eukaryotic cells, including complicated wall structures. [page 564](#)

The earliest fossil eukaryotes that can be placed into one of the present-day superkingdoms are red algae from rocks dated as 1050 million years old. [page 565](#)

Eukaryotic fossils diversified greatly about 800 million years ago, reflecting a new capacity for predation on other protists, increased nutrient levels in surface seawater, and, perhaps, a modest increase in oxygen. [page 565](#)

Protists continue to diversify even today. Green algae and cyanobacteria dominated primary production in earlier seas, but, since about 200 million years ago, dinoflagellates, coccolithophorids, and diatoms have become the primary photosynthetic organisms in the oceans. [page 565](#)

Protists have evolved to take advantage of the environments provided by animals and plants; these protists include many that cause disease in humans. [page 566](#)

## CHAPTER 26 Being Multicellular

---

### CORE CONCEPTS

**26.1 THE PHYLOGENETIC DISTRIBUTION OF MULTICELLULAR ORGANISMS:** Complex multicellularity arose several times in evolution.

**26.2 DIFFUSION AND BULK FLOW:** In complex multicellular organisms, bulk flow circumvents the limitations of diffusion.

**26.3 HOW TO BUILD A MULTICELLULAR ORGANISM:** Complex multicellularity depends on cell adhesion, communication, and a genetic program for development.

**26.4 PLANTS VERSUS ANIMALS:** Plants and animals evolved complex multicellularity independently of each other, and solved similar problems with different sets of genes.

**26.5 THE EVOLUTION OF COMPLEX MULTICELLULARITY:** The evolution of large and complex multicellular organisms, which required abundant oxygen, is recorded by fossils.

---

[Chapters 24](#) and [25](#) introduced the extraordinarily diverse, but largely unseen world of microorganisms. Among the Bacteria, Archaea, and protists, each cell usually functions as an individual, growing and reproducing, moving from one place to another, taking in nutrients, and both sensing and transmitting molecular signals. In contrast, complex multicellular organisms can contain more than a trillion cells that work in close coordination. In your own body, for example, different cells are specialized for specific functions, so that while your body as a whole can perform the broad range of tasks accomplished by microorganisms, individual cells for the most part cannot. Cells lining the intestine absorb food molecules, but the bloodstream must then transport nutrients to other parts of the body. Cells lining the inner surface of lungs take up oxygen from inhaled air, but red blood cells must distribute it to other tissues and organs. And while cells at the body's surface sense signals from the environment, the signals

affecting interior cells come mostly from surrounding cells.

The biological gulf between microorganisms and complex multicellular organisms is enormous, but complex multicellularity has evolved a half dozen times. In the chapters that follow, we explore the structure and diversity of plants, fungi, and animals. Here, we address the broader question of how complex multicellular organisms evolved in the first place.

# 26.1 THE PHYLOGENETIC DISTRIBUTION OF MULTICELLULAR ORGANISMS

Most prokaryotic organisms are composed of a single cell, although some form simple filaments or live in colonies. A few types of bacteria, notably some cyanobacteria, form simple multicellular structures with several distinct cell types. Nevertheless, no bacteria develop macroscopic bodies with differentiated tissues having specialized functions. Only eukaryotes have evolved those structures. Simple multicellular organisms, composed of multiple similar cells, occur widely within the eukaryotic tree of life, and a few of these evolved into complex multicellular organisms characterized by differentiated tissues and organs. How are these different types of organization distributed on the eukaryotic tree of life?

## Simple multicellularity is widespread among eukaryotes.

A recent survey of eukaryotic organisms recognized 119 major groups within the superkingdoms discussed in [Chapter 25](#). Of these, 83 contain only single-celled organisms. These groups consist of predominantly cells that engulf other microorganisms or ingest small organic particles, photosynthetic cells that live suspended in the water column, or parasitic cells that live within other organisms. Each of the 36 remaining branches exhibits some cases of simple multicellularity,

mostly in the form of filaments, hollow balls, or sheets of little-differentiated cells ([Fig. 26.1](#)).

**FIG. 26.1 Simple multicellularity.** Cells in simple multicellular organisms show little differentiation and remain in close contact with the external environment. Many groups of eukaryotic organisms display simple multicellularity: (a) *Uroglena*, a stramenopile alga found commonly in lakes; (b) *Epistylis*, a stalked ciliate protozoan that lives attached to the surfaces of fish and crabs; and (c) *Prasiola*, a bladelike green alga only a single cell thick, found on tree trunks and rock surfaces.

Simple multicellular eukaryotes share several properties. In many of these organisms, cell adhesion molecules cause adjacent cells to stick together, but there are few specialized cell types and relatively little communication or transfer of resources between cells. Most or all of the cells retain a full range of functions, including reproduction, such that the organism usually pays only a small penalty for individual cell death. Importantly, in simple multicellular organisms, nearly every cell is in direct contact with the external environment, at least during those phases of the life cycle when the cells must acquire nutrients.

Simple multicellularity is most common among algae. In addition, stalk-like colonies of particle feeders have evolved in at least three groups of heterotrophic protists, and simple filamentous fungi absorb

organic molecules as sources of carbon and energy. Four other eukaryotic groups have achieved simple multicellularity by a different route, aggregating during just one stage of the life cycle. Slime molds are the best-known example ([Chapter 25](#)).

Six groups (two algal, three protozoan, and one fungal) include species characterized by coenocytic organization. In coenocytic organisms, the nucleus divides multiple times, but the cell does not, so the nuclei are not partitioned into individual cells. The result is a large cell—sometimes even visible to the naked eye—with many nuclei. The green algae *Codium* and *Caulerpa*, found along the shorelines of temperate and tropical seas, respectively, are common examples of coenocytic organisms ([Fig. 26.2](#)). Coenocytic rhizarians on the deep seafloor can be 10 to 20 cm long. There is no evidence that any coenocytic organisms evolved from truly multicellular ancestors, nor has any given rise to complex multicellular descendants.

Sources: a. Marevision/AGE Fotostock; (b) Wolfgang Poelzer/Wa/AGE Fotostock.

**FIG. 26.2** Coenocytic organization. Nuclei divide repeatedly but are not partitioned into individual cells. Two different groups of green algae have evolved large size as coenocytic organisms: (a) *Codium*, found abundantly along temperate coastlines, and (b) *Caulerpa*, common in shallow tropical seas and aquaria.

Which selection pressures favored the evolution of simple multicellular organisms from single-celled ancestors? One selective advantage is that multicellularity helps organisms avoid getting eaten. In an illuminating experiment, single-celled green algae were grown in the presence of a protistan predator. Within 10 to 20 generations, most of the algae were living in eight-cell colonies that were essentially invulnerable to predator attack. Another advantage is that multicellular organisms may be able to maintain their position on a surface or in the water column better than their single-celled relatives. Seaweeds, for example, live anchored to the seafloor in places where light and nutrients support growth. Feeding provides a third potential advantage: in colonial heterotrophs such as the stalked ciliate *Epistylis* (see [Fig. 26.1b](#)), the coordinated beating of flagella directs currents of food-laden water toward the cells.

Multicellularity also has some costs, particularly for complex multicellular organisms with differentiated reproductive tissues. In these organisms, most cells do not reproduce, instead supporting the few cells that do. This separation of function requires cooperation among cells, but also creates opportunities for cells to “cheat,” by using nutrients for their own proliferation, rather than directing them toward the growth and reproduction of the organism as a whole. Cancer is the most conspicuous and lethal example of non-cooperation. Indeed, it might be considered the defining disease of complex multicellular organisms.

As we will see, complex multicellular organisms evolved from simple multicellular ancestors, but most taxonomic groups containing

simple multicellular organisms never gave rise to complex descendants.

## Complex multicellularity evolved several times.

Complex multicellular organisms are conspicuous parts of our daily existence. Plants, animals, and (if you look a bit more closely) mushrooms and complex seaweeds are what we notice when we view a landscape or the coastal ocean ([Fig. 26.3](#)). Complex multicellular organisms differ from one another in many ways, but they share three general features. First, they have highly developed molecular mechanisms for adhesion between cells. Second, they display specialized structures that allow cells to communicate with one another. Third, they display complex patterns of cellular and tissue differentiation, guided by networks of regulatory genes. Without these features, complex multicellularity would be impossible.

Sources: a. Dr. Keith Wheeler/Science Source; b. Dave Fleetham/Design Pics/Getty Images; c. Filmfoto/Dreamstime.com; d. Jack Milchanowski/AGE Fotostock; e. AntiMartina/Getty Images.

**FIG. 26.3 Complex multicellular organisms.** Complex multicellularity evolved independently in (a) red algae, (b) brown algae, (c) land plants, (d) animals, and (e) fungi (at least twice).

For example, both plants and animals have differentiated cells and tissues with specialized functions. Only some tissues photosynthesize or absorb organic molecules; other tissues transport food and oxygen through the body; and still others generate the molecular signals that govern development. Only a small subset of all cells contributes to reproduction. Because of this functional differentiation, cell or tissue loss can be lethal for the entire organism.

One other feature of complex multicellular organisms is key to understanding their biology: they have a three-dimensional organization, so only some cells are in direct contact with the environment. Cells that are buried within tissues, relatively far from the exterior of the organism, do not have direct access to nutrients or

oxygen. Therefore, interior cells cannot grow as fast as surface cells unless there is a way to transfer resources from one part of the body to another. Similarly, interior cells do not receive signals directly from the environment, even though all cells must be able to respond to environmental signals if the organism is to grow, reproduce, and survive. Complex multicellular organisms, therefore, require mechanisms for transferring environmental signals received by cells at the body's surface to interior cells, where genes will be activated or repressed in response. Development in complex multicellular organisms can, in fact, be defined as increasing or decreasing gene expression in response to molecular signals from surrounding cells ([Chapter 19](#)).

Complex multicellularity evolved at least six separate times in different eukaryotic groups ([Fig. 26.4](#)). Although complex multicellularity certainly characterizes animals, it also evolved at least twice in the fungi, once in the green algal group that gave rise to land plants, once in the red algae, and once in the brown algae, producing the giant kelps that form forests in the sea.

FIG. 26.4 Complex multicellularity within the eukaryotic tree of life. Complex multicellular organisms (found on branches marked by blue) evolved at least six times within three superkingdoms of eukaryotes.

#### Self-Assessment Question

1. How do simple multicellular organisms differ from complex

multicellular organisms?

## 26.2 DIFFUSION AND BULK FLOW

We already mentioned a key challenge of complex multicellularity: transporting food, oxygen, and molecular signals rapidly across large distances within the body. To illustrate the point, how does oxygen get from the air in your lungs into your bloodstream? How does carbon dioxide get from the atmosphere into leaves? And how does ammonia get from seawater into the cells of seaweeds? The answers to all three questions are the same: by diffusion. Even so, oxygen absorbed by your lungs doesn't reach your toes by diffusion alone. Instead, it is transported actively, and in bulk, by blood pumped through your circulatory system. Bulk flow of oxygen, nutrients, and signaling molecules, at rates and across distances far larger than diffusion alone can achieve, lies at the heart of how complex multicellular organisms function.

### Diffusion is effective only over short distances.

Diffusion is the random motion of molecules, with net movement from areas of higher concentration to areas of lower concentration ([Chapter 5](#)). Diffusion is effective only over small distances. The distance over which molecules can diffuse quickly depends in part on how great the concentration difference is. Because diffusion supplies key molecules for metabolism, it exerts a strong constraint on the size, shape, and function of cells. It strictly limits the size and shape of bacterial cells, as discussed in [Chapter 24](#), and also constrains how eukaryotic

organisms function.

Oxygen provides a good example. Most eukaryotes require oxygen for respiration. If a cell or tissue must rely on diffusion for its oxygen supply, its thickness is limited by the difference in oxygen concentration between the cell or tissue and its environment. The concentration difference itself depends on the amount of oxygen in the environment and the rate at which oxygen is used for respiration inside the organism. In shallow water that is in direct contact with the atmosphere, animals relying on diffusion can reach thicknesses of about 1 mm to 1 cm, depending on their metabolic rate. Of course, a quick swim along the seacoast will reveal many animals that are much larger. And, obviously, you are larger. How do you and other large animals get enough oxygen to all of your cells?

## Animals achieve large size by circumventing limits imposed by diffusion.

Sponges can reach overall dimensions of a meter or more, but they actually consist of only a few types of cell that line a dense network of pores and canals ([Fig. 26.5a](#)). As a result of this organization, their cells remain in close contact with circulating seawater. In essence, the large size of a sponge is achieved without placing metabolically active cells at any great distance from their environment. Similarly, in jellyfish, active metabolism is confined to thin tissues that line the inner and outer surfaces of the body. Essentially, a large flat surface is folded up to produce a three-dimensional structure ([Fig. 26.5b](#)). The

jellyfish's bell-shaped body is often thicker than the metabolically active tissue, but its massive interior is filled by materials that are not metabolically active. This material constitutes the mesoglea, the jellyfish's "jelly." The mesoglea provides structural support but does not require much oxygen.

Sources: a. Andrew J. Martinez/SeaPics.com; b. D. R. Schrichte/SeaPics.com.

FIG. 26.5 Circumventing limits imposed by diffusion. (a) Sponges can attain a large size because the many pores and canals in their bodies ensure that all cells are in close proximity to the environment. (b) Jellyfish also have thin layers of metabolically active tissue, but their familiar bell can be relatively thick because it is packed with metabolically inert molecules (the mesoglea, or "jelly").

But what about us? How does the human body circumvent the constraints of diffusion? Our lungs gather the oxygen we need for respiration, but the lung is a prime example of diffusion in action, not a means of avoiding it. Because lung tissues have a very high surface area to volume ratio, oxygen can diffuse efficiently from the air you breathe into lung tissue ([Chapter 37](#)). A great deal of oxygen can be taken into the body in this way, but how does it get from the lungs to our brains or toes? The distances are far too large for diffusion to be effective. The answer is that oxygen binds to molecules of hemoglobin

in red blood cells and then is carried through the bloodstream to distant sites of respiration. We circumvent diffusion by actively pumping oxygen-rich blood through our bodies.

## Complex multicellular organisms have structures specialized for bulk flow.

We have seen how humans circumvent the limitations of oxygen diffusion. Many other animals similarly rely on the active circulation of fluids to transport oxygen and other essential molecules, including food and molecular signals, across distances far larger than those that could be traversed by diffusion alone. Indeed, without a mechanism like bulk flow, animals could not have achieved the range of size, shape, and function familiar to us.

**Bulk flow** is any means by which molecules move through organisms at rates beyond those possible by diffusion across a concentration gradient ([Fig. 26.6](#)). In humans and other vertebrate animals, the active pumping of blood through blood vessels supplies oxygen to tissues that may be more than a meter distant from the lungs ([Fig. 26.6a](#)). Most invertebrate animals lack well-defined blood vessels but pump fluids into the body cavity, where they circulate freely.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 26.6 Bulk flow. (a) The circulatory system in animals and (b) the vascular system in plants allow these organisms to get around the size limits of diffusion.

Bulk flow also distributes nutrients throughout the body. Intestinal cells absorb organic molecules required for respiration, but it is active transport through the bloodstream that distributes these molecules over large distances. Endocrine signaling molecules such as hormones ([Chapters 9](#) and [36](#)) also move rapidly through the body by means of the blood and other fluids.

Complex organisms other than animals also rely on bulk flow. A redwood tree must transport water upward from its roots to leaves that may be 100 m above the soil. Plants that rely on diffusion to transport water are only a few millimeters tall. How, then, do most plants move water? Bulk flow operates in plants through a system of specialized tissues powered by the evaporation of water from leaf surfaces ([Fig. 26.6b](#); [Chapter 27](#)). Vascular plants also have specialized tissues for the transport of nutrients and signaling molecules upward and

downward through roots, stems, and leaves.

Still other complex multicellular organisms also have specialized tissues to transport essential materials over long distances. Fungi transport nutrients through networks of filaments that may be meters long, relying on osmosis to pump materials from sites of absorption to sites of metabolism ([Chapter 32](#)). The giant kelps have an internal network of tubular cells that transports molecules through a body that can be tens of meters long. We will discuss the biology of plants, fungi, and animals in subsequent chapters. For now, it is important to understand the functional similarities among these diverse multicellular organisms. In general, when some cells within an organism are buried within tissues, far from the external environment, bulk flow is required to supply those cells with the molecules needed for metabolism.

#### Self-Assessment Questions

2. How does diffusion limit the size of organisms?
3. How do multicellular organisms get around the size limits imposed by diffusion?

## 26.3 HOW TO BUILD A MULTICELLULAR ORGANISM

We have emphasized three general requirements for complex multicellular life: cells must stick together, they must communicate with one another, and they must participate in a network of genetic interactions that regulates cell division and differentiation. Once these elements are in place, the stage is set for the evolution of the specialized tissues and organs observed in plants, animals, and other complex multicellular organisms.

### Complex multicellularity requires adhesion between cells.

If a fertilized egg is to develop into a complex multicellular organism, it must divide many times, and the cells produced from those divisions must stick together. In addition, they must retain a specific spatial relationship with one another for the developing organism to function properly. [Chapter 10](#) introduced the molecular mechanisms that hold multicellular organisms together. We begin by reviewing those mechanisms briefly before placing them in evolutionary context.

In animal development, proliferating cells commonly become organized into sheets of cells called epithelia that line the inside and cover the outside of the body. Within epithelia, adjacent cells adhere to each other by means of transmembrane proteins, especially cadherins, which form molecular attachments between cells. Epithelial cells also

secrete an extracellular matrix called the basal lamina, made of proteins and glycoproteins, and these cells attach themselves to this matrix by means of other transmembrane proteins called integrins. In this way, cadherins, integrins, and additional transmembrane proteins provide the molecular mechanisms for adhesion in animals.

Cadherins and integrins do not exist in complex multicellular organisms other than animals, but all such organisms require some means of keeping their cells stuck together. How do they do it? Plants also synthesize cell adhesion molecules that bind cells into tissues, but, in this case, the molecules are polysaccharides called pectins (pectins are what make fruit jelly jell). Cell adhesion molecules are less well known in other complex multicellular organisms, but the general picture is clear. Without adhesion there can be no complex multicellularity, and different groups of eukaryotes have evolved distinct types of molecular “glue” for this purpose.

## How did animal cell adhesion originate?

The genome of the choanoflagellate *Monosiga brevicollis* provides fascinating insight into the evolution of cell adhesion molecules. Choanoflagellates, the closest protistan relatives of animals, are unicellular microorganisms. Therefore, it came as a surprise that the genes of *M. brevicollis* code for many of the same protein families that promote cell adhesion in animals. In fact, the choanoflagellate genome contains genes for both cadherin and integrin proteins. Clearly, these proteins are not supporting epithelia in *M. brevicollis*, so what are they doing?

One possible answer comes from the observation that cells stick not only to one another but also to rock or sediment surfaces. Proteins that originally evolved to promote adhesion of individual cells to sand grains or a rock surface may have been modified during evolution to allow cell–cell adhesion. It is also possible that adhesion molecules were originally used in the capture of bacterial cells, to make prey adhere to the predator.

An intriguing clue to the role of these proteins in choanoflagellates comes from careful laboratory studies ([Fig. 26.7](#)). Although choanoflagellates are unicellular, molecular signals induce some choanoflagellates to form a simple multicellular structure. Unexpectedly, the source of these signals is a bacterium, the preferred prey of the choanoflagellates. The function of the multicellular structures in these choanoflagellates has not yet been determined, but these observations support the hypothesis that they aid predation.

#### HOW DO WE KNOW?

### FIG. 26.7

## How do bacteria influence the life cycles of choanoflagellates?

#### BACKGROUND

Choanoflagellates are the closest protistan relatives of animals. Biologists are studying cell adhesion, cell differentiation, and multicellularity in these organisms to increase our understanding of early events in the evolution of animal multicellularity. American biologist Nicole King and her colleagues cultured the choanoflagellate species *Salpingoeca rosetta* in the laboratory. High-speed videos revealed that these choanoflagellates

differentiate into several distinct cell types in the course of their life cycle. Actively swimming cells can be fast swimmers or slow swimmers that differ in shape and ornamentation ([Fig. 26.7a](#)). When swimming cells make contact with a solid surface, they can differentiate to form a stalk that tethers them to the substrate ([Fig. 26.7b](#)). Simple multicellular colonies in the shape of rosettes ([Fig. 26.7c](#)) were seen when the choanoflagellates were cultured in the presence of many bacteria, including *Algoriphagus machipongonensis*.

Photo source: Reprinted from M. Dayel et al., 2011, "Cell Differentiation and Morphogenesis in the Colony-Forming Choanoflagellate *Salpingoeca rosetta*," *Developmental Biology*, 357:73–82. Copyright 2011, with permission from Elsevier.

#### HYPOTHESIS

The bacterium *Algoriphagus machipongonensis* induces the choanoflagellate to form rosette-like colonies.

#### EXPERIMENT

The scientists grew the choanoflagellates in a medium containing only *A. machipongonensis*, as well as in a medium without this prey bacterium.

#### RESULTS

The multicellular state formed only when *A. machipongonensis* was present ([Fig. 26.7c](#)).

#### CONCLUSION

Choanoflagellates differentiate into several cell types upon receiving cues from the environment. In particular, molecular signals from prey bacteria can induce a simple form of multicellularity. The direct ancestors of animals may have attained simple multicellularity by a similar route.

#### FOLLOW-UP WORK

Researchers continue to investigate the molecular mechanisms of cell differentiation, cell adhesion, and signal reception in these distant relatives of ours.

SOURCE M. Dayel et al. 2011. “Cell Differentiation and Morphogenesis in the Colony-Forming Choanoflagellate *Salpingoeca rosetta*.” *Developmental Biology* 357:73–82.

To date, cadherins have been found only in choanoflagellates and animals, but proteins of the integrin complex extend even deeper into eukaryotic phylogeny: they are found in single-celled protists that branch from basal nodes of the opisthokont superkingdom ([Chapter 25](#)). Such a phylogenetic distribution provides strong support for the general hypothesis that cell adhesion in animals resulted from the redeployment of protein families that evolved to perform other functions before animals diverged from their closest protistan relatives.

## Complex multicellularity requires communication between cells.

In complex multicellular organisms, it is not sufficient for cells to adhere to one another; they must also be able to communicate.

Communication is important during development, guiding the patterns of gene expression that differentiate cells, tissues, and organs. The flow of information among cells is also necessary to coordinate the activity

of cells within tissues and the activity of tissues within organs.

As discussed in [Chapter 9](#), cells communicate by molecular signals. A signaling molecule (generally a protein) synthesized by one cell binds with a receptor protein on the surface of a second cell, essentially flipping a molecular switch that activates or represses enzymes or gene expression in the receptor cell's nucleus. Both plants and animals have receptors of the receptor kinase type, and these initiate similar signaling pathways within the cell. As in the case of adhesion molecules, these signaling pathways, or components of the pathways, have also been identified in their close protistan relatives. Evidently, many of the signaling pathways used for communication between cells in complex multicellular organisms first evolved in single-celled eukaryotes. Again we can ask, what function did molecular signals and receptors have in the protistan ancestors of complex organisms?

All cells have transmembrane receptors that respond to signals from the environment. In some cases, the signal is a molecule released by a food organism (such as the bacteria that induce simple multicellularity in choanoflagellates). In other cases, the cells sense nutrients, temperature, or oxygen level. Single-celled eukaryotes also communicate with other cells within the same species. For example, they need to communicate to ensure that two cells can find each other to fuse in sexual reproduction. Signaling between two cells within an animal's body can be seen as a variation on this more general theme of a cell responding to other cells and the physical environment.

While all eukaryotic cells have molecular mechanisms for

communication between cells, complex multicellular organisms have distinct pathways for the movement of molecules from one cell to another. For example, animals more complex than sponges have **gap junctions**, protein channels that allow ions and signaling molecules to move from one cell into another (**Fig. 26.8**). Gap junctions not only help cells to communicate with their neighbors, but also allow *targeted* communication between a cell and specific cells adjacent to it (**Chapter 10**).

Plants, in contrast, have an intrinsic barrier to intercellular communication: the cell wall. Careful observation of plant cell walls with the electron microscope reveals that these walls have tiny holes through which thin strands of cytoplasm extend from one cell to the next (**Fig. 26.9**). Called **plasmodesmata**, these intercellular channels are lined by extensions of the cell membrane (**Chapter 10**). Tubules of endoplasmic reticulum run through these channels, connecting the

endomembrane systems of the two cells. Like gap junctions, plasmodesmata permit signaling molecules to pass between cells in such a way that they can be targeted to only one or a few adjacent cells.

Complex red and brown algae also have plasmodesmata, and complex fungi have pores between cells that enable cytoplasm that carries signals to flow between cells. As similar channels do not occur in most other eukaryotic organisms, they appear to represent an important step in the evolution of complex multicellularity.

Complex multicellularity requires a genetic program for coordinated

## growth and cell differentiation.

All of the cells in your body derive from a single fertilized egg, and most of those cells contain the same genes. Yet your body contains some 200 distinct cell types precisely arranged in a variety of tissues and organs. How can two cells with the same genes become different cell types? The answer lies in development, the system of gene regulation that guides growth from zygote to adult ([Chapter 19](#)).

Development is the result of molecular communication between cells. Cells have different fates depending on which genes are switched off or on, and genes are switched off and on by the molecular signals that cells receive. A signal commonly alters the production of proteins—inducing the reorganization of the cytoskeleton, for example. As a result, a stem cell may become an epithelial cell, or a muscle cell, or a neuron. This observation leads to another question: what causes the same gene to be turned on in one cell and turned off in another? The ultimate answer is that two cells in the same developing organism can be exposed to very different environments.

When we think about development as a process of programmed cell division and differentiation, the link to unicellular ancestors becomes clearer. Many biological innovations accompanied the evolution of complex multicellularity, but, as noted in [Chapter 25](#), the differentiation of distinct cell types is not one of them. Many unicellular organisms have life cycles in which different cell types alternate in time, depending on environmental conditions. For example, if we experimentally starve dinoflagellate cells, two cells undergo sexual fusion to form resting cells protected by thick walls. That is, a

nutrient shortage induces a change in gene expression that leads to the formation of a distinct type of cell. When food becomes available again, the cells undergo meiotic cell division to form new feeding cells. Many other single-celled eukaryotes form resting cells in response to environmental cues, especially deprivation of nutrients or oxygen.

The key innovation associated with complex multicellularity was the differentiation of cells in *space* instead of in *time*. In a three-dimensional multicellular organism, only surface cells are in direct contact with the outside environment. Interior cells are exposed to a different physical and chemical environment because nutrients, oxygen, and light become less abundant with increasing depth within tissues. In effect, a gradient of environmental signals exists within multicellular organisms. We might, therefore, hypothesize that in the earliest of these organisms, a nutrient or oxygen gradient triggered oxygen- or nutrient-starved interior cells to differentiate, much as these conditions trigger the formation of resting cells in their single-celled relatives. As cellular responses to signaling gradients came under genetic control, the seeds of complex development were sown.

Green algae provide a fascinating example that links cell differentiation in unicellular and multicellular organisms. The simple multicellular organism *Volvox* (see [Fig. 25.15](#)) has two types of cells: vegetative cells that photosynthesize and control movement of the organism, and reproductive cells. Cell differentiation in *Volvox* is regulated by a gene that is also involved in the formation of distinct cell types in the life cycle of *Volvox*'s single-celled relative *Chlamydomonas*. The similar function of this gene in the two

organisms supports the hypothesis that the spatial differentiation of cells in multicellular organisms began with the redeployment of genes that regulate cell differentiation in single-celled relatives.

Bulk flow, which transports nutrients, oxygen, and water within complex multicellular organisms, also carries developmental signals. As with the molecular transport described earlier, bulk flow can carry signals for far greater distances through the body than is possible by diffusion alone. For example, in animals the endocrine system releases hormones directly into the bloodstream. These hormones can then act on cells far distant from those in which they formed ([Chapter 36](#)). Thus, the sex hormones estrogen and testosterone are synthesized in reproductive organs but regulate development throughout the body, contributing to the differences between males and females. In this way, signals carried by bulk flow can induce the formation of distinct cell types and tissues along the path of signal transport.

The genome of the choanoflagellate *Monosiga brevicollis*, discussed earlier, has been a treasure trove of information on the antiquity of signaling molecules deployed in animal development. In addition to expressing proteins that govern cell adhesion and tissue cohesion in animals, *M. brevicollis* expresses a number of proteins that are active in animal cell differentiation. For example, signaling through specific receptor kinases was long thought to be restricted to animals, but it also occurs in *M. brevicollis*. In other cases, individual components of signaling proteins are present in the *M. brevicollis* genome, but not the complex multidomain proteins formed by animals. This is true, for example, of several protein complexes that are important in

development. Similarly, molecules that play an important role in plant development have been identified in the genomes of morphologically simple green algae. The key point is that genome sequences interpreted in light of eukaryotic phylogeny are now enabling biologists to piece together the patterns of gene evolution that accompanied the evolution of morphologic complexity and diversity in plants and animals.

#### Self-Assessment Questions

4. Which arose first: animals with many cells or cell adhesion molecules?
5. All cells in your body derive from a single fertilized egg, yet your body contains many different types of cells. How can we explain this phenomenon?

## 26.4 PLANTS VERSUS ANIMALS

Plants and animals are the best-known examples of complex multicellular organisms. The study of phylogenetic relationships makes it clear that complex multicellularity evolved independently in the two groups. In other words, they do not share a common ancestor that was multicellular. We can see the results of these separate evolutionary events by examining cell adhesion, signaling, and development in plants and animals.

Both plants and animals have evolved sophisticated systems for cell adhesion and molecular signaling. The underlying mechanisms must differ, however, because plant cells have cell walls and animal cells do not. Likewise, plants and animals have evolved similar genetic logic to govern development, but use mostly distinct sets of genes. In both plants and animals, many proteins switch genes encoding other proteins on or off, so that the spatial organization of multicellular organisms arises from networks of interacting genes and their protein products. Ancestral plants and animals simply recruited distinct families of genes to populate regulatory networks.

### Cell walls shape patterns of growth and development in plants.

The plant cell wall ([Chapter 5](#)), made of cellulose, provides structural support to cells. In fact, the cell wall provides the mechanical support that allows plants to stand erect ([Chapter 27](#)). The presence of cell walls has largely determined the evolutionary fate of plants. For

example, because all plant cells except eggs and sperm are completely surrounded by cell walls, they cannot engulf particles or absorb organic molecules. Instead, most plants gain carbon and energy only through photosynthesis. Another consequence is that plant cells have no pseudopodia and no flagella (in conifers and flowering plants, even sperm have lost their flagella). This being the case, plant cells cannot move. Therefore, the plant must obtain nutrients, evade predators, and cope with environmental stress without any moving parts.

The inability of plant cells to move has major consequences for development. At the level of the cell, the entire program of growth and development involves cell division, cell expansion (commonly by developing large vacuoles in cell interiors), and cell differentiation. As a consequence, plant growth is confined to **meristems** ([Fig. 26.10](#)), populations of actively dividing cells at the tips of stems and roots ([Chapter 29](#)). The cells in meristem regions are more or less permanently undifferentiated cells that repeatedly undergo mitosis. A few millimeters from the region of active cell division in a stem or root meristem, cells stop dividing and begin to expand. Within another few millimeters, expansion is curtailed as well. There, signaling molecules induce cells to differentiate, forming the mature cells that will function in photosynthesis, storage, bulk flow, or mechanical support.

FIG. 26.10 A meristem. Because of their cell walls, plant cells can't move. For this reason, roots grow by cell division of the undifferentiated cells in the meristem region at the root tip.

Because their cell walls render plants immobile, plants have evolved mechanisms to transport water and nutrients from the soil to leaves without the use of any moving parts or even the expenditure of ATP. Moreover, because plants are anchored in place, they are unable to move when growth conditions are unfavorable. Instead, plants respond to environmental signals by adjusting their meristem activity and, hence, growth pattern. Heat, drought, floods, and fire can all leave their mark in altered patterns of growth—just compare amply and poorly watered tomato plants. In addition, plants can't flee predators, so they

have evolved mechanical structures (hairs and spines) and poisons to keep from being eaten. Indeed, it has been suggested that, in terms of responding to the environment, growth plays a role in plants similar to that played by behavior in animals.

The details of plant growth, development, reproduction, and function are presented in [Chapters 27–31](#). Here, the key point to bear in mind is that the properties of a pine tree or a rice plant depend fundamentally on the basic features of cell adhesion, intercellular communication, and a regulatory network to guide development, all carried out under the constraints imposed by cell walls.

## Animal cells can move relative to one another.

Having outlined the growth and development of plants, we can appreciate anew the remarkable ballet that characterizes development in animal embryos ([Fig. 26.11](#); [Chapter 40](#)). Fertilized eggs undergo several rounds of mitosis to form a hollow ball called a **blastula**, formed of a single layer of undifferentiated cells. Then something happens that has no parallel in plant development: unconstrained by cell walls, animal cells move relative to one another. Blastula cells migrate, becoming reorganized into a hollow ball that folds inward at one location to form a second layer under the first. This multilayered structure is called the **gastrula**.

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

FIG. 26.11 Gastrula formation. The movement of cells during embryogenesis in animals transforms a blastula into a gastrula.

Gastrula formation brings new populations of cells into direct contact with one another, inducing patterns of molecular signaling and gene regulation that begin the long process of growth and tissue specification. As cells proliferate, molecular signals are expressed in

some cells and diffuse into others, generating what amounts to a three-dimensional molecular map of the organism that guides cell differentiation. Gradients in signaling molecules define top, bottom, front, back, left, and right. Plants do much the same thing, but because animal cells can move during development, animal embryos are not restricted to growth only from localized regions like meristems. Instead, cell division and tissue differentiation occur throughout the developing animal body.

Because they are not constrained by cell walls, animals can form organs with moving parts—muscles that power active transport of food and fluids within the organism and allow movement. Thus, animals have possibilities for function that are far different from those of plants. If drought or predators strike, animals can respond by changing their behavior; for example, they can move to a new location ([Chapter 35](#)).

Plants and animals, then, display contrasting patterns of development and function that reflect both their independent origins from different groups of protists and the constraints imposed by cell walls in plants.

#### Self-Assessment Questions

6. How do plants and animals differ in the ways their cells adhere, communicate, and differentiate during development?
7. What is a key difference in structure between the cells of multicellular plants and the cells of multicellular animals?

## 26.5 THE EVOLUTION OF COMPLEX MULTICELLULARITY

The differences between an amoeba and a lobster might seem vast, but research over the past decade increasingly shows how this apparent gap was bridged through a series of evolutionary innovations. Throughout this chapter, we have emphasized that complex multicellular organisms have three requirements: mechanisms for cell adhesion, modes of communication between cells, and a genetic program to guide growth and development. These three requirements had to be acquired in a specific order. If the products of cell division don't stick together, there can be no complex multicellularity. Even so, adhesion is not sufficient: it must be followed by mechanisms for communication between cells. Moreover, cells must be able to send molecular messages to specific targets or regions, assisted in animals by gap junctions and in plants by plasmodesmata.

With these first two requirements in place, natural selection would favor the increase and diversification of genes that regulate growth and development, making possible more complex morphology and anatomy. Thus, the stage was set for the final key to complex multicellularity: the differentiation of tissues and organs that govern the bulk flow of fluids, nutrients, signaling molecules, and oxygen through increasingly large and complex bodies. This differentiation freed organisms from the tight constraints imposed by diffusion. When all these features are placed onto phylogenies, they show both the

predicted order of acquisition and the tremendous evolutionary consequences of complex multicellularity ([Fig. 26.12](#)).

FIG. 26.12 The evolution of complex multicellularity. Phylogenetic relationships of complex (a) animals and (b) plants, with their close evolutionary relatives, show similar patterns of character accumulation and its consequences for biological diversity. Estimated species numbers are shown.

Fossil evidence of complex multicellular organisms is first observed in rocks deposited 575–555 million years ago.

In [Chapter 22](#), we noted that phylogenies based on living organisms

make predictions about the fossil record. Characters and groups associated with lower branches in phylogenies should appear as earlier fossils than those associated with later branches. Although fossils don't preserve molecular features, the record supports the phylogenetic pattern shown in [Fig. 26.12](#).

Single-celled protists are found in sedimentary rocks as old as 1800 million years, and a number of simple multicellular forms have been discovered that are nearly as old (see [Fig. 25.23](#)). Nonetheless, the oldest fossils that record complex multicellularity are found in rocks that were deposited only 575–555 million years ago. [Fig. 26.13a](#) shows one of the oldest known animal fossils, a frondlike form preserved in 570-million-year-old rocks from Newfoundland, near the eastern tip of Canada. This fossil and many others found in rocks of this age are enigmatic. There is complex morphology to be sure, but it is difficult to understand these forms by comparing them to the body plans of living animals. The Newfoundland fossils show no evidence of head or tail, no limbs, and no opening that might have functioned as a mouth. They appear to be very simple organisms that obtained both carbon and oxygen by diffusion. These fossils are long and wide, but they are not thick. In fact, it is likely that active metabolism occurred only along the surfaces of these structures.

FIG. 26.13 The earliest fossils of animals. (a) Among the oldest known macroscopic animal fossils is a frond-like form made up of tubular structures, preserved in 570-million-year-old rocks from Newfoundland. (b) The oldest known animal fossil showing bilateral symmetry is a mollusk-like form preserved in 560–555-million-year-old rocks from northern Russia. (c) The oldest tracks and trails of mobile animals are found in rocks 560 million years old and younger.

Such animals lie near the base of the animal tree ([Chapter 42](#)), and probably would have developed under the guidance of regulatory genes similar to those present in modern sponges or, perhaps, jellyfish. By 560–555 million years ago, more complex animals, with a distinct head and tail, top and bottom, left and right, enter the record ([Fig. 26.13b](#)). At the same time, we begin to see tracks and trails made by animals that moved across and through surface sediments with the aid of muscles ([Fig. 26.13c](#)). These tracks are an indirect record, complementary to fossils, of increasing animal complexity. These, then, are the first known occurrences of the types of animal that dominate ecosystems today, both in the sea and on land. These animals must have possessed a diverse array of genes to guide development, something akin to those seen today in insects or snails.

Clearly, by 575–555 million years ago, the animal tree was beginning to branch. This development, however, raises a new question: why did complex multicellular animals appear so much later than simple multicellular organisms?

## Oxygen is necessary for complex multicellular life.

Earlier in the chapter, we discussed the key biological requirements for complex multicellularity. There is a critical environmental requirement as well: the presence of oxygen. Other potential electron acceptors for respiration exist, such as sulfate and ferric iron. However, they not only occur in much lower abundances than oxygen, but also are not gases and so do not accumulate in air. In addition, only the oxidation of organic molecules by  $O_2$  provides sufficient energy to support large and active predators like wolves and lions. And only oxygen in concentrations approaching those of the present day can diffuse into the interior cells of large, active organisms. On our planet—and, probably, on all planets—no other molecule is both sufficiently abundant and has the oxidizing power needed to support the biology of large complex organisms.

On the present-day Earth, lake or ocean bottoms with oxygen levels below approximately 8% of surface levels support only a limited diversity of animals, and those animals tend to be tiny. Large animals with energetic modes of life—carnivores, for example—live only in oxygen-rich environments. Clearly, then, clear restrictions on animal form and diversity exist at lower oxygen levels today. These restrictions have important implications for the distribution of large,

active, and diverse animals through time. We noted in [Chapter 24](#) that oxygen first began to accumulate in the atmosphere and surface oceans about 2400 million years ago, but the chemistry of sedimentary rocks deposited after that time tells us that oxygen levels remained low for a very long time. Our modern world of abundant oxygen came to exist only 580–560 million years ago, about the time when fossils first record large multicellular organisms ([Fig. 26.14](#)).

Scientists continue to debate the causes of this increase in oxygen levels, but the correspondence in time between oxygen enrichment and the first appearance of large, complex animals (and algae) suggests that more oxygen permitted animals to attain greater size and adopt more energetic modes of life. Their greater size created opportunities for tissue differentiation, leading to transport of nutrients and signaling

molecules by bulk flow. The evolution of bulk flow in turn permitted still larger size, setting up a positive feedback that eventually resulted in the complex multicellular organisms we see today.

With morphologic complexity came new functions, including predation on other animals. Protozoan predators capture other microorganisms, but do so one cell at a time. In contrast, animals that obtain food by filtering seawater gather cells by the thousands, and larger animals can eat smaller ones. Predation by animals opened up endless possibilities for evolutionary specialization and, therefore, diversification. Among photosynthetic organisms, multicellular red and green algae were able to establish populations in wave-swept coastlines and other environments where simpler organisms lacked the mechanical strength to hold their position along the shoreline.

The key point is that complex multicellular organisms didn't succeed by doing the same things as simpler eukaryotes. Instead, complex multicellularity spread through the oceans because it opened up new and unprecedented evolutionary possibilities.

## Land plants evolved from green algae that could carry out photosynthesis on land.

Complex multicellular land plants originated about 465 million years ago, well after marine animals and seaweeds. Nonetheless, in some ways, the pattern of land plant evolution parallels that of animals. Ancestral green algae evolved molecular means for cell–cell adhesion

and communication between cells, and the algae that form the sister group to land plants share with them the innovation of plasmodesmata. Then, as they developed larger and more complex three-dimensional bodies, the plant ancestors evolved a succession of genes and their protein products to guide cell division, expansion, and differentiation. Land plants, however, faced a different challenge from that of animals. They now had to carry out photosynthesis, which had evolved earlier in aquatic organisms, within their own tissues bathed by air. Their diversification across the land surface also required that these plants absorb nutrients and water from the soil and transport these substances throughout the plant, rather than simply taking them in by diffusion from the surrounding water.

Fossils indicate that by 400 million years ago, plants with specialized tissues for bulk flow of water and nutrients had begun to spread across the continents. As plant biomass built up on land, it created opportunities for additional types of complex multicellular organisms. In particular, the fungi, which decompose organic matter, radiated by taking advantage of this resource ([Fig. 26.15](#)), evolving complex multicellularity in two distinct lineages ([Chapter 32](#)).

Sources: Carol Hotton; b. Martha E. Cook, School of Biological Sciences, Illinois State University.

FIG. 26.15 Evolution of complex fungi. (a) This trunklike fossil, discovered in France, is actually a giant fungus that towered over early land plants 375 million years ago. (b) This image shows the interior of the fungus, which consists of tubes that transported nutrients through the large body.

## Regulatory genes played an important role in the evolution of complex multicellular organisms.

Complex multicellular organisms account for a large proportion of all eukaryotic species. Thus, one consequence of complex multicellularity was an increase in biological diversity. Let's compare the diversity of complex multicellular groups with their simpler phylogenetic sisters. Choanoflagellates, for example, number about 150 species; simple animals such as sponges and jellyfish about 20,000; and complex animals with circulatory systems perhaps as many as 10 million. Plants and their relatives show a comparable pattern. There are about 6000 species of green algae on the branch that includes land plants, but about 400,000 species of anatomically complex land plants capable of bulk flow. Similarly, complex fungi and red algae include more species

by an order of magnitude than their simpler relatives.

How did this immense diversity arise? At one level, the answer is functional and ecological. Complex multicellular organisms can perform a range of functions that simpler organisms cannot, so they have evolved many specific types of interaction with other organisms and the physical environment. Carnivory, for example, requires both sophisticated sensory systems and jaws or limbs to locate and capture prey. Once established, though, carnivorous animals radiated throughout the oceans and, eventually, on land, providing an ecological driver of diversification. This explanation, however, prompts another question: what is the genetic basis for the bewildering range of sizes and shapes displayed by complex multicellular organisms?

The answer has to do with the network of genes that guide development. Since the 1950s, biologists have learned a remarkable amount about this genetic network and its host of interacting genes ([Chapter 19](#)). Many of the genes involved in development are what we might consider “middle managers”: a molecular signal induces the expression of such a gene, and its protein product in turn prompts the expression or repression of another gene. It is the complex interplay of these genetic switches—turning specific genes on in one cell and off in another, depending on where those cells occur in the developing body—that results in crabs with large pincers and butterflies with patterned wings ([Fig. 26.16](#)).

HOW DO WE KNOW?

FIG. 26.16

# What controls color pattern in butterfly wings?

## BACKGROUND

Butterfly wings commonly show a striking pattern of color, including circular features known as eyespots. Eyespots are adaptive, for example, in deterring predation by birds.

## HYPOTHESIS

The expression of regulatory genes during wing development governs eyespot formation on wing surfaces.

## EXPERIMENT

Paul Brakefield and his colleagues mapped the expression of a regulatory gene called *Distalless* in developing butterfly wings. They identified an antibody that binds with the protein expressed by *Distalless* genes and fused this antibody to green fluorescent protein (GFP). GFP glows vivid green when illuminated under blue light, enabling the biologists to visualize the spatial pattern of *Distalless* expression in developing wings.

## RESULTS

In both wild-type and mutant butterflies, the expression pattern of *Distalless* (on the left in each panel of the figure) in developing wings closely resembles the pattern of eyespots on the wing (on the right in each panel).

## CONCLUSION

Regulatory genes play an important role in butterfly wing coloration, and mutations in these genes can account for differences in wing color patterns among species. Continuing research using new tools for genomic analysis has enabled biologists to understand how interacting genes and their products give rise to morphologic pattern in butterfly wings and many other organ systems.

SOURCE P. M. Brakefield et al. 1996. "Development, Plasticity and Evolution of Butterfly Eyespot Patterns." *Nature* 384:236–242.

It makes sense that if regulatory genes guide development of the body in each complex multicellular species, then mutations in regulatory genes may account for many of the differences we observe among different species. A whole new field of biology called

evolutionary-developmental biology, or [evo-devo](#) for short, examines how developmental genes underpin evolutionary change. In evo-devo research, scientists compare the genetic programs for growth and development in species found on different branches of phylogenetic trees. One goal is to discover the molecular mechanisms that guide development in individual species. Another is to understand the genetic differences associated with differences in form and function among species.

Evo-devo is an exciting and rapidly expanding field of research because it is helping to illuminate long-suspected relationships between the development of individuals and patterns of evolutionary relatedness among species. Continuing research promises to shed new light on the similarities and differences among plants, animals, and other complex multicellular organisms.

#### Self-Assessment Questions

8. Which environmental change(s) are recorded by the sedimentary rocks that contain the oldest fossils of large active animals?
9. How does evo-devo research help us to understand how animals have diversified to form so many distinct species?

## CORE CONCEPTS SUMMARY

### 26.1 THE PHYLOGENETIC DISTRIBUTION OF

**MULTICELLULAR ORGANISMS:** Complex multicellularity arose several times in evolution.

Bacteria are unicellular or form simple multicellular structures.

[page 569](#)

Eukaryotes can be unicellular or multicellular and exhibit both simple and complex multicellularity. [page 569](#)

Simple multicellularity requires the adhesion of cells although there is little cell differentiation; complex multicellularity requires cell adhesion, cell signaling, and differentiation and specialization among cells. [page 569](#)

Complex multicellular organisms have evolved independently at least six times: in animals, in vascular plants, in red algae, in brown algae (the kelps), and at least twice in the fungi. [page 572](#)

**26.2 DIFFUSION AND BULK FLOW:** In complex multicellular organisms, bulk flow circumvents the limitations of diffusion.

Diffusion is the random motion of molecules, with net movement occurring from regions of higher concentration to regions of lower concentration. It generally acts over small distances, placing limits on the size of multicellular organisms. [page 572](#)

Bulk flow is an active process that allows multicellular organisms to nourish or send signals to cells located far from the external environment, thereby circumventing the constraints imposed by

diffusion. [page 573](#)

### **26.3 HOW TO BUILD A MULTICELLULAR ORGANISM:**

Complex multicellularity depends on cell adhesion, communication, and a genetic program for development.

Animal and plant cells are organized into tissues characterized by specific molecular attachments between cells. [page 574](#)

Choanoflagellates express some of the same proteins that permit cell adhesion in animals, even though choanoflagellates are unicellular. Experiments suggest that choanoflagellates may use these proteins to capture bacteria, not for cell adhesion. [page 575](#)

Gap junctions in animals and plasmodesmata in plants allow cells to communicate with each other in a targeted fashion. [page 576](#)

The cells of complex multicellular organisms are genetically programmed to differentiate into multiple cell types in space. [page 578](#)

A number of gene families known to play developmental roles in multicellular organisms are also present in their unicellular relatives, where at least some of them play a role in life cycle differentiation. [page 578](#)

**26.4 PLANTS VERSUS ANIMALS:** Plants and animals evolved complex multicellularity independently of each other and solved similar problems with different sets of genes.

The cell wall characteristic of plant cells provides structural and mechanical support, but does not allow plant cells to move. [page](#)

The cell wall of plants has led to distinct solutions to the problems of cell adhesion, cell communication, and development. For example, plants grow by the activity of meristems, populations of actively dividing cells at the tips of stems and roots. [page 579](#)

Animal cells do not have cell walls, allowing cell movement that is not possible in plants. For example, during animal development, cells of the embryo migrate inward to form a layered structure called a gastrula. [page 579](#)

## **26.5 THE EVOLUTION OF COMPLEX**

**MULTICELLULARITY:** The evolution of large and complex multicellular organisms, which required abundant oxygen, is recorded by fossils.

Oxygen may be required for the evolution of complex multicellularity because of its chemical properties and its abundance. [page 582](#)

The evolution of complex multicellularity observed in the fossil record correlates with increases in atmospheric oxygen that occurred 580–560 million years ago. [page 582](#)

Complex multicellular organisms evolved later on land, as ancestral plants evolved the capacity to photosynthesize surrounded by air rather than water. [page 583](#)

Evolutionary-developmental biology, or evo-devo, is a field of research that looks at both individual development and evolutionary

patterns in an attempt to understand the developmental changes that allowed organisms to diversify and adapt to changing environments. [page 584](#)

---

## CASE 6

### Agriculture

#### *Feeding a Growing Population*

*With the demand for food increasing, what will be the impact on our planet?*

In 2008, people around the world, from South Asia to Africa to the Caribbean, took to the streets to protest rising

food prices. Their fear and frustration were understandable: in the years between 2005 and 2008, food prices skyrocketed. The price of corn almost tripled, while the price of wheat and rice nearly doubled. The poor, who spend a large part of their income on food, were the hardest hit. The Food and Agricultural Organization of the United Nations estimates that higher prices pushed an additional 40 million people into hunger in 2008 alone.

The sharp increase in food prices raised many questions. Had the human population outstripped its food supply? In 1798, Thomas Malthus's *An Essay on the Principle of Population* made the point that while populations have the potential to increase geometrically, their food supply is limited. Malthus's essay influenced Charles Darwin, who saw it as describing the great struggle of nature and, therefore, the

survival of the fittest.

Yet there is no evidence that the 2008 spike in world food prices was due to overpopulation. Instead, a number of factors contributed to the rise in food prices, two of which especially stand out.

The first factor driving up food prices was drought in a number of key grain-producing regions. The lesson here is that even in developed countries, weather matters. In particular, drought and high temperature can slow or halt crop growth. Irrigation can help, but it's expensive, especially given the immense amounts of water that plants need. For example, a cow raised for meat drinks approximately 15,000 liters of water each year—a trivial amount compared to the roughly 3 million liters of water needed to grow the grain the cow will consume over the same time period.

The second factor creating the increased food prices was a steep rise in oil prices, which increased the cost of producing food. Historically, the sun's rays and the sweat of the farmer's brow were the major sources of energy for food production. Today, however, fossil fuels power tractors, are used to produce fertilizers and pesticides, and run irrigation pumps. Thus, when oil prices spike, the price of food also rises.

When oil prices began to fall during the second half of 2008, food prices declined. This provided relief for consumers, but can Malthus's concerns be ignored? Sometime in 2011, Earth's human population surpassed 7 billion. The United Nations estimates that by 2100 the human population will exceed 10 billion. Factor in the impacts of

climate change, the spread of pests and pathogens, and the degradation of agricultural soils, and the challenge of producing enough food for all can seem daunting. With the demand for food increasing, what will be the impact on our planet?

Before humans began to cultivate plants, they hunted and gathered their food. These early hunter-gatherers favored plants that were easy to harvest, allowing them to gather large amounts of food in a short amount of time.

As humans began to settle in one place, they learned to cultivate food plants. The early agriculturalists needed to remove nonfood species (weeding), as well as save seeds to sow in the next season. Instead of pulling the seeds off in the field, they developed tools to cut stems and carry home entire seed heads. Harvesting became more efficient.

This new way of harvesting had a profound impact on plants. Only seeds that remained firmly attached to the stem were carried back to the village, so only these seeds would be replanted the next year. In this way, humans inadvertently became agents of artificial selection.

Consider wheat. In the wild, natural selection favors wheat whose seeds are protected by tough barbs and separate easily from the plant, allowing dispersal. Farmers, however, preferred wheat whose seeds remained attached to the plant and so were easier to harvest. Over time, crop plants lost the ability to disperse their own seeds. In this way, plant species became domesticated: they were no longer able to survive and reproduce on their own.

Sources: (left) Bob Gibbons/FLPA/Science Source; (right) Nigel Cattlin/Science Source.

**Domestication of wheat.** Wild wheat (left) and modern domesticated wheat (right). The seeds of wild wheat are protected by tough barbs (the long spikes), and they fall easily from the plant, enhancing dispersal. The seeds of domesticated wheat remain attached to the plant, making the grain easier to harvest.

Humans have had a close association with wheat and other grasses for a long time. Today, more than 60% of the world's food energy comes from grasses, with wheat, rice, and corn (maize) being the three most important.

The earliest crops were domesticated a little more than 10,000 years ago. Humans made the transition from hunter-gatherers to agriculturists in at least six sites around the world. From these locations, agriculture spread along with technological innovations. For example, animal-drawn plows could break up heavy soils that could not be easily worked with hand tools. Irrigated crops could be grown

during periods of low rainfall.

In late nineteenth century and early twentieth centuries, scientists began to recognize the role of microbes in plant diseases and the importance of nutrients such as nitrogen and phosphorus for plant growth. With the invention of the internal combustion engine, agriculture became mechanized. Yet increases in yield (measured in weight of crop output per area of land) remained modest.

By the 1940s, scientists had developed industrially produced nitrogen fertilizers that significantly boosted plant growth. They had also learned enough about genetics to begin applying that knowledge to plant breeding. These advances led to an amazingly productive period known as the Green Revolution. During the second half of the twentieth century, crop yields ballooned.

In the case of rice and wheat, both of which produce their seed heads at the tops of their stalks, a key factor was breeding for shorter and stronger stems. Plants with short, strong stems could allocate more resources to seed production without causing the stems to bend over. In addition, rice varieties were developed that mature more quickly, so farmers could harvest several crops in a single year.

Today, we are entering a new phase of agriculture with the use of genetic engineering. Most of the corn and soy products now consumed in the United States come from plants that have been genetically engineered to resist certain pests and herbicides. Some of the genes come from different species altogether. For example, corn and cotton plants are often engineered to contain a gene from the bacterium

*Bacillus thuringiensis (Bt)* that confers pest resistance.

Without question, humans have made great strides in increasing yields to feed our ever-growing population. At the same time, though, crop pests and pathogens have continued to evolve ways to evade our savviest plant breeders.

The nature of modern agriculture compounds this problem. Most modern farms consist largely of monocultures, single crop species grown over a large area. In a given field of corn or wheat, the individual plants are often genetically quite similar to one another. Growing only a single crop at a time makes it much easier to mechanize planting and harvesting. Unfortunately, it also means that a pathogen that can overcome a plant's natural defenses has the potential to wipe out an entire field.

In 2010, a new strain of yellow wheat rust fungus emerged in the Middle East. In its first year, the disease wiped out as much as half of Syria's wheat crop. It has since spread to other countries in the region. Meanwhile, crop scientists have warned that Ug99, a strain of an even more damaging fungal pathogen that first surfaced in eastern Africa, could devastate global wheat crops.

Today, yields continue to increase, although not as fast as they once did. If yield increases cannot be maintained, we may have to depend on the age-old method of increasing food production: we will have to add more agricultural land. While it might seem as if the planet has plenty of additional land that can be used to produce more food, some of this land is too dry, too cold, or too steep to be useful in agriculture. Other

regions not under cultivation now are home to countless other species that would be vulnerable to the loss of their habitats.

One of humanity's greatest challenges is to produce enough food for all while saving room for nature. As plants are the cornerstone of agricultural systems, understanding what encourages plants' growth and reproduction and what constrains them is central to feeding us all in an increasingly crowded world.

## DELVING DEEPER INTO CASE 6

**For each of the Cases, we provide a set of questions to pique your curiosity. The questions cannot be answered directly from the Case itself, but instead introduce issues that will be addressed in chapters to come. We revisit this Case in [Chapters 27–32](#) on the pages indicated below.**

1. How has nitrogen availability influenced agricultural productivity?  
See [page 613](#).
2. How did scientists increase crop yields during the Green Revolution? See [page 635](#).
3. What is the developmental basis for the shorter stems of high-yielding rice and wheat? See [page 646](#).
4. Can modifying plants genetically protect crops from herbivores and pathogens? See [page 680](#).
5. What can be done to protect the genetic diversity of crop species?  
See [page 706](#).

6. How do fungi threaten global wheat production? See [page 731](#).

## CHAPTER 27 Plant Form, Function, and Evolutionary History

Frank Krahmer/Getty Images

---

## CORE CONCEPTS

**27.1 PHOTOSYNTHESIS ON LAND:** A major challenge in the evolution of plants was being able to acquire carbon dioxide for photosynthesis without drying out.

**27.2 CARBON DIOXIDE GAIN AND WATER LOSS:** Leaves have a waxy cuticle and stomata, which allow plants to acquire carbon dioxide while limiting water loss.

**27.3 WATER TRANSPORT:** Xylem transports water and dissolved nutrients from the soil, allowing leaves to remain hydrated.

**27.4 TRANSPORT OF CARBOHYDRATES:** Phloem transports carbohydrates throughout the plant for use in growth and respiration.

**27.5 UPTAKE OF WATER AND NUTRIENTS:** Roots expend energy to obtain nutrients from the soil.

---

Single-celled organisms are the principal photosynthesizers of the seas, but plants carry out nearly all of the photosynthesis that occurs on land. This means that plants are the main entry point for both energy and carbon into terrestrial ecosystems. Directly or indirectly, plants are the source of most of what humans, and all other animals on land, eat. Only after land plants evolved did animals move out of the ocean and onto the land.

The closest living relatives to land plants are green algae that primarily grow in or close to streams and ponds. This relationship suggests that land plants originated in moist areas close to sources of fresh water. From this starting point, plants have spread out to colonize

nearly all environments on land; some plants have even evolved to live in aquatic habitats, both fresh water and marine. But perhaps the most important event was the appearance of plants able to carry out photosynthesis far above the ground. The challenges of living on land and growing up into the air transformed plants from small, relatively simple forms into organisms with complex vascular tissues and organs specialized for nutrient uptake and photosynthesis.

In turn, the appearance of land plants had a profound impact on the environment. The terrestrial habitats of the first land plants were very different from today. In particular, there would have been no soil and very little shade. The presence of plants transformed the land: plants contributed to the formation of soil and, by growing tall, they created forests and other habitats in which plants and other land-dwelling organisms live. In this chapter, we focus on the structural and physiological innovations that allow plants to carry out photosynthesis so successfully on land. In later chapters, we explore how plants reproduce ([Chapter 28](#)), grow ([Chapter 29](#)), and defend themselves against pathogens and herbivores ([Chapter 30](#)).

# 27.1 PHOTOSYNTHESIS ON LAND

Organisms that live on land typically look nothing like those that live in water. The reason is that air and water differ in many fundamental properties. For example, water is denser than air, so organisms on land invest more in structures that can support the weight of their bodies. They are also exposed to higher amounts of ultraviolet radiation and wider swings in external temperatures. Nevertheless, the major risk of exposure to air is the potential to dry out.

Excessive water loss, or **desiccation**, is a constant hazard for photosynthetic organisms on land. Recall from [Chapter 8](#) that photosynthesis uses energy from sunlight to synthesize organic (carbon-containing) molecules. Plants expose large surface areas to the air to obtain the sunlight and carbon dioxide (CO<sub>2</sub>) needed for photosynthesis. Evaporation of water from these exposed surfaces can lead to desiccation. Consequently, many aspects of plant form and function can be understood in light of how they help sustain the hydration of photosynthetic cells.

## Land plants share many cellular features with green algae.

Let's begin by revisiting where plants sit on the tree of life. In [Chapter 25](#), we saw that “land plants” occur within the eukaryotic supergroup known as the Archaeplastids. Within this group, land plants are found within the Viridiplantae, or “green plants” (*viridi* = green, *plantae* = plants). The other members of the Viridiplantae are green algae. Land

plants are monophyletic, meaning that they include all of the descendants of a single common ancestor ([Fig. 27.1](#)). Green algae are paraphyletic because the descendants of their last common ancestor also include the land plants. In this and succeeding chapters, we use “plants” and “land plants” interchangeably to denote the group that has diversified to become the dominant photosynthetic organisms on land. The scientific name for land plants (Embryophyta) highlights a feature shared by all plants: the formation of an embryo. We discuss the significance of this feature in [Chapter 28](#).

FIG. 27.1 The phylogenetic tree of land plants. Land plants can be divided into two types: the vascular plants, which actively control their hydration, and the bryophytes, which do not.

Land plants are the only members of the Viridiplantae that have evolved complex multicellularity. Recall from [Chapter 26](#) that organisms with complex multicellularity produce three-dimensional bodies with differentiated tissues and organs. In contrast, green algae are either unicellular or exhibit simple multicellularity, in which nearly every cell is in direct contact with the external environment.

Nevertheless, plant cells share many features with the cells of green algae. The cells of both plants and green algae contain chloroplasts with chlorophyll *a* and *b* and include a large membrane-bound vacuole that stores ions, metabolites, and water. Of particular importance, a cellulose-containing cell wall surrounds almost every cell (gametes are the exception). One consequence of this cell wall is that turgor pressure can develop within the cell. As water moves into a cell by osmosis, the cytoplasm pushes outward on the cell wall. At the same time, the cell wall resists being stretched and pushes back on the cytoplasm. The result is an increase in the pressure inside the cell ([Chapter 5](#)). Turgor pressure contributes to the mechanical support of plant tissues. In fact, many plant tissues visibly deform or “wilt” when excessive water loss results in a loss of turgor pressure.

In green algae, most cells have thin walls and contain chloroplasts for photosynthesis. Most likely the cells of the first plants did as well. As plants evolved, they produced a greater diversity of cell types. Many of these new cell types had thicker, and in some cases stiffer, walls that provided the mechanical support needed for plants to grow tall and to transport water and nutrients internally via bulk flow. As we will see, the evolution of specialized cell types played a key role in

how plants have become so successful on land.

## Bryophytes rely on surface water for hydration.

How have plants evolved the ability to survive and photosynthesize on land, even though the land surface is often dry? We can identify two main strategies. Plants called bryophytes rely on surface moisture for hydration, and they have evolved the ability to withstand intermittent drying. In contrast, vascular plants are able to pull water from the soil and to regulate their water loss. As a result, vascular plants maintain a more stable level of hydration compared to bryophytes.

The bryophytes include mosses, liverworts, and hornworts ([Fig. 27.1](#)). These three groups of plants share many features, including how they acquire water. The evolutionary relationships among the groups are unclear, however: we do not know which one is most closely related to vascular plants, or even if one or more might form a monophyletic group. Even so, the last common ancestor of mosses, liverworts and hornworts likely lived early in the evolutionary history of land plants.

Bryophytes are small plants, most less than 5 cm tall. Many look like small green tufts, and they are often found growing on rocks or logs ([Fig. 27.2](#)). A distinctive feature of bryophytes is that the majority of their aboveground surfaces are permeable to water. When it rains, these surfaces take up water and dissolved nutrients. Bryophytes do not produce roots. Instead, hair-like outgrowths from their lower surfaces anchor bryophytes in place. Like their green algal relatives, bryophytes

lack specialized surfaces or organs for resource uptake.

Source: Fulton Rockwell.

FIG. 27.2 Bryophytes. The understory of this northern forest is dominated by mosses and liverworts.

In addition to being small, bryophytes have a high ratio of surface area to volume. This explains why most bryophytes rely entirely on diffusion to distribute water internally. Recall that diffusion is an effective transport mechanism only over short distances ([Chapter 26](#)). Because no cell is very far from an external surface in bryophytes, water is able to move into and through their cells by diffusion. A few moss do grow to more than 10 cm tall; these species produce elongated cells that allow fluids to be transported from one part of the plant to another by bulk flow.

Paradoxically, it is their dependence on the uptake of surface moisture that puts bryophytes at risk of drying out. Put simply, any surface that takes up water when wet will lose water to the surrounding air when dry. Because bryophytes do not have a way to regulate water loss, they desiccate quickly when their surfaces are dry. Thus, the

water content of bryophyte cells fluctuates with that of their environment.

All cells require a high degree of hydration to function. As bryophyte cells dry out, these plants lose their ability to carry out photosynthesis. At the same time, many bryophytes exhibit [desiccation tolerance](#), a set of biochemical traits that allows their cells to survive extreme dehydration without damage to membranes or macromolecules. As a result, they can resume photosynthesis when their surfaces once again come into contact with water.

## Water pulled from the soil moves through vascular plants by bulk flow.

Vascular plants evolved a completely different approach to achieving the hydration needed to carry out photosynthesis on “dry” land. Their strategy has been highly successful: vascular plants are, by far, the dominant plant type found today. Ferns, sunflowers, and pine trees are all examples of vascular plants.

Vascular plants differ from bryophytes in several ways. The first one is obvious: vascular plants do not rely on diffusion to distribute materials internally, but instead transport water and other molecules by means of bulk flow through specialized, tube-like cells. This mechanism means that they can become much larger in size than bryophytes.

A second major difference is that water uptake primarily occurs in specialized organs that grow belowground—the roots. Through their

roots, vascular plants can access the large amounts of water held by the soil. Because the plant's water comes from the soil, the aboveground surfaces of vascular plants can be relatively impermeable to water, limiting its loss.

The net result of these features is that vascular plants can carry out photosynthesis even when their aboveground surfaces are dry. Moreover, they can sustain the hydration of photosynthetic organs elevated as much as 100 m into the air. In many ways, the capacity to control the uptake, transport, and loss of water made possible the extraordinary evolutionary success of vascular plants.

More than 95% of all land plant species found today are vascular plants, and they provide almost all the photosynthetic output of terrestrial environments. Thus, the remainder of this chapter focuses on the structure and function of vascular plants. We return to bryophytes when we examine plant reproduction ([Chapter 28](#)) and diversity ([Chapter 31](#)).

## Vascular plants produce four major organ types.

Vascular plants are monophyletic, with four main subgroups ([Fig. 27.1](#); [Fig. 27.3](#)). [Lycophytes](#) and [ferns and horsetails](#) are mostly small plants ([Fig. 27.3a](#) and [b](#)). The [gymnosperms](#) include pine trees and other conifers ([Fig. 27.3c](#)). The [angiosperms](#), or flowering plants, include oak trees, grasses, and sunflowers ([Fig. 27.3d](#)). Many of the features that distinguish these groups are related to how they reproduce. For example, only gymnosperms and angiosperms produce

seeds, while flowers and fruits occur only in angiosperms.

**FIG. 27.3 The four major groups of vascular plants.** Example species include (a) a lycophyte (*Lycopodium annotinum*), (b) a fern (*Athyrium filix-femina*), (c) a gymnosperm (*Pseudotsuga menziesii*), and (d) an angiosperm (*Punica granatum*).

Vascular plants exhibit tremendous diversity of form, yet they are all built from the same four types of organs: leaves, reproductive organs, stems, and roots ([Fig. 27.4](#)). Leaves are specialized for photosynthesis. Reproductive organs promote genetic diversity and dispersal. Stems elevate and position both leaves and reproductive organs. These aboveground organs—leaves, reproductive organs, and stems—collectively form the [shoot](#). Roots grow below ground, anchoring the plant and taking up nutrients and water. Variation in form arises from differences in length, size, and branching patterns of

stems and roots, as well as in the structure of individual organs.

Although plant organs such as leaves come in all shapes and sizes, they are constructed from only three main types of tissues: epidermis, vascular, and ground tissues ([Fig. 27.4](#)). An outer layer of cells, the [epidermis](#), forms the interface between the plant and the external environment. Epidermal cells provide protection to the plant. Some epidermal cells have specialized structures that enhance uptake of water and nutrients from the soil or uptake of CO<sub>2</sub> from the air. Fluids are transported in [vascular tissues](#), from roots to leaves and also from leaves to roots. Vascular plants produce two types of vascular tissues: the [xylem](#), whose primary function is to transport water, and the

**phloem**, whose primary function is to transport carbohydrates. Both contain many specialized cell types that enable the long-distance transport of water, sugars, and signaling molecules. **Ground tissue** is the term for all of the remaining cells. In many cases, these will be **parenchyma**, thin-walled cells that are capable of further division and differentiation. Parenchyma cells perform most of a plant's metabolic functions, including photosynthesis and storage of nutrients, carbohydrates, and water.

We are now ready to answer the question of how vascular plants photosynthesize on land by examining how leaves, stems, and roots work together.

#### Self-Assessment Question

1. Why are vascular plants better able to sustain photosynthesis than are bryophytes?

## 27.2 CARBON DIOXIDE GAIN AND WATER LOSS

The [leaf](#) is the principal site of photosynthesis in most vascular plants. In this section, we explore how the structure of leaves allows vascular plants to photosynthesize in air without drying out.

### CO<sub>2</sub> uptake results in water loss.

Plants use large amounts of water. In fact, water is the resource that most often limits a plant's ability to grow and function. This fact becomes readily apparent when you forget to water your houseplants or garden. And when you drive across a continent, you see that the plants growing in wet places look very different from those growing in dry ones. Why do plants require so much water?

The answer is *not* water's role as an electron donor in photosynthesis ([Chapter 8](#)): that process accounts for less than 1% of the water required by vascular plants. Instead, most of a plant's need for water is a consequence of the plant taking up the CO<sub>2</sub> needed for photosynthesis from the air. CO<sub>2</sub> is a minor constituent of air, present at about 400 parts per million. This low concentration limits the rate at which CO<sub>2</sub> can diffuse into the leaf. Therefore, how fast a leaf can take up CO<sub>2</sub> depends in large part on the extent to which its photosynthetic cells are exposed to the surrounding air.

A cross section shows the leaf's three major tissues: sheets of epidermal cells line the leaf's upper and lower surfaces; loosely packed photosynthetic cells make up the [mesophyll](#) (literally, “middle leaf”);

and the system of vascular conduits called [veins](#) connects the leaf to the rest of the plant ([Fig. 27.5](#)). If we look inside a leaf, we see that each mesophyll cell is surrounded by air spaces. The mesophyll cells obtain  $\text{CO}_2$  from these air spaces. If the air spaces within the leaf were completely sealed off, photosynthesis would quickly run out of  $\text{CO}_2$  and come to a halt. But they're not sealed off; instead, the leaf's air spaces are connected to the air surrounding the leaf by pores in the epidermis. As photosynthesis uses up  $\text{CO}_2$ , the concentration of  $\text{CO}_2$  molecules within the leaf's air spaces decreases relative to the concentration of  $\text{CO}_2$  in the outside air. Because molecules diffuse from regions of higher concentration to regions of lower concentration,  $\text{CO}_2$  diffuses into the leaf, replenishing the supply of  $\text{CO}_2$  for photosynthesis.

**FIG. 27.5 Leaf structure.** The uptake of  $\text{CO}_2$  by diffusion is accompanied by a much larger outward diffusion of water vapor.

The ability of leaves to draw in  $\text{CO}_2$  comes at a price: as  $\text{CO}_2$  diffuses into the leaf, water vapor diffuses out ([Fig. 27.5](#)). Furthermore, water vapor diffuses out of a leaf at a much faster rate than  $\text{CO}_2$  diffuses inward. Recall that molecules diffuse from regions of higher concentration to regions of lower concentration and that the rate of diffusion is proportional to the difference in concentration. On a sunny summer day, the difference in water vapor concentration between the air spaces within a leaf and the air outside can be more than 100 times greater than the difference in concentration of  $\text{CO}_2$ . Add the fact that water is lighter than  $\text{CO}_2$ , and so diffuses 1.6 times faster *for the same concentration gradient*, and it becomes clear why, on a sunny summer day, several hundred water molecules can be lost for every molecule of  $\text{CO}_2$  acquired for photosynthesis.

The loss of water vapor from leaves is referred to as **[transpiration](#)**. The rates at which plants transpire are often quite high. A sunflower leaf, for example, can transpire an amount equal to its total water content in as little as 20 minutes. To put this rate of water loss in perspective, you would have to drink about 2 liters per minute to survive a similar rate of loss. Vascular plants can sustain such high rates of water loss because they can access the only consistently available source of water on land: the soil. Water moves from the soil, through the bodies of vascular plants, and then, as water vapor, into the atmosphere. Therefore, the challenge of keeping photosynthetic cells hydrated is met partly by the continual supply of water from the soil. As we discuss next, it is also met by limiting the rate at which water already in leaf tissues is lost to the atmosphere.

## The cuticle restricts water loss from leaves but inhibits the uptake of CO<sub>2</sub>.

Epidermal cells secrete a waxy [cuticle](#) on their outer surface that limits water loss. Without a cuticle, the humidity within the internal air spaces would drop and the photosynthetic mesophyll cells would quickly dry out. However, the cuticle prevents CO<sub>2</sub> from diffusing into the leaf even as it restricts water vapor from diffusing out of it.

As noted earlier, small pores in the epidermis allow CO<sub>2</sub> to diffuse into the leaf ([Fig. 27.6a](#)). These pores are called [stomata](#) (singular, [stoma](#)). Stomata can be numerous, with many plants having hundreds per square millimeter on their epidermis. Yet because each stoma is small, less than 1% to 2% of the leaf surface is actually covered by these pores.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Photo source: Dr. Jeremy Burgess/Science Source.

FIG. 27.6 Stomata. (a) A scanning electron microscope (SEM) image of stomata on a leaf surface; (b) guard cells of a stoma in open and closed positions.

The epidermis with its stomatal pores represents a compromise between the challenges of providing food ( $CO_2$  uptake) and preventing thirst (water loss). However, because both the dryness of the air and the wetness of the soil vary over time, leaves must be able to alter how

much water and CO<sub>2</sub> pass through the leaf epidermis so that the plant can maintain a balance between the rates of water loss to the atmosphere and water delivery from the soil. Leaves can do this by opening and closing their stomata.

## Stomata allow leaves to regulate water loss and carbon gain.

Stomata are more than just holes in the leaf epidermis: they are hydromechanical valves that can open and close. Each stoma consists of two [guard cells](#) surrounding a central pore. The guard cells can shrink or swell, changing the size of the pore between them ([Fig. 27.6b](#)). Let's consider how this valve system works.

Recall that cellulose provides strength to plant cell walls. In guard cells, the long cellulose molecules are oriented radially—that is, wrapped around the cell. Confined by this arrangement of cellulose, swelling guard cells tend to expand in length rather than in girth. Because the guard cells are firmly connected at their ends, an increase in length causes them to bow apart, opening the stomatal pore. Conversely, a decrease in guard cell volume causes the pore to close.

Guard cells control their volume by altering the concentration of solutes, such as potassium ions (K<sup>+</sup>) and chloride ions (Cl<sup>-</sup>), in their cytoplasm. ATP drives the uptake of solutes across the plasma membrane against their concentration gradient. An increase in solute concentration causes water to move into the cell by osmosis. Recall from [Chapter 5](#) that osmosis is the net movement of water molecules across a selectively permeable membrane, such as the cell's plasma

membrane, from a region of lower solute concentration to a region of higher solute concentration. As water enters the guard cells, their turgor pressure increases. Higher turgor pressure causes the walls to stretch, allowing the cells to swell.

Stomata close by the same process, only in reverse. That is, solutes leave the guard cells; as the solute concentration decreases, water exits the cells, causing the turgor pressure to decrease and the cells to shrink.

To function effectively, stomata must open and close in response to factors that affect CO<sub>2</sub> uptake and water loss. Stomata are thus key sites for the processing of physiological information. In most plants, light stimulates stomata to open, while high levels of CO<sub>2</sub> inside the leaf (a signal that CO<sub>2</sub> is being supplied faster than photosynthesis can take it up) cause stomata to close. Guard cell volume also changes in response to signaling molecules. For example, abscisic acid, a hormone produced during drought, causes stomata to close. Thus, stomata open when the conditions for photosynthesis are favorable, and close when a water shortage endangers the hydration of the leaf.

Our own experience leads us to think of evaporation (for example, of sweat) as a means of preventing overheating. Is there any evidence that plants control the temperature of their leaves by regulating transpiration? The answer, perhaps surprisingly, is no. Transpiration does cool leaves, but plants transpire whether their leaves are too hot, too cold, or at their optimal temperature. When leaves are above their optimal temperature for photosynthesis, cooling through transpiration is beneficial. But when temperatures are below the optimum,

transpiration lowers leaf temperatures to become even less favorable. In addition, evaporative cooling would be most beneficial when temperatures spike above normal, yet often during heat waves, little water is available in the soil. For this reason, plants in arid regions tend to rely on mechanisms other than evaporative cooling, such as reflective hairs and waxes and small leaf size, to prevent their leaves from overheating.

## CAM plants use nocturnal CO<sub>2</sub> storage to avoid water loss during the day.

In most plants, water loss and photosynthesis peak at the same time, when the sun is high overhead. What if a plant could open its stomata to capture CO<sub>2</sub> at night, when cool air limits rates of evaporation?

In fact, a number of plants have evolved precisely this mechanism to help balance CO<sub>2</sub> gain and water loss ([Fig. 27.7](#)). The mechanism is called **crassulacean acid metabolism (CAM)**; it is named after the Crassulaceae family of plants, which uses this pathway. CAM provides a system for storing CO<sub>2</sub> overnight by converting it into a form that will not diffuse away. The storage form of CO<sub>2</sub> is produced by the enzyme PEP carboxylase, which combines a dissolved form of CO<sub>2</sub> (bicarbonate ion, HCO<sub>3</sub><sup>-</sup>) with a 3-carbon compound called phosphoenolpyruvate (PEP). The resulting product is a 4-carbon organic acid that is stored in the cell's vacuole.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Photo sources: b. Charles Harker/Getty Images; c. John Mason/ARDEA.

FIG. 27.7 CAM photosynthesis. (a) CAM plants store  $\text{CO}_2$  at night in the vacuole; leaves can then photosynthesize during the day without opening their stomata. (b) A saguaro cactus, a CAM plant. (c) An epiphytic orchid (*Dendrobium* species), also a CAM plant.

When the sun comes up the next morning, the stomata close, conserving water ([Fig. 27.7a](#)). At the same time, the 4-carbon organic acids are transferred from the vacuole to the chloroplasts and their  $\text{CO}_2$  is released. Because the stomata are now closed, this newly released  $\text{CO}_2$  does not diffuse out of the leaf. Instead, it becomes incorporated into carbohydrates by the Calvin cycle. As we saw in [Chapter 8](#), the Calvin cycle can operate only in the light because it requires a

continual supply of energy in the form of ATP and NADPH produced by the light reactions of photosynthesis. The 3-carbon PEP molecules remaining after CO<sub>2</sub> release are converted into starch and stored in the chloroplast until the sun goes down and they are again needed to capture and store CO<sub>2</sub> in the vacuole.

By opening their stomata only at night, CAM plants greatly increase the amount of CO<sub>2</sub> gain per unit of water loss. Indeed, the CO<sub>2</sub> : H<sub>2</sub>O exchange ratio for CAM plants is in the range of 1 : 50, nearly 10 times higher than that of plants that open their stomata during the day. However, CAM has a drawback. CAM photosynthesis produces carbohydrates slowly because it uses some of the plant's ATP to drive the uptake of organic acids into the vacuole and because only so much organic acid can accumulate overnight in the vacuole. For these reasons, CAM is most commonly encountered in habitats such as deserts, where water conservation is crucial, and among [epiphytes](#), plants that grow on the branches of other plants, without contact with the soil ([Fig. 27.7b](#) and [27.7c](#)).

Because CAM uses enzymes (for example, PEP carboxylase) and compartments (for example, vacuoles) that exist in almost all plant cells, it is not surprising that it has evolved multiple times. CAM occurs in all four groups of vascular plants shown in [Fig. 27.1](#). It is most widespread among the angiosperms, found in 5% to 10% of these species. Vanilla orchids and Spanish moss, two well-known epiphytes, are CAM plants, and so are many cacti.

## C<sub>4</sub> plants suppress photorespiration by

## concentrating CO<sub>2</sub> in bundle-sheath cells.

Photorespiration adds another wrinkle to the challenge of acquiring CO<sub>2</sub> from the air. Recall from [Chapter 8](#) that either CO<sub>2</sub> or O<sub>2</sub> can be a substrate for rubisco, the key enzyme in the Calvin cycle. When CO<sub>2</sub> is the substrate, the Calvin cycle produces carbohydrates through photosynthesis. When O<sub>2</sub> is the substrate, there is a net loss of energy and a release of CO<sub>2</sub>, through a process called photorespiration. (Photorespiration is similar to aerobic respiration only in the sense that it uses O<sub>2</sub> and releases CO<sub>2</sub>. However, plants do not gain energy in photorespiration, but rather lose it.)

Photorespiration presents a significant challenge for land plants for two reasons. First, air contains approximately 21% O<sub>2</sub> but only 0.04% CO<sub>2</sub>. Although rubisco reacts more readily with CO<sub>2</sub> than with O<sub>2</sub>, the sheer abundance of O<sub>2</sub> means that without some means of concentrating CO<sub>2</sub>, rubisco will use O<sub>2</sub> as a substrate some of the time. Second, air provides much less of a thermal buffer than does water. As a result, organisms on land experience higher and more variable temperatures than do organisms that live in water. Temperature has a major effect on photorespiration because rubisco becomes less able to distinguish between CO<sub>2</sub> and O<sub>2</sub> as temperatures increase. At moderate leaf temperatures, O<sub>2</sub> is the substrate instead of CO<sub>2</sub> as often as 1 time out of 4. At higher temperatures, O<sub>2</sub> is even more likely to be the substrate for rubisco.

Some plants have evolved a way to reduce the energy and carbon

losses associated with photorespiration. These [C<sub>4</sub> plants](#) suppress photorespiration by increasing the concentration of CO<sub>2</sub> in the immediate vicinity of rubisco. C<sub>4</sub> plants take their name from the fact that they, like CAM plants, use PEP carboxylase to produce 4-carbon organic acids that subsequently supply the Calvin cycle with CO<sub>2</sub>. The Calvin cycle produces 3-carbon compounds ([Chapter 8](#)), and plants that do not use 4-carbon organic acids to supply the Calvin cycle with CO<sub>2</sub> are called [C<sub>3</sub> plants](#).

Both CAM and C<sub>4</sub> plants produce 4-carbon organic acids as the entry point for photosynthesis. However, in CAM plants, CO<sub>2</sub> capture and the Calvin cycle take place *at different times*; in C<sub>4</sub> plants, they take place *in different cells*.

C<sub>4</sub> plants initially capture CO<sub>2</sub> in mesophyll cells, whereas the Calvin cycle takes place in the bundle sheath, a cylinder of cells that surrounds each vein. The 4-carbon compounds produced in mesophyll cells diffuse through plasmodesmata into bundle-sheath cells ([Fig. 27.8](#)). Once inside these cells, the 4-carbon compounds release CO<sub>2</sub>, which is then incorporated into carbohydrates through the Calvin cycle ([Chapter 8](#)). The C<sub>4</sub> cycle is completed as the 3-carbon molecules generated during CO<sub>2</sub> release diffuse back to the chloroplasts in the mesophyll cells. There, ATP is used to re-form the original 3-carbon compound (PEP) that combines with CO<sub>2</sub>.

FIG. 27.8 C<sub>4</sub> photosynthesis. C<sub>4</sub> plants suppress photorespiration by concentrating CO<sub>2</sub> in bundle-sheath cells.

The significance of the C<sub>4</sub> cycle is that it operates much faster than the Calvin cycle. As a result, the concentration of CO<sub>2</sub> within bundle-sheath cells increases dramatically, reaching levels as much as 5 times higher than the levels in the air surrounding the leaf. The high concentration of CO<sub>2</sub> in bundle-sheath cells makes it unlikely that rubisco will use O<sub>2</sub> as a substrate. Thus, the C<sub>4</sub> cycle functions like a “fuel-injection” system that increases the efficiency of the Calvin cycle in bundle sheath cells.

C<sub>4</sub> plants have high rates of photosynthesis because they do not suffer the losses in energy and reduced carbon associated with photorespiration ([Fig. 27.9](#)). At the same time, C<sub>4</sub> plants lose less water because they can restrict diffusion through their stomata to a

greater extent than a  $C_3$  plant can, while still maintaining high concentrations of  $CO_2$  in bundle-sheath cells. However,  $C_4$  photosynthesis consumes more energy than conventional ( $C_3$ ) photosynthesis, because ATP must be used to regenerate PEP in the  $C_4$  cycle. Thus,  $C_4$  photosynthesis confers an advantage in hot, sunny environments where rates of photorespiration and transpiration would otherwise be high. This type of photosynthesis has evolved as many as 20 times, but is most common among tropical grasses and plants of open habitats with warm temperatures.  $C_4$  plants include a number of important crops, such as maize (corn), sugarcane, and sorghum, as well as some of the most noxious agricultural weeds.

#### HOW DO WE KNOW?

### FIG. 27.9

## Does $C_4$ photosynthesis suppress photorespiration?

#### BACKGROUND

Before biologists knew about the  $C_4$  pathway, studies had suggested there was something unusual about the Calvin cycle in certain species. Studies using radioactively labeled  $CO_2$  showed that some species initially incorporate  $CO_2$  into 4-carbon compounds instead of the 3-carbon compounds that are the first products in the Calvin cycle. These  $C_4$  plants also have high rates of photosynthesis. How can these findings be explained? Are these 4-carbon compounds part of a new, more efficient photosynthetic pathway? Or do  $C_4$  plants have high rates of photosynthesis because they are able to avoid the carbon and energy losses associated with photorespiration?

#### HYPOTHESIS

C<sub>4</sub> plants do not exhibit photorespiration.

#### EXPERIMENT

Olle Björkman and colleagues at the Carnegie Institution of Washington compared C<sub>3</sub> and C<sub>4</sub> species of the genus *Atriplex*. They measured rates of CO<sub>2</sub> uptake by plant leaves, first in normal air (21% O<sub>2</sub>) and then in an experimental gas mixture in which the concentration of O<sub>2</sub> was only 1%. When the concentration of O<sub>2</sub> is low, rubisco has a low probability of using O<sub>2</sub> (instead of CO<sub>2</sub>) as a substrate, so photorespiration does not occur.

Measurements of CO<sub>2</sub> uptake by leaves represent the sum of photosynthesis, which takes in CO<sub>2</sub>, and photorespiration, which releases CO<sub>2</sub>. Mitochondrial respiration also releases CO<sub>2</sub>, but in an illuminated leaf the rates are low relative to photosynthesis and invariant across this range of O<sub>2</sub> concentrations. Consequently, the rate of CO<sub>2</sub> uptake measured in 1% O<sub>2</sub> tells us what the rate of photosynthesis is in normal air (21% O<sub>2</sub>) under the same conditions (e.g., same light intensity, temperature).

#### RESULTS

#### CONCLUSION

The rate of CO<sub>2</sub> uptake in C<sub>4</sub> plants is the same at the two different O<sub>2</sub> concentrations, indicating that significant photorespiration is not occurring in these plants. In contrast, CO<sub>2</sub> uptake of the C<sub>3</sub> plants increases in the low O<sub>2</sub> environment, indicating that photorespiration decreases net carbon

gain in these plants in 21% O<sub>2</sub>.

#### FOLLOW-UP WORK

The higher photosynthetic efficiency of C<sub>4</sub> photosynthesis has prompted efforts, so far unsuccessful, to incorporate this pathway into C<sub>3</sub> crops such as rice.

5. Diagram how the enzyme PEP carboxylase allows CAM plants to reduce transpiration rates and C<sub>4</sub> plants to suppress photorespiration.

## 27.3 WATER TRANSPORT

On a summer day, a tree can transport many hundreds of liters of water from the soil to its leaves. Impressively, this feat is accomplished without any moving parts. Even more remarkably, trees and other plants transport water without any direct expenditure of ATP. The structure of vascular plants allows them to use the evaporation of water from leaves to pull water from the soil.

**Fig. 27.10** shows the cross section of a sunflower stem. Like a leaf, it has a surface layer of epidermal cells. This layer encloses thin-walled, undifferentiated **parenchyma** cells in the interior. Notice that the stem also contains differentiated tissues that lie in a ring near the outside of the stem. These are the vascular tissues, which form a continuous pathway that extends from near the tips of the roots, through the stem, and into the network of veins within leaves. The outer tissue, called **phloem**, transports carbohydrates from leaves to the rest of the plant body. The inner tissue, called xylem, transports water from the roots to the leaves.

 Photo source: Garry DeLong/Science Source.

FIG. 27.10 Xylem and phloem. A cross section of the stem of a sunflower shows the two types of vascular tissues: xylem and phloem.

In addition, both the xylem and the phloem transport dissolved nutrients and signaling molecules, such as hormones, throughout the plant. Importantly, the xylem is the pathway used to transport nutrients absorbed from the soil to the aboveground portions of the plant. Because the total concentration of solutes in the xylem is very low (typically less than 0.01%), here we will focus on the xylem as a means for transporting water from soil to leaves. We discuss the uptake of nutrients in [section 27.5](#).

## Xylem provides a low-resistance

## pathway for the movement of water.

Water travels with relative ease through xylem: it would take 10 orders of magnitude greater force to drive water through living parenchyma cells than it takes to transport the same amount of water through the xylem. This ease of flow is explained by the structure of the water-transporting cells within the xylem. These cells have cell walls but lack any cytoplasm or cell membranes at maturity, so water can flow unimpeded through their hollow centers ([Fig. 27.11](#)).

**FIG. 27.11 Xylem structure.** Xylem conduits are formed by hollow cells with stiff walls and no cell content or membrane. (a) Single-celled tracheids and (b) multicellular vessels are interconnected by pits.

These open tubes do not extend the length of a plant. Instead, the xylem is made up of many hollow conduits, each of which tapers to a closed end. Thus, as water travels from the soil to the leaves, it must

repeatedly flow from one conduit to another. The frequent transfer from one conduit to the next increases the resistance compared to an open tube. However, this arrangement has the advantage that if a conduit “fails” (a topic we discuss later), it eliminates only a small part of the xylem’s capacity to transport water.

Xylem conduits have lignified secondary cell walls ([Chapter 10](#)). Lignin is a chemical compound that strengthens the cell wall, but also impedes the movement of water across the wall. As a result, water enters and exits xylem conduits primarily through **pits**, circular or ovoid regions lacking the secondary cell wall layer. The only barrier to water flow across pits is the water-permeable primary cell wall. As we will see, pits play an important role because they allow the passage of water, but not air, from one conduit to another.

A xylem conduit can be formed from a single cell or from multiple cells stacked to form a hollow tube. Unicellular conduits are called **tracheids** ([Fig. 27.11a](#)), whereas multicellular conduits are called **vessels** ([Fig. 27.11b](#)). Because tracheids are the product of a single cell, they are typically only 5–50  $\mu\text{m}$  in diameter and less than 1 cm long. Vessels, which are made up of many cells called **vessel elements**, can be much wider and longer. Vessel diameters range from 10 to 500  $\mu\text{m}$ , and their lengths can be up to several meters.

Fossils show that the first vascular plants produced only tracheids. Today, tracheids remain the principal conduit type in lycophytes, ferns and horsetails, and most gymnosperms. Xylem vessels have evolved several times. Some ferns, such as the widespread bracken fern,

produce multicellular xylem conduits, as does one group of gymnosperms. Nearly all angiosperms produce vessels.

Water enters a tracheid through pits, travels upward through the conduit interior, and then flows outward through other pits into an adjacent, partially overlapping, tracheid. Water also enters and exits a vessel through pits. Once the water is inside the vessel, little or nothing blocks the flow of water from one vessel element to the next. During the development of a xylem vessel, the end walls of the vessel elements are digested away, which means that water is able to flow along the entire length of the vessel without having to cross any pits. At the end of a vessel, however, the water must flow through pits as it enters an adjacent vessel and thereby continues its journey from the soil to the leaves.

The rate at which water moves through xylem depends on both the number of conduits and their size. Water flows faster through longer conduits because it does not need to flow so often from conduit to conduit across pits, which exert a significant resistance to flow. Water flow through xylem conduits is also greater when the conduits are wider. For any open pipe, the flow rate is proportional to the radius of the conduit raised to the fourth power, so doubling the radius increases the flow 16-fold. Because vessels can be both longer and wider than tracheids, plants with vessels can achieve greater rates of water transport.

The xylem of many angiosperms has a much greater water transport capacity than the xylem of plants that have only tracheids. As a result,

angiosperms can support the high rates of transpiration needed to obtain large amounts of CO<sub>2</sub> for photosynthesis. The evolution of angiosperms led to substantial increases in terrestrial productivity as well as an intensification of the water cycle on land, as higher rates of transpiration resulted in more water being returned to the atmosphere, where it became able to fall again as rain.

## Water is pulled through xylem by an evaporative pump.

A leafy shoot placed in a sunny spot with its cut end in water will continue to transpire. This result demonstrates that the driving force for water transport is not generated in the roots, but instead comes from the leaves.

In the vascular systems of plants and animals, bulk flow is driven by differences in pressure. Pressure has units of force per area, and the direction of flow is always from higher to lower pressure. In your body, a mechanical pump—your heart—*raises* the pressure of the blood, causing it to flow from the heart through your arteries and veins. In plants, transpiration *lowers* the pressure of the water in the xylem near the sites of evaporation in the leaf, causing water to flow from the soil to the leaves. Plants face a challenge owing to this process: to transport water from the soil to the leaves at rates equal to the water loss from transpiration, the pressures in the leaf xylem must be very low, typically well below zero ([Fig. 27.12](#)).

HOW DO WE KNOW?

FIG. 27.12

# Do plants generate negative pressures?

## BACKGROUND

The idea that water is pulled through the plant by negative pressures in leaves was first suggested in 1895. However, without a way to measure these pressures, there was no way to know how large they were.

## HYPOTHESIS

In 1912, German physiologist Otto Renner hypothesized that leaves are able to exert stronger suctions than could be generated with a vacuum pump.

## EXPERIMENT

Renner measured the rate at which water flowed from a reservoir into the cut tip of a branch of a transpiring plant. He next cut off about 10 cm of the branch and attached a vacuum pump in place of the transpiring plant. He compared the flow rate through the branch when attached to the transpiring plant with the flow rate through the branch generated by the vacuum pump.

## RESULTS

Renner found that the flow rates generated by transpiring plants were two to nine times greater than the flow rates generated by the vacuum pump.

## CONCLUSION

A transpiring plant pulls water through a branch faster than a vacuum pump. Therefore, the pulling force generated by a transpiring plant must be greater than that of a vacuum pump. Because vacuum pumps create suction by reducing the pressure in the air, a vacuum pump can reduce the pressure only to zero. For the transpiring leaves to pull even harder, the pressures in the xylem must be less than zero. Thus, transpiration generates negative pressures in the xylem.

The maximum height that one can lift water using a vacuum pump is 10 m (33 feet). The forces that pull water through plants have no comparable limit because the strong hydrogen bonds between water molecules mean that the xylem can sustain very large negative pressures. This is why plants can pull water from dry soils and why they can grow to more than 100 m, the height of a 30-story building.

## FOLLOW-UP WORK

In 1965, Per Fredrick Scholander developed a pressurization technique that uses reverse osmosis to measure the magnitude of the negative pressures exerted by leaves of intact plants. Using this technique, he demonstrated that the leaves at the top of a Douglas fir tree 100 m tall exert pressures that are even more negative than those exerted by leaves closer to the ground.

SOURCES Renner, O. 1925. "Zum Nachweis negativer Drucke im Gefäßwasser bewurzelter Holzgewächse." *Flora* 118/119:402–408; Scholander, P. F., et al. 1965. "Sap Pressure in Vascular Plants." *Science* 148:339–346.

We commonly think of pressure as the result of molecules bouncing

into one another and pushing outward on the walls of a container. Negative pressures result when the forces between molecules act in the opposite direction. The molecules pull, rather than push, on one another and the forces on the container walls are oriented inward. For this reason, negative pressure in the xylem is sometimes described as “tension.”

Water stands out among liquids for its ability to sustain large negative pressures. The strong hydrogen bonds that form between water molecules and between water molecules and many surfaces allow tensile (pulling) forces to be transmitted from one water molecule to another. In contrast, negative pressures cannot develop in gases because the molecules are so widely separated that they do not form intermolecular bonds and, therefore, cannot pull on one another.

Essentially, the water in the xylem functions as the “rope” in a game of tug-of-war between the soil and the leaves. Soils hold onto water due to surface tension at air–water interfaces. As soils dry out, they hold on even harder. If the leaf is to win the game, it has to pull harder than the soil, *and* it has to pull hard enough to overcome the force of gravity and the frictional resistance of moving water through xylem conduits. But how does transpiration generate tension in xylem?

As stomata open to allow CO<sub>2</sub> needed for photosynthesis to enter, water evaporates from the surface of the cells lining the leaf’s air spaces ([Fig. 27.13](#)). The partial dehydration of these cell walls causes water to flow from the cytoplasm of nearby cells to the sites of evaporation, similar to how water flows into a freshly wrung-out

sponge. The forces that pull water toward the sites of evaporation include surface tension at the air–water interface and interactions between water molecules and the components of the cell wall. The loss of water from the cytoplasm both increases the solute concentration and decreases the cell’s turgor pressure. The net result is that water flows from adjacent, more hydrated cells toward the sites of evaporation, until eventually water is drawn from xylem conduits in leaf veins.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 27.13 Xylem transport from roots to leaves. Water is pulled through the plant by forces generated in the leaves, preventing them from drying out.

The loss of a water molecule from the xylem causes the pressure to decrease. Because the walls of xylem conduits are very stiff, the water molecules remaining in the xylem must stretch a tiny bit if the conduit is to remain full of water. Just as when you pull on a rubber band, the

water molecules resist being stretched. This resistance causes the pressure in the xylem to decrease because the water molecules pull harder on each other and also exert an inward force on the conduit walls. Ultimately, the decrease in pressure causes another water molecule to be pulled up to take the place of the one that has been drawn into the leaf toward the sites of evaporation.

Water can enter the xylem from any part of the plant that is more hydrated than the leaf. Typically, roots are the wettest part of the plant because they are in contact with the soil. Thus, during transpiration, most of the water moving into the leaf comes from the roots, which in turn obtain water from the soil. If the soil becomes very dry, however, the leaf may be unable to generate sufficient tension without experiencing damaging levels of dehydration. This is why stomata close as soil water is depleted.

Many different processes affect the movement of water through plants. In soils, the surface tension of air–water interfaces dominates, whereas in living cells osmosis plays a central role. In the xylem, pressure gradients are the driving force for water movement, and everywhere gravity has an effect. **Water potential** is a parameter that combines all of the various factors that influence the movement of water, such as pressure, osmosis, and gravity. In a thermodynamic framework, water potential is the free energy of water and, therefore, its capacity to do work ([Chapter 6](#)). Water moves from areas with higher water potential to areas with lower water potential, just as happens when water flows downhill. Thus, if we know the water potential at any two points, we can say which way the water will flow.

For example, in a transpiring plant, the water potential of the leaf is lower than the water potential of the soil, so water moves upward.

## Xylem transport is at risk of conduit collapse and cavitation.

Two distinct risks arise when the tensions in the xylem are large ([Fig. 27.14](#)). The first is the danger of collapse. If you suck too hard on a drinking straw, it collapses inward, blocking flow. Much the same thing can happen in xylem ([Fig. 27.14a](#)). To prevent collapse, xylem conduits have thick walls that contain lignin. Although lignin is more costly to produce than cellulose, lignin makes conduit walls rigid, reducing the risk of collapse.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 27.14 Collapse and cavitation. The negative pressures exerted by transpiring leaves can cause xylem conduits to collapse inward or to cavitate, in both cases blocking flow.

A second way that xylem conduits can fail is through [cavitation](#), which occurs when liquid water under tension is replaced by water vapor. Cavitation blocks flow because gases such as water vapor cannot transmit tensions. As a consequence, water can be pulled through the xylem only if a continuous column of water extends from the roots to the leaves. Cavitation in plants is thought to result from the expansion of tiny gas bubbles due to the tension in the water pulling outward on the bubble. Once a bubble starts to grow, it continues to expand until it fills the entire conduit. Initially, the gas is water vapor, but soon diffusion results in the conduit becoming filled with air.

One way to maintain liquid water in the xylem is to prevent bubbles from entering in the first place. Root tissues prevent the passage of any water bubbles that enter the xylem from the soil. However, bubbles can become introduced into the xylem in two other ways.

First, if xylem tensions are excessive, tiny air bubbles that can “seed” cavitation may be pulled in through a pit ([Fig. 27.14b](#)). Cavitation is more likely to develop in this way during drought, when the tensions in the xylem are large.

Second, bubbles can form in the xylem when gas comes out of solution during freezing ([Fig. 27.14c](#)). Gases are much less soluble in ice than in water, so as a conduit freezes, dissolved gas molecules

aggregate into tiny bubbles. These bubbles can then expand when the conduit thaws and the water again experiences tensions. The wide vessels found in angiosperms are especially vulnerable to cavitation at freezing temperatures, which partly explains why the boreal forests of the subarctic contain few angiosperms.

The xylem is organized in ways that minimize the impact of cavitation. For example, xylem consists of many conduits in parallel, so the loss of any one conduit to cavitation does not result in a major loss of transport capacity. Similarly, as water flows from the soil to the leaves, it passes from one conduit to another, each time by flowing across pits. The likelihood that cavitation will spread is thereby reduced because only large pressure differences can pull air through pits.

#### Self-Assessment Question

6. How is the statement that water is transported through the xylem without requiring any input in energy by the plant both correct and incorrect?

## 27.4 TRANSPORT OF CARBOHYDRATES

Central to the success of vascular plants is their ability to pull water from the soil. But to do that, vascular plants need roots, and these roots need to be able to grow belowground. Without sunlight to power photosynthesis, growing roots depend on carbohydrates imported from aboveground. Vascular plants have evolved a second transport tissue, the phloem, capable of moving carbohydrates efficiently across the entire length of the plant. The phloem supports not only the growth of roots, but also the development of non-photosynthetic organs such as reproductive structures and stems.

### Phloem transports carbohydrates from sources to sinks.

Whereas the direction of xylem transport is typically from the soil to the leaves, phloem moves carbohydrates from wherever they are synthesized or stored to wherever they are needed to support growth and respiration. In plants, regions that produce or store carbohydrates are referred to as [sources](#). For example, leaves are sources because they produce carbohydrates by photosynthesis, and mature potato tubers (the part we eat) are sources because they have stored carbohydrates that can be supplied to the rest of the plant body when needed. [Sinks](#) are any portion of the plant that needs carbohydrates to fuel growth and respiration; examples are roots, young leaves, and developing fruits. Storage organs can also act as sinks—for example, developing potato tubers. Thus, the direction of phloem transport can

be either up or down, depending on where the source and the sink are relative to each other.

In contrast to the xylem, phloem transport takes place through living cells containing cytoplasm. During development, these cells lose much of their intracellular structure, including the nucleus and the vacuole. At maturity, phloem transport cells retain an intact plasma membrane that encloses a modified cytoplasm containing only smooth endoplasmic reticulum and a small number of organelles, including mitochondria. Cellular functions such as protein synthesis are carried out by neighboring cells (called [companion cells](#) in angiosperms). Numerous plasmodesmata connect the phloem transport cells to these neighbors.

The cytoplasm of phloem transport cells is rich in sugars, 10% to 30% by weight. For comparison, a can of regular Coke has a sugar content of approximately 10%. These sugars and other solutes flow from one cell to another through pores connecting the cells. [Phloem sap](#) refers to the soluble components of the cytoplasm that can pass through these pores. In angiosperms, phloem sap moves through [sieve tubes](#) composed of cells that are connected by [sieve plates](#), which are modified end walls with large pores (1–1.5  $\mu\text{m}$  in diameter) ([Fig. 27.15](#)). The plasma membrane of adjacent cells is continuous through each of these pores, so each multicellular sieve tube can be considered a single cytoplasm-filled compartment.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 27.15 Phloem structure. Phloem conduits are formed of living cells. (a) Sieve tubes and associated companion cells and (b) scanning electron microscope image showing sieve plates of squash (*Cucurbita maxima*).

Plants that are not angiosperms have narrow phloem conduits that lack well-defined sieve plates. Their capacity for phloem sap transport appears to be much lower than that of angiosperms, paralleling the differences in the xylem between tracheids and vessels. We have seen that the more conductive xylem of angiosperms allows higher rates of photosynthesis. Their more conductive phloem allows angiosperms to transport the additional sugars produced at these higher rates to the rest of the plant.

Phloem transports carbohydrates as sucrose or larger sugars. Phloem also transports amino acids, inorganic forms of nitrogen, and ions including  $K^+$ , which are all present in much lower concentrations than the carbohydrates. Finally, phloem transports informational molecules such as hormones, protein signals, and even RNA. Thus, phloem forms a multicellular highway for moving raw materials and signaling molecules through the entire length of the plant.

## Carbohydrates are pushed through phloem by an osmotic pump.

How does phloem transport sugars from source to sink? The overall mechanism results from the buildup of sugars in sources relative to a lower concentration of sugars in sinks. In sources, a high concentration of sugars in sieve tubes causes water to be drawn into the phloem by

osmosis. Because the cell walls of the sieve tube resist being stretched outward, the turgor pressure ([Chapter 5](#)) at the source end increases. At sinks, sugars are transported out of the phloem into surrounding cells. This withdrawal of sugars causes water to leave the sieve tube, again by osmosis, reducing turgor pressure at the sink end. It is the difference in turgor pressure that drives the movement of phloem sap from source to sink ([Fig. 27.16](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 27.16 Phloem transport from source to sink. Sources produce carbohydrates or supply them from storage, and sinks require carbohydrates for growth and respiration.

In some plants, sugars are actively transported into sieve tubes using energy from ATP. In others, sugars diffuse passively from the sites of

photosynthesis into the sieve tubes as the sugar concentration builds up in photosynthesizing cells. These mechanisms are quite effective. Indeed, the pressures that develop in sieve tubes are approximately 100 times greater than the pressures that occur in our own circulatory system.

In sinks, sugars are thought to exit sieve tubes by diffusion, although this remains an area of active research. Sink cells use up sugars, either in respiration or to synthesize larger molecules such as cellulose or starch, so their sugar concentration is lower than that in the phloem. This difference in concentration provides a driving gradient for diffusion into sink cells. The water that exits with the sugars can remain within the sink or it can be carried back to the leaves in the xylem ([Fig. 27.16](#)). The volume of water that moves through the phloem, however, is tiny compared to the amount that must be transported through the xylem to replace water lost by transpiration. Therefore, the number and size of xylem conduits greatly exceeds the number and size of sieve tubes.

Like the xylem, the phloem is subject to risks that arise from the way the flow is generated. The contents of damaged sieve tubes can leak out, pushed by high turgor pressures in the phloem. Damage is an ever-present danger because the sugar-rich phloem is an attractive target for insects. Cell damage activates sealing mechanisms that block flow through sieve plates, thereby preventing phloem sap from leaking out. In some respects, these mechanisms are comparable to the formation of blood clots in humans, except that phloem can seal itself much more rapidly, typically in less than a second.

## Phloem feeds both the plant and the rhizosphere.

With the exception of a few cell types that lack cytoplasm, all the cells in a plant's body contain mitochondria that carry out respiration to provide a constant supply of ATP. Typically, about 50% of the carbohydrates produced by photosynthesis in one day are converted back to CO<sub>2</sub> by respiration within 24 hours.

Carbohydrates that are not immediately consumed in respiration can be used as raw materials for growth, or they can be stored for later use. Carbohydrates may be stored as starch within roots and stems or within tubers (specialized storage organs such as potatoes). Stored carbohydrates can support new growth in the spring or following a period of drought, and they can replace leaves consumed by insects or grazing mammals.

What determines how carbohydrates become distributed within the plant? Phloem transport to reproductive organs appears to have priority over transport to stems and developing leaves, and transport to stems and developing leaves has priority over transport to roots. In [Chapter 29](#), we discuss the role that hormones play in controlling the growth and development of plants. These hormones may influence the ability of different sinks to compete successfully for resources transported in the phloem.

Phloem also supplies carbohydrates to fungi and bacteria that form symbiotic associations with roots ([section 27.5](#)). A fraction of the carbohydrates transported to the roots even spills out into the

**rhizosphere**, the soil layer that surrounds actively growing roots.

Nourished by these carbohydrates, a dense population of soil microbes flourishes near roots. These soil bacteria decompose soil organic matter rich in nutrients such as nitrogen and phosphorus. By releasing carbohydrates into the soil, roots are thought to acquire more nutrients from the soil.

#### Self-Assessment Questions

7. How is phloem able to transport carbohydrates from the shoot to the roots, as well as from the roots to the shoot (but not at the same time)?
8. How are the xylem and the phloem similar? How are they different?
9. Why is phloem necessary to produce roots?

## 27.5 UPTAKE OF WATER AND NUTRIENTS

As anyone who has dug a hole in a forest or a field can tell you, plants make a lot of roots ([Fig. 27.17](#)). Laid end to end, the roots of a single corn plant would extend for more than 600 km. Why do plants make such an extensive investment belowground? A major reason is that, with the important exceptions of CO<sub>2</sub> and sunlight, everything that a vascular plant needs to build and sustain its body enters through its roots.

FIG. 27.17 Roots and root hairs. Extensive branching of roots (a) and the presence of root hairs (b) create a large surface area in contact with the soil.

So far, we have focused on the importance of roots for obtaining water from the soil. To carry out photosynthesis, plants must also

acquire the nutrients needed to produce the enzymes of the Calvin cycle and the components of the photosynthetic electron chain. Thus, as vascular plants evolved roots able to obtain water from the soil, they evolved mechanisms for these roots to acquire nutrients as well.

## Plants obtain nutrients from the soil.

On average, plants are 85% water and only 15% dry material.

Approximately 96% of the dry material, by weight, is made up of three elements: carbon, oxygen, and hydrogen. The remaining 4% comes from nutrients that plants obtain from the soil. Nutrients play essential roles in plant metabolism and structure ([Table 27.1](#)). A deficiency in any one of them results in a plant that grows poorly and has a low rate of photosynthesis.

**TABLE 27.1 Nutrients Essential for Plant Metabolism and Structure**

| ELEMENT                                                  | CONCENTRATION<br>IN DRY MATTER<br>(%) | FUNCTIONS                                                                                                  |
|----------------------------------------------------------|---------------------------------------|------------------------------------------------------------------------------------------------------------|
| <b>Nutrients covalently bonded with carbon compounds</b> |                                       |                                                                                                            |

| Chlorine, zinc, sodium                       | each $\leq 0.01$ | Cofactor for enzymes involved in photosynthesis and other reactions                                                                                     |
| <b>Nutrients involved in redox reactions</b> |                  |                                                                                                                                                         |
| Iron, manganese, copper, nickel, molybdenum  | each $\leq 0.01$ | Component of enzymes that catalyze electron transfer (for example, in the electron transport chains used in cellular respiration and photosynthesis)    |
| <b>Nutrients present in cell walls</b>       |                  |                                                                                                                                                         |
| Silica, boron                                | 0.1, $<0.01$     | Contribute to the structural integrity of cell walls and defense against herbivores                                                                     |

Data from Table 5.2 in Lincoln Taiz et al., *Plant Physiology and Development*, 6th ed., 2015, Sinauer Associates, Inc.; Table 8.1 in Emmanuel Epstein and Arnold J. Bloom, *Mineral Nutrition of Plants: Principles and Perspectives*, 2nd ed., 2004, Sinauer Associates, Inc.

The essential nutrients can be divided up into four groups. Nitrogen, phosphorus, and sulfur are components of many organic molecules, including amino acids, nucleic acids, and phospholipids. Another group of nutrients remain in an ionic (charged) form and play important roles as enzyme cofactors and second messengers (for example, calcium) and in maintaining the osmotic balance of cells (for example, potassium). The magnesium ions present in chlorophyll are critical for photosynthesis. Metal elements such as iron and copper are primarily electron donors and acceptors in reactions that transfer

electrons from one molecule to another. The final group includes elements that contribute to the structural integrity of the cell wall, such as calcium, silica, and boron.

## Nutrient uptake by roots is highly selective.

Nutrients from the soil enter roots dissolved in water and are transported from the roots to the rest of the plant in the xylem. Xylem, however, is never in direct contact with the soil. The living cells that surround the xylem allow roots to select which nutrients move from the soil into the xylem. Thus, the nutrient composition of the water in the xylem differs markedly from that of the water that can be easily extracted from the soil. Some elements, such as nitrogen and phosphorus, are more concentrated within the xylem, whereas others, such as sodium and calcium, are more abundant in the soil solution. Given that water travels in a continuous pathway from the soil to the leaves, how are roots able to concentrate some nutrients and exclude others?

The uptake of water and nutrients takes place primarily in young, actively growing roots. Like leaves and stems, newly formed roots have an outer cell layer of epidermis ([Fig. 27.18](#)). Epidermal cells near the root tip produce slender outgrowths known as [root hairs](#). Root hairs greatly increase the surface area of the root available for absorbing nutrients. Inside the epidermis is the [cortex](#), composed of parenchyma cells. Depending on the species, the cortex can vary in thickness from a single cell to many cells. Xylem and phloem are located at the center of the root and are surrounded by the [endodermis](#),

a layer of cells that acts as a gatekeeper controlling which nutrients move into the xylem.

FIG. 27.18 Water movement through endodermal cells. As water carrying nutrients flows from the soil to the xylem of roots, it must pass through the plasma membranes of endodermal cells, which act as a selective barrier.

In [Chapter 5](#), we learned how cells control the movement of molecules across their plasma membranes. Ions and other charged molecules diffuse passively across cell membranes at a relatively slow rate. Alternatively, they can be transported across cell membranes by proteins embedded in the lipid bilayer. By coupling the hydrolysis of ATP to the activity of such transport proteins, cells can both accumulate desired nutrients and remove unwanted ones. These protein transporters form the basis for how the root functions as a living filter.

Epidermal and root cortex cells use protein transporters to increase the uptake of nutrients that the plant needs and to actively excrete

undesired solutes. Once in the cytoplasm, nutrients can move from cell to cell via plasmodesmata. In addition, water and nutrients can move through the relatively porous walls that surround each cell. To prevent these “unfiltered” nutrients from reaching the xylem, each cell of the endodermis is encircled by a **Casparian strip**, a thin band of hydrophobic material that prevents water and any dissolved materials from moving through the cell wall. Water can still flow through the endodermis by crossing the plasma membranes of the endodermal cells, but whether a specific solute will be taken up or excluded will depend on which protein transporters are present. As a result, roots can concentrate nutrients that are needed in large amounts (for example, nitrogen) in the xylem and exclude others that can damage plant cells (for example, sodium).

High concentrations of salts in the soil make it difficult for plants to obtain water. The reason is that to prevent salt from building up to toxic levels in leaves, plants must prevent salt from entering the xylem. As a result, salt concentrations build up in and around roots. Plants must then pull harder to overcome the osmotic effects of these salts if they are to obtain water from the soil. Thus, salt buildup in the soil resulting from poor irrigation practices may cause crop yields to plummet.

## Nutrient uptake requires energy.

Roots expend a great deal of energy acquiring nutrients from the soil. We have already seen that energy is required to move nutrients across the cell membranes of the endodermis on their journey to the xylem. Energy is also required to make certain nutrients in the soil accessible

to the root. The mitochondria of root cells must, therefore, respire at high rates to provide the energy needed for nutrient uptake. Their high respiration rates explain why plants are harmed by flooding: waterlogged soils slow the diffusion of oxygen, limiting respiration.

To understand how roots acquire nutrients and why this process requires energy, let's first look at how nutrients move through the soil. Nutrients move by diffusion through the films of water that surround individual soil particles. The active uptake of nutrients by root cells decreases nutrient concentrations at the root surface. As a result, a concentration gradient forms between the bulk soil and the root surface that drives the diffusion of nutrients to the root. However, because diffusion is efficient only over short distances, each root is able to acquire nutrients only from a small volume of soil. This limitation explains why plants produce so many roots and have so many root hairs: both structures increase the volume of soil from which a root can obtain nutrients. It also explains why roots elongate more or less continuously, exploiting new regions of soil to obtain nutrients required for growth.

Nutrients vary dramatically in the ease and speed with which they move through the soil. For example, nitrate ( $\text{NO}_3^-$ ) and sulfate ( $\text{SO}_4^{2-}$ ) are extremely mobile because they do not bind to soil particles. When transpiration rates are high, the flow of water through the soil can help to convey such mobile nutrients toward the root. In contrast, zinc and inorganic phosphate stay firmly attached to soil particles. One way that roots gain access to highly immobile nutrients is by releasing protons or compounds that make the soil environment close to the root more

acidic. This requires energy in the form of ATP, but the decrease in pH weakens the attachment of immobile nutrients to soil particles. As a result, these formerly immobile nutrients are able to move by diffusion to the root.

Soil microorganisms—both fungi and bacteria—are more adept than plants at obtaining nutrients. Fungi ([Chapter 32](#)) are particularly good at mobilizing phosphorus and at decomposing organic matter, which releases nitrogen. Meanwhile, some bacteria can convert gaseous nitrogen ( $N_2$ ) into a chemical form that can be incorporated into proteins and nucleic acids ([Chapter 24](#)). What plants have at their disposal is a renewable source of carbohydrates. Using these carbohydrates, plants support the growth of symbiotic fungi and bacteria, in effect exchanging carbon for phosphorus or nitrogen.

## Mycorrhizae enhance nutrient uptake.

Plants can increase their access to soil nutrients by forming partnerships with fungi. [Mycorrhizae](#) are symbioses between roots and fungi that enhance nutrient uptake: the plant provides carbohydrates produced by photosynthesis, and the fungus provides nutrients it has obtained from the soil.

Mycorrhizae are of two main types ([Fig. 27.19](#)). [Ectomycorrhizae](#) produce a thick sheath of fungal cells that surrounds the root tip. Some of the fungus extends into the interior of the root, producing a dense network of filaments that surrounds individual root cells. Fungi and root cells exchange nutrients across this interface. In contrast, [endomycorrhizae](#) do not form structures that are visible on the outside

of the root. Instead, they form highly branched structures, called arbuscules, that grow inside root cells and provide a large surface area for nutrient exchange. Both types of mycorrhizae produce an extensive network of hyphae that extend outward into the soil.

FIG. 27.19 Mycorrhizae. These fungus–root associations allow plants to gain nutrients from the soil and fungi to obtain carbohydrates.

How do fungi enhance the ability of roots to obtain nutrients from the soil? Fungal networks can extend more than 10 cm from the root surface, greatly increasing the absorptive surface area in contact with the soil. And because fungal filaments are so thin, they can penetrate tiny spaces between soil particles and access nutrients that would

otherwise be unavailable to roots. Another way fungi enhance nutrient uptake is by secreting enzymes that make soil nutrients more available. Endomycorrhizae are important in enhancing phosphorus uptake, while ectomycorrhizal fungi provide host plants with access to nitrogen that would be otherwise unavailable. Both kinds of mycorrhizae may also offer other benefits to plants. For example, mycorrhizal roots may be less susceptible to infection by pathogens.

Mycorrhizal associations are costly to the plant, consuming between 4% and 20% of its total carbohydrate production. The plant has some control over whether the roots become colonized by mycorrhizal fungi: when nutrients are readily available, as in a well-fertilized garden or field, the percentage of mycorrhizal roots decreases. In natural ecosystems, soil nutrients are usually not so abundant, and mycorrhizal roots are the norm rather than an exception. Fossils from more than 400 million years ago show that interactions between plants and fungi are ancient. Perhaps fungi helped plants gain a foothold on land.

## Symbiotic nitrogen-fixing bacteria supply nitrogen to both plants and ecosystems.

Nitrogen is the nutrient that plants must acquire in greatest abundance from the soil, and in many ecosystems nitrogen is the nutrient that most limits growth. Nitrogen itself is not rare; 78% of Earth's atmosphere is nitrogen gas ( $N_2$ ). However, as discussed in [Chapter 24](#), plants and other eukaryotic organisms cannot use  $N_2$  directly. Only certain bacteria and archaeons are able to convert  $N_2$  into a biologically useful

compound in the process of **nitrogen fixation**. Nitrogen-fixing bacteria transform  $N_2$  into forms such as ammonia ( $NH_3$ ) that can be used to build proteins, nucleic acids, and other compounds. The bacteria release a portion of these usable forms of nitrogen into the soil, where they are available to plants and other organisms.

Although many nitrogen-fixing bacteria live freely in the soil, some live in plant roots. When the level of available soil nitrogen is low, some plants form symbiotic relationships with nitrogen-fixing bacteria (**Fig. 27.20**). In response to chemical signals released from the root, bacteria multiply within the rhizosphere. At the same time, chemical signals from the bacteria trigger root cells to divide, leading to the formation of a pea-sized protrusion called a **root nodule**. Nitrogen-fixing bacteria enter the root either through root hairs or through breaks in the epidermis. They then move into the center of the nodule and begin to fix nitrogen. Even though the bacteria appear to have taken up residence within the cytoplasm of nodule cells, each bacterial cell is actually contained within a membrane-bound vesicle produced by the host plant cell.

FIG. 27.20 Symbiosis between roots and nitrogen-fixing bacteria. (a) Symbiotic root nodules on alfalfa; (b) the formation of a root nodule.

The plant supplies its nitrogen-fixing partners with carbohydrates transported by the phloem and carries away the products of nitrogen fixation in the xylem. As in mycorrhizal symbioses, the carbon cost to the plant is high: as much as 25% of the plant's total carbohydrate goes to nitrogen-fixing bacteria. Relatively few plant species have evolved

symbiotic associations with nitrogen-fixing bacteria, but those that have—especially members of the legume (bean) family—represent an important way in which biologically available nitrogen enters into ecosystems. In addition, nitrogen fixation in legume roots helps to sustain fertility in many agricultural systems.

---

## CASE 6 AGRICULTURE: FEEDING A GROWING POPULATION

### How has nitrogen availability influenced agricultural productivity?

Harvesting crops removes nutrients, including nitrogen, from an ecosystem. These nutrients must be returned if the land is to remain fertile. In the early days of agriculture, farmers left fields unplanted for long periods between crops. During these periods, nitrogen-fixing bacteria replenished soil nitrogen, either in symbiotic association with roots or as free-living bacteria in the soil.

As populations grew, fields could not be left unplanted for long periods. Organic fertilizers such as crop residues, manure, and even human feces recycled some of the lost nitrogen. Unless they are brought in from off the farm, however, they cannot replace all the nitrogen removed during harvest.

Crop rotation is one way to sustain soil fertility. Every few years, a field is planted with legumes harboring nitrogen-fixing bacteria. The legume plants are not harvested, but instead are treated as “green

manure” that is allowed to decay and replenish soil nitrogen. During the eighteenth and nineteenth centuries, legume rotation contributed to the higher crop yields needed to support increasing populations. Therefore, along with the mechanization of agriculture, nitrogen-fixing symbioses contributed to the social conditions that fueled the Industrial Revolution.

By the second half of the nineteenth century, more abundant and concentrated supplies of nitrogen fertilizers were sought. Mining of guano and sodium nitrate mineral deposits helped meet the demand for nitrogen, but with time these natural sources of nitrogen were depleted. Some way was needed to obtain nitrogen fertilizer from the vast storehouse of nitrogen in the atmosphere.

German chemist Fritz Haber developed a laboratory method for fixing nitrogen in the years 1908–1911, and Karl Bosch subsequently adapted it for industrial production. Their method allows humans to achieve what, until then, had been accomplished only by prokaryotes. Like nitrogen fixation by bacteria, the Haber–Bosch process requires large inputs of energy; unlike nitrogen fixation by bacteria, it occurs only at high temperatures and pressures. The prospect of an essentially unlimited supply of nitrogen in a form that plants can readily use has proved irresistible. Today, industrial fertilizers produced by the Haber–Bosch process account for more than 99% of all fertilizers used. Industrial fixation of nitrogen is approximately equal to the entire natural fixation of nitrogen, which is largely due to bacteria, although a small amount of nitrogen is fixed by lightning.

As we discuss in [Chapter 48](#), human use of fertilizer is altering the nitrogen cycle on a massive scale, posing a threat to biodiversity and the stability of natural ecosystems. The problems arise when nitrogen added as fertilizers leaks out of agricultural fields and enters into either groundwater or, carried through the air, uncultivated areas. Nitrogen addition to terrestrial ecosystems can cause a variety of unwanted effects. For example, it may alter species composition by favoring the growth of nitrogen-demanding and often weedy species, or it may alter soil pH, leading to the loss of cations such as calcium and magnesium needed as nutrients. The compounds used in fertilizer may also release nitrogen-containing greenhouse gases. Nitrogen runoff into aquatic systems can stimulate algal blooms and reduce the quality of drinking water.

Nevertheless, nitrogen fertilizer is a cornerstone of modern agriculture. The high-yielding varieties of corn, wheat, and rice introduced in the mid-twentieth century result in high levels of grain production only when those crops are abundantly supplied with nitrogen. The fact that plants such as legumes (including beans, soybeans, alfalfa, and clover) form symbiotic relationships with nitrogen-fixing bacteria suggests a possible way around this problem. It might be possible to engineer nitrogen fixation into crops such as wheat and rice, either by inducing them to form symbiotic relationships with nitrogen-fixing bacteria or by transferring the genes that would enable them to fix nitrogen on their own. But would that eliminate the need for nitrogen fertilizers? The answer is yes, but with a caveat. As we have seen, nitrogen fixation requires a large amount of energy, diverting resources that plants could otherwise use to support growth

and reproduction.

Self-Assessment Question

10. What are four adaptations of roots that enhance the uptake of nutrients from the soil?

## CORE CONCEPTS SUMMARY

**27.1 PHOTOSYNTHESIS ON LAND:** A major challenge in the evolution of plants was being able to acquire carbon dioxide for photosynthesis without drying out.

Land plants evolved within the group of green algae. Their cells share many features with green algal cells, including cell walls containing cellulose, large membrane-bound vacuoles, and chloroplasts containing chlorophyll *a* and *b*. [page 591](#)

Bryophytes balance CO<sub>2</sub> gain and water loss passively, photosynthesizing in wet conditions and tolerating desiccation in dry ones. [page 592](#)

Vascular plants maintain the hydration of their photosynthetic cells with water pulled from the soil. [page 593](#)

Vascular plants produce four organ types: roots, stems, leaves, and reproductive organs. All four organ types are built from the same three tissue layers: epidermis, ground, and vascular. [page 594](#)

**27.2 CARBON DIOXIDE GAIN AND WATER LOSS:** Leaves have a waxy cuticle and stomata, which allow plants to acquire carbon dioxide while limiting water loss.

The low concentration of CO<sub>2</sub> in the atmosphere forces plants to expose their photosynthetic cells directly to the air. The outward diffusion of water vapor leads to a massive loss of water. [page 595](#)

The waxy cuticle on the outside of the epidermis slows rates of water loss from leaves but also slows the diffusion of CO<sub>2</sub> into

leaves. [page 596](#)

Stomata are pores in the epidermis that allow CO<sub>2</sub> to diffuse into the leaf, but also allow water vapor to diffuse out of the leaf. [page 596](#)

Stomata can open or close to regulate the amount of water leaving the leaf. [page 596](#)

CAM plants capture CO<sub>2</sub> at night when evaporative rates are low. During the day, they close their stomata and use this stored CO<sub>2</sub> to supply the Calvin cycle, increasing the exchange ratio of CO<sub>2</sub> and water. [page 597](#)

C<sub>4</sub> plants suppress photorespiration by concentrating CO<sub>2</sub> in bundle-sheath cells. The buildup of CO<sub>2</sub> in bundle-sheath cells results from the rapid production of C<sub>4</sub> compounds in mesophyll cells. The C<sub>4</sub> compounds diffuse into the bundle-sheath cells and release CO<sub>2</sub> that can be used in the Calvin cycle. [page 599](#)

**27.3 WATER TRANSPORT:** Xylem transports water and dissolved nutrients from the soil, allowing leaves to remain hydrated.

Water flows through xylem conduits from the soil to the leaves. [page 601](#)

Xylem conduits are formed from cells that have thick, lignified cell walls and which lose their cell contents as they mature. Water flows into xylem conduits across small thin-walled regions called pits. [page 601](#)

Xylem conduits are of two types: tracheids and vessels. Tracheids

are unicellular xylem conduits; vessels are formed from many cells.

[page 601](#)

As water evaporates from leaves, water is drawn toward the sites of evaporation from the xylem. As water exits the xylem, the pressure falls, generating the driving force for water movement in the xylem. Because of the strong hydrogen bonds between water molecules, water can be pulled from the soil and transported through the xylem. [page 602](#)

Pulling water through the xylem creates the risk of mechanical failure, either by the collapse inward of conduit walls or by cavitation, in which a gas bubble expands to fill the entire conduit. [page 605](#)

**27.4 TRANSPORT OF CARBOHYDRATES:** Phloem transports carbohydrates throughout the plant for use in growth and respiration.

Carbohydrates are transported in the phloem through living cells. These cells lack a nucleus or vacuole at maturity. [page 606](#)

In angiosperms, phloem transport cells are connected end to end by sieve plates, forming multicellular sieve tubes. Phloem sap flows from one sieve tube cell to another through large pores in the sieve plates. [page 606](#)

High solute concentration brings water into sieve tubes by osmosis, increasing the turgor pressure. At sites of use, the removal of solutes leads to an outflow of water and a drop in turgor pressure. [page 607](#)

The difference in turgor pressure drives the movement of phloem sap from source to sink. [page 607](#)

Carbohydrates released from roots provide carbon and energy sources for the rhizosphere microbial community, stimulating decomposition of organic matter and increasing nutrient availability. [page 608](#)

**27.5 UPTAKE OF WATER AND NUTRIENTS:** Roots expend energy to obtain nutrients from the soil.

The endodermis allows roots to control which dissolved solutes from the soil enter the xylem. The uptake of solutes by roots is therefore highly selective. [page 609](#)

Plants exchange carbohydrates with symbiotic fungi in return for assistance obtaining nutrients from the soil. [page 611](#)

Plants supply carbohydrates to symbiotic nitrogen-fixing bacteria in exchange for usable forms of nitrogen. [page 612](#)

Agricultural productivity is closely linked to nitrogen supply. [page 613](#)

## CHAPTER 28 Plant Reproduction

### Finding Mates and Dispersing Young

SCIENCE PHOTO LIBRARY/Science Source

---

## CORE CONCEPTS

**28.1 ALTERNATION OF GENERATIONS:** Alternation of generations evolved by the addition of a diploid sporophyte generation that allows plants to disperse spores through the air.

**28.2 SEED PLANTS:** Pollen allows the male gametophyte to be transported through the air, while resources stored in seeds support the development of the embryo.

**28.3 FLOWERING PLANTS:** Angiosperms produce flowers and fruits that increase the efficiency of pollination and seed dispersal, and provide resources for seeds after fertilization.

**28.4 ASEXUAL REPRODUCTION:** Many plants can reproduce asexually.

---

As plants evolved on land, the challenges of carrying out photosynthesis in air were matched by the difficulties of completing their life cycle. The algal ancestors of land plants relied on water currents to carry sperm to egg and to disperse their offspring. On land, however, plants are surrounded by air. Air is less buoyant than water, provides a poor buffer against changes in temperature and ultraviolet radiation, and increases the risk of drying out. Thus, as plants diversified on land, structures evolved that would allow gametes and offspring to survive being transported through air. For these structures to be useful, plant life cycles had to undergo radical change. The modification of land plant life cycles is a major theme in plant evolution.

The gametes and offspring of many land plants are carried passively by the movement of the air (or in a few cases, water—think coconuts). However, some plants evolved the ability to use animals as transport agents. In particular, the flowers and fruits of angiosperms (flowering plants) attract animals through their colors, scents, and food resources. Animals attracted by flowers transport male gametes from one flower to another, while animals that eat fruits are key agents of seed dispersal. Coevolution with animals is a second major theme in plant evolution.

# 28.1 ALTERNATION OF GENERATIONS

Land plants are rooted in one place, yet must be able to disperse their offspring to minimize competition for space and resources with the parent plant. Early land plants evolved the capacity to disperse their offspring through the air, but they still required water for fertilization. How could these plants exist in both water and air? They couldn't—at least not at the same time. Instead, early land plants evolved a life cycle with two distinct multicellular generations: one generation released sperm into a moist environment, and the following generation dispersed offspring through the air ([Fig. 28.1](#)). A pattern of alternating generations, one haploid and one diploid, still exists in all plants today.

FIG. 28.1 The phylogeny of land plants. This phylogenetic tree shows the evolutionary trajectory of the environmental setting for fertilization and dispersal.

## The algal sister groups of land plants have one multicellular generation in their life cycle.

Molecular sequence comparisons have identified three groups of green algae as being closely related to land plants. Although these three groups are diverse in form, their life cycles share many features. Here we use *Chara*, a member of one of these groups, to gain insights into the evolution of land plant life cycles ([Fig. 28.2](#)).

Source: A. Jagel/AGE Fotostock.

FIG. 28.2 *Chara*, a green alga that is closely related to land plants. *Chara* is an upright alga found along the margins of lakes and estuaries.

In animals, the multicellular body consists of diploid ( $2n$ ) cells. *Chara* has a multicellular body as well, shown in [Fig. 28.2](#), but it consists entirely of haploid ( $1n$ ) cells. In animals, haploid gametes are formed by meiosis. In *Chara*, haploid eggs and sperm are formed instead by mitosis. The egg is retained within the female reproductive

organ, while the sperm are released into the water ([Fig. 28.3](#)). Fertilization occurs when one egg and one sperm fuse to form a diploid zygote. In *Chara*, the zygotes are released and dispersed by water currents until they settle. The zygote then undergoes meiosis to produce four haploid cells. One of these haploid cells develops into a new multicellular (haploid) individual representing the beginning of the next generation.

In *Chara*, both fertilization and dispersal take place in water. Because they live along the margins of lakes and streams, however, *Chara* are occasionally left high and dry by drought. Their

photosynthetic bodies shrivel quickly, but these algae survive because their zygotes are surrounded by a tough outer wall. When water once again covers the resting zygotes, they undergo meiosis and produce new haploid algae. This is the condition from which the more complicated life cycles of land plants evolved.

## Land plants have two multicellular generations in their life cycle.

In [Chapter 27](#), we saw that bryophytes—liverworts, mosses, and hornworts—share many features related to their dependence on surface moisture for hydration. They also share many reproductive traits. Here, we consider the life cycle of *Polytrichum commune*, a moss commonly found in forests and the edges of fields. *Polytrichum* illustrates how the evolution of two multicellular generations, one specialized for fertilization and the other for dispersal, contributed to the ability of plants to colonize the land.

Like *Chara*, *Polytrichum* has a photosynthetic body—the familiar green tufts observed on the forest floor—that is made of haploid cells and that forms gametes by mitosis. And like *Chara*, *Polytrichum* and other bryophytes release swimming sperm into the environment. For fertilization to occur, the sperm must swim through films of water that coat moist surfaces to reach eggs retained within reproductive organs.

Bryophytes produce their gametes near the ground, where they are most likely to encounter a continuous film of water. They tend to be small, as sperm are able to swim only a few centimeters. Many bryophytes release their sperm only when agitated by raindrops.

Raindrops signal the presence of surface water, and their impact can splash sperm farther than they could swim on their own.

It is after the fusion of egg and sperm gives rise to a diploid zygote that the life cycles of plants and their green algae relatives diverge. In plants, the zygote does not undergo meiosis, and it does not disperse. Instead, the zygote is retained within the female reproductive organ. There, it divides repeatedly by mitosis to produce a new multicellular plant—this one made of diploid cells ([Fig. 28.4](#)). Because the fertilized egg begins to develop while surrounded and supported by the maternal (that is, egg-producing) plant, it can be described as an embryo. Recall from [Chapter 27](#) that the scientific name for land plants is Embryophyta. This name highlights the fact that in all land plants the fertilized egg is retained and develops in place, forming an embryo.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 28.4 The life cycle of the mos. *Polytrichum commune*. The multicellular sporophyte generation is a major innovation of land plants.

As the embryo develops into a mature diploid plant, some cells undergo meiosis. The haploid products of meiosis develop into **spores**, cells that disperse and give rise to new haploid individuals. Because the diploid multicellular plant produces spores, it is called the **sporophyte**, and this generation is called the sporophyte generation. In contrast, because the haploid multicellular plant produces gametes, it is called the **gametophyte**, and that generation is called the gametophyte generation. The resulting life cycle is called **alternation of generations** because a haploid gametophyte generation and a diploid

sporophyte generation follow one after the other. All land plants exhibit alternation of generations.

## Bryophytes illustrate how the alternation of generations allows the dispersal of spores in the air.

How might the new diploid generation have made it possible for plants to colonize land? To answer this question, let's look at the sporophyte of *Polytrichum*. Late in the growing season, the green tufts of this moss sprout an extension, consisting of a small brown capsule at the end of a cylindrical stalk a few centimeters high ([Fig. 28.5a](#)). This is the sporophyte, which originated from a fertilized egg. Because the fertilized egg was retained within the female reproductive organ, the sporophyte grows directly out of the gametophyte's body. Thus, the *Polytrichum* specimen pictured in Fig. 28.5a shows both a gametophyte (green) and several sporophytes (brown). The gametophyte is photosynthetically self-sufficient, but the sporophytes must obtain water and nutrients needed for their growth from the gametophyte.

Sources: a. Keith Burdett/AGE Fotostock; b. Power and Syred/Science Source.

FIG. 28.5 Moss sporangia. (a) When spores of *Polytrichum commune* are mature, a cap falls off, allowing the salt shaker–like sporangium to release the spores. (b) The sporangia of *Homalothecium sericeum* have a ring of teethlike projections that curl back as they dry, flinging spores into the air.

The significance of the multicellular sporophyte is that it enhances the ability of plants to disperse on land. The capsule at the top of the *Polytrichum* sporophyte is a **sporangium**, a structure in which many thousands of diploid cells undergo meiosis, producing huge numbers of haploid spores. In contrast, fertilization in *Chara* is followed by meiosis in only a single cell (the zygote).

Spores are small and can be carried for thousands of kilometers by the wind. However, their tiny size puts spores at risk of being washed from the air by raindrops. The sporangia of many bryophytes release their spores only when the air is dry. *Polytrichum* releases spores through small openings in the sporangium the way a salt shaker releases salt. When the air is wet, the spores form clumps that are too big to fit through these openings. More commonly, a ring of teethlike

projections curls over the top of the sporangia. These bend backward when air humidity is low, flinging the spores into the air ([Fig. 28.5b](#)).

The spores are protected as they travel through the air. Earlier, we noted that the zygotes of *Chara* secrete a tough wall. This wall protects the zygote enclosed within it from environmental stresses such as ultraviolet radiation and desiccation. The wall contains [sporopollenin](#), a complex mixture of polymers that is remarkably resistant to degradation. In mosses and other land plants, it is the spore, not the zygote, that secretes sporopollenin. This suggests that early land plants retained a capacity present in their algal ancestors, the ability to synthesize sporopollenin, but the timing of gene expression changed in these plants.

Following dispersal, most spores germinate within a few days. Some, however, can survive within the spore wall for months or even years. When conditions for growth are favorable, the spore wall ruptures, and the haploid cell inside can then develop into a multicellular and free-living gametophyte.

## Dispersal enhances reproductive fitness in several ways.

With the evolution of the multicellular sporophyte generation, land plants were able to make many spores and disperse them across large distances on land. Dispersal is one of the most important stages in a plant's life cycle. To understand why, imagine what would happen if a plant's spores (or seeds) simply dropped straight down onto the ground below the parent plant. All the plant's offspring would then attempt to

grow in a very small space that might contain enough nutrients and light for only a few to establish themselves. In contrast, offspring dispersed by wind or other means are more likely to settle in a spot where they will not be forced to compete with closely related individuals for resources.

In addition, dispersal allows offspring to avoid pathogens and parasites. Viruses and bacteria travel easily from individual to individual in a densely packed population. An individual that settles away from the parent plant is less likely to encounter a pathogen. Finally, dispersal allows offspring to colonize new habitats. The evolution of new structures to enhance dispersal on land is a major theme in plant evolution.

## Spore-dispersing vascular plants have free-living gametophytes and sporophytes.

In [Chapter 27](#), we saw that the evolution of vascular tissues allowed plants to grow tall. Xylem and phloem are present only in the sporophyte generation because spore dispersal is enhanced by height. In contrast, gametophytes must remain small and close to the ground to increase their chances of fertilization. A major change in the plant life cycle is that in vascular plants the sporophyte is the dominant generation, both because the sporophyte is physically larger than the gametophyte and because its photosynthetic production is much higher.

Two groups of vascular plants, the lycophytes and the ferns and

horsetails, depend on swimming sperm for fertilization and disperse by spores that are released into the air (see [Fig. 28.1](#)). In these ways, their life cycle is similar to that of the bryophytes. Unlike bryophytes, however, both the gametophyte and the sporophyte generation are free-living, meaning that each is able to supply its own nourishment.

Let's examine the life cycle of the bracken fern *Pteridium aquilinum*. We begin with the largest component of the life cycle, the leafy diploid sporophyte generation ([Fig. 28.6](#)). If you examine a bracken leaf closely, you may find tiny brown packets along its lower margin. These are sporangia, and each contains diploid cells that undergo meiosis to generate haploid spores. Each spore becomes covered by a thick wall containing sporopollenin, making it well suited for dispersal through the air. The photo on the first page of this chapter shows fern sporangia (photographed through a microscope in ultraviolet light) that have not yet opened.

FIG. 28.6 The life cycle of the bracken fer. *Pteridium aquilinum*. A free-living gametophyte generation, which remains small, alternates with a free-living vascularized sporophyte generation, which grows tall.

As the sporangia dry out, they break open, releasing the spores. Most spores travel for only short distances, but a few may end up far from their parent. Bracken ferns can be found on every continent except Antarctica, as well as on isolated oceanic islands. This distribution is testimony to the ability of spores to travel over long distances.

Spores that land in a favorable location can germinate and grow to form the haploid gametophyte generation. You have probably never seen a fern gametophyte—or never noticed one. Like most fern gametophytes, the bracken gametophyte is less than 2 cm long and only one to a few cells thick ([Fig. 28.6](#)). Because of its small size, one might assume that the haploid generation is a weak link in the fern life cycle. In reality, fern gametophytes often live longer and withstand stressful environmental conditions better than the much larger sporophytes. As discussed in [Chapter 27](#), plants that lack roots must be able to tolerate drying out; this group includes both bryophytes and free-living fern gametophytes.

Fern gametophytes typically produce either male or female gametes. The female gametes (eggs) are retained within reproductive organs that remain attached to the gametophyte. The male gametes are released and swim to the egg of a nearby gametophyte through a film of water. The union of a male gamete and a female gamete forms a diploid

zygote, which develops in place and is supported by the gametophyte as it begins to grow. Eventually, the developing sporophyte forms leaves and roots that allow it to become a physiologically independent diploid plant.

Ferns release swimming sperm, so they are able to reproduce only when conditions are wet. That is true of the other spore-dispersing plants (lycophytes, horsetails, and bryophytes) as well. What if a plant could eliminate the requirement for swimming sperm? Seed plants did just that.

#### Self-Assessment Questions

1. How is the evolution of alternation of generations an adaptation for reproduction on land?
2. In what ways are spores similar to gametes, and in what ways do spores and gametes differ?
3. In what ways is fern reproduction similar to moss reproduction? In what ways is fern reproduction different from moss reproduction?

## 28.2 SEED PLANTS

Seed plants have the remarkable ability to bring male and female gametes together when conditions are dry. How is this possible? Stand beneath a pine tree on a spring day, and you will see the answer all around you: tiny yellow grains that cover the ground and everything else close to the tree. These pollen grains are produced by all seed plants.

In fact, in seed plants we encounter two new structures: pollen and seeds. Pollen is what liberates seed plants from the need to release swimming sperm into the environment, and seeds are multicellular structures adapted for dispersing offspring. The evolution of pollen and seeds required dramatic changes in the seed plant life cycle.

Seed plants form a monophyletic group. Their scientific name, Spermatophyta, comes from the Greek word for seed (*spermato* = seed, *phyte* = plant). There are two main types of seed plants: gymnosperms, which include conifers such as pine trees, and angiosperms, which are the flowering plants (see [Fig. 28.1](#)). In this section, we examine features of the life cycle that are common to all seed plants and use pine, a gymnosperm, to illustrate how seed plants reproduce without releasing swimming sperm into the environment. In [section 28.3](#), we examine features of angiosperm reproduction, such as flowers and fruits, that distinguish their life cycle from that of other seed plants.

**The seed plant life cycle is distinguished by four major steps.**

Pollen and seeds are produced only by seed plants, with these structures taking on some of the roles previously played by sperm and spores. To understand them, we consider four signature steps of the life cycle of seed plants.

The first step is the formation of two types of spore, each produced in separate sporangia. One type develops into a male gametophyte and the other into a female gametophyte. Male gametophytes produce only male gametes, and female gametophytes produce only female gametes. Although this condition is not unique to seed plants (it also occurs in a small number of spore-dispersing vascular plants), without it the rest of the modifications that result in the life cycle exhibited by seed plants could not have evolved.

The second step is unique to seed plants. Seed plant spores are not dispersed. Instead, spores undergo mitosis while remaining inside their sporangia. As a consequence, the gametophytes develop while they are attached to and supported by the sporophyte.

The significance of this step is most apparent in the development of the female gametophyte. By developing in place, the female gametophyte can draw resources from the sporophyte to produce female gametes (eggs) and to store energy and raw materials that the embryo can make use of following dispersal. Within each sporangium, only a single haploid spore develops into a female gametophyte, and this gametophyte continues growing until it fills the sporangium. The haploid female gametophyte is protected by one or more layers of sporophyte tissue that surround the sporangium. This entire structure,

consisting of sporangium, female gametophyte, and protective outer layers, is the **ovule**. Ovules, if fertilized, develop into seeds.

The male gametophyte also develops while still attached to the sporophyte. Many cells within each sporangium undergo meiosis, forming large numbers of haploid spores. Within each of these spores, a male gametophyte develops, producing a handful of cells by mitosis that all fit within the wall of the original spore. **Pollen** consists of the multicellular male gametophyte and a surrounding outer wall containing sporopollenin.

The third step begins when pollen is shed. **Pollination** is the transport of pollen, either in the air or by an animal, from the sporangium where it was produced to a location near an ovule. Because the male gametophyte produces male gametes, pollination eliminates the need to release swimming sperm into the environment. Nevertheless, pollination alone is not sufficient to ensure fertilization. The male gametophyte must germinate and grow through the tissues of the ovule to deliver the male gametes to the egg. For this reason, you should not think of pollen as flying sperm. The growth of the male gametophyte plays an essential role in bringing the male and female gametes together.

The fourth and final step is the maturation of a fertilized ovule into a **seed**. A seed consists of an embryo, stored resources, and an outer, protective coat. Seeds increase the probability that offspring will survive because their stored resources can be used to fuel the early growth of the next generation.

Pine trees illustrate how the transport of pollen in air allows fertilization to occur in the absence of external sources of water.

To illustrate how seed plants have freed themselves from a dependence on surface moisture for fertilization, let's look at the life cycle of a pine tree ([Fig. 28.7](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
Photo source: Charles O. Cecil/Alamy.

FIG. 28.7 The life cycle of the loblolly pine tree. *Pinus taeda*.

In pines, as in all vascular plants, what we think of as “the plant” is the diploid sporophyte. However, a significant part of the pine’s life cycle—from the production of haploid spores to the growth of the gametophyte from a spore, to the production of gametes, and ultimately to fertilization and the development of an embryo within a seed—takes place within reproductive structures called cones. Cones are compact shoots with modified leaves that produce sporangia on their surface. Pines develop two types of cones. **Ovulate cones** typically are located on upper branches and produce spores that develop into female gametophytes. **Pollen cones** are commonly found in clusters near the tips of branches lower in the tree; they produce spores that develop into male gametophytes.

In ovulate cones, each sporangium is surrounded by a jacket of protective tissue. Within each sporangium, a single cell undergoes meiosis, producing four haploid spores. Three of these spores degrade, leaving a single functional spore inside the sporangium. This spore is not dispersed, but instead undergoes repeated mitoses to form a multicellular female gametophyte consisting of a few thousand haploid cells. The female gametophyte produces one or more reproductive organs in which a haploid cell develops into an egg. The entire structure of protective outer layers surrounding a sporangium, with a multicellular female gametophyte inside, constitutes the ovule, and it remains attached to the sporophyte.

In pollen cones, many cells within each sporangium divide by meiosis to form haploid spores. Each haploid spore then divides mitotically to form a multicellular male gametophyte inside the spore

wall. In pine, the male gametophyte consists of only four cells at the time the pollen is released from the parent plant. After the pollen is released, the pollen cones are also shed.

The pine pollen is carried to the ovule by the wind. Pollination occurs as much as 15 months before fertilization. In fact, it is the arrival of the pollen that stimulates the development of the female gametophyte. When the pollen germinates, the male gametophyte produces a pollen tube that grows outward through an opening in the sporopollenin coat and into the tissues of the ovule. Then, when the egg is ready to be fertilized, the male gametophyte's pollen tube grows to the female gametophyte, attracted by chemical signals. Two sperm, which lack flagella, travel down the pollen tube, and one of them fuses with the egg to form a zygote. Fertilization in seed plants thus takes place without the male gametes ever being exposed to the external environment.

Following fertilization, the ovules develop into seeds, while the ovulate cone enlarges and becomes quite woody. The mature ovulate cone (also called a seed cone) is what is commonly referred to as a "pinecone." The seeds it contains, once released and dispersed, can give rise to a new, free-living sporophyte.

In seed plants, the relationship between sporophyte and gametophyte has been reversed completely from that found in bryophytes. The gametophyte, so prominent in mosses, is reduced to a small number of cells that depend entirely on their parent sporophyte for nutrition ([Fig. 28.8](#)).

FIG. 28.8 Life-cycle evolution in land plants. A major trend in the evolution of land plants is a decrease in the size and independence of the gametophyte generation and a corresponding increase in the prominence of the sporophyte generation.

## Seeds enhance the establishment of the next sporophyte generation.

The union of gametes triggers the ovule to develop into a seed that can carry the new embryo away from the parent plant. Because seeds develop from fertilized ovules, they contain tissues produced by three generations ([Fig. 28.9](#)). On the outside is the protective **seed coat**, which is formed from tissues that surround the sporangium and, therefore, is a product of the diploid sporophyte. At the center is the embryo, which develops from the zygote and represents the next sporophyte generation. In gymnosperms such as pine trees, the embryo is surrounded by the haploid female gametophyte, which provides the raw materials that support the growth of the embryo. In angiosperms, the origin of this storage tissue differs, but it serves the same role of nourishing the embryo.

Source: Jim French.

FIG. 28.9 Structure of a pine seed. A pine seed contains tissues from three generations: the seed coat formed from diploid sporophyte layers, the haploid female gametophyte, and the diploid embryo, which will grow into the next sporophyte generation.

Compared with a unicellular spore, a seed is able to store more resources to support the growth and establishment of a new sporophyte generation. Many seeds contain high levels of protein and energy-rich oils ([Chapter 2](#)). As a result, seeds are an important food resource for animals and are the cornerstone of agricultural production.

Because seeds are larger than spores, they are not as easily dispersed by wind. As a result, seed plants have evolved structures to enhance seed dispersal. For example, many pine seeds have flattened extensions, referred to as “wings,” that increase the distances over which they can be carried by a breeze. Other seed plants produce brightly colored and/or fleshy structures to attract and reward animals that may inadvertently carry seeds away from the parent plant. Many plants dispersed by animals develop seed coats that allow their seeds to pass unharmed through an animal’s digestive system.

As seeds mature, most lose water. The seeds' metabolic activity drops to extremely low levels and the embryo ceases to grow. In this state, seeds can survive for long periods, in many cases one to several years, and sometimes much longer. Some seeds exhibit [dormancy](#), meaning that they can delay germination even when conditions for growth, notably temperature and moisture, are favorable. Dormancy prevents seeds from germinating at the wrong time, such as on an uncharacteristically warm day at a time of year when the seedlings would be unable to survive. It also prevents seeds from germinating all at once, thereby spreading the risk of making the transition from embryo to seedling over a larger time span and range of conditions.

Seeds span more than 11 orders of magnitude in terms of their size ([Fig. 28.10](#)). The 100-nanogram (ng) seeds of orchids are so small (100 ng = 0.0001 mg) that they cannot germinate successfully without obtaining nutrients from a symbiotic fungus. At the other end of the spectrum are the 30-kilogram (kg) seeds of the coco-de-mer, a palm tree found on islands in the Indian Ocean. Large seeds, being better provisioned, are well adapted for the deep shade of a forest understory. However, large seeds typically disperse over shorter distances and often have little or no dormancy. In contrast, for the same investment in resources, a plant can make many small seeds, which can persist in the soil until the right combination of conditions triggers germination. As a result, most weeds produce small seeds.

#### Self-Assessment Questions

4. How do the male and female gametophyte generations differ in seed plants?
5. What are two advantages of seeds over spores in terms of the probability that the next sporophyte generation will become successfully established?

## 28.3 FLOWERING PLANTS

Suppose you want to send a postcard to a friend, but your only means of doing so is to throw the card into the air and hope the wind carries it to your friend's front door. How many cards would you have to send aloft to achieve a high probability of success? The answer, of course, is *many*, and this is precisely the reason that pines produce huge numbers of pollen grains each year. Now suppose instead that you can give your card to the letter carrier whose route goes by your friend's house: the odds of successful delivery are now much greater. This analogy gives some idea of a key evolutionary innovation that appeared in the angiosperms. The "letter carriers" in angiosperm fertilization are animals, and the evolution of flowers is what allowed angiosperms to use animals to transport pollen.

Animal pollination is far more efficient than pollination by wind; that is, a higher proportion of pollen reaches an egg when it is dispersed by this means. Thus, a plant that relies on animal pollination can afford to produce less pollen. Flowers may have initially evolved to make animal pollination possible in dense tropical forests. However, as angiosperms diversified into many habitats, some species reverted to wind pollination. Today, angiosperms make use of a wide range of pollination strategies. Here, we examine how angiosperms reproduce, beginning with flowers, which when fertilized develop into fruits.

**Flowers are reproductive shoots specialized for the transfer and receipt of pollen.**

Angiosperms are seed plants whose life cycle is similar to that of pine trees (see [Fig. 28.7](#)), with a few important differences. One of these differences is that in angiosperms pollen and ovules are produced in a single structure, the flower ([Fig. 28.11](#)), rather than in separate cones. The significance of this arrangement is that, because pollen and ovules are so close together, an animal pollinator can deliver pollen to one plant and take up pollen to carry to another plant in a single visit. Approximately 12% of flowering plant species produce pollen and ovules in separate flowers, but all of these species descend from ancestors whose flowers produced both. Such “unisexual” flowers are often found in the approximately 20% of angiosperm species that have reverted to wind pollination.

FIG. 28.11 Flower diversity. Shown here are (a) a lady's-slipper orchid

(*Cypripedium reginae*); (b) a magnolia (*Magnolia grandiflora*); (c) French lavender (*Lavandula stoechas*); and (d) a tropical tree (*Brownea grandiceps*).

Flowers are spectacularly diverse in size, color, scent, and form, but they all have the same basic organization: concentric whorls of floral organs (**Fig. 28.12**; [Chapter 19](#)). The outer whorls consist of **sepals** and **petals**, while the inner whorls are made up of pollen-producing **stamens** and ovule-producing **carpels**. Let's look at the floral organs in more detail, starting with the carpels at the center of the flower.

FIG. 28.12 Flower organization. The four whorls of organs in a flower are carpels, stamens, petals, and sepals.

Carpels are modified leaves that have become folded over and sealed along the edges to form a hollow chamber. Ovules are produced

on the inner surface of this cavity ([Fig. 28.13a](#)). Ovule development begins with the growth of sporangia, each of which is surrounded, typically, by two protective layers. Within each sporangium a single cell undergoes meiosis, forming four haploid spores. One of these spores develops into a multicellular female gametophyte. Recall that ovules, when fertilized, develop into seeds. The fact that the ovules develop within the carpel is what gives rise to the name “angiosperm,” which is derived from Greek words meaning “vessel” and “seed.” In gymnosperms, the ovules are not enclosed, and their name, again from the Greek, literally means “naked seeds.”

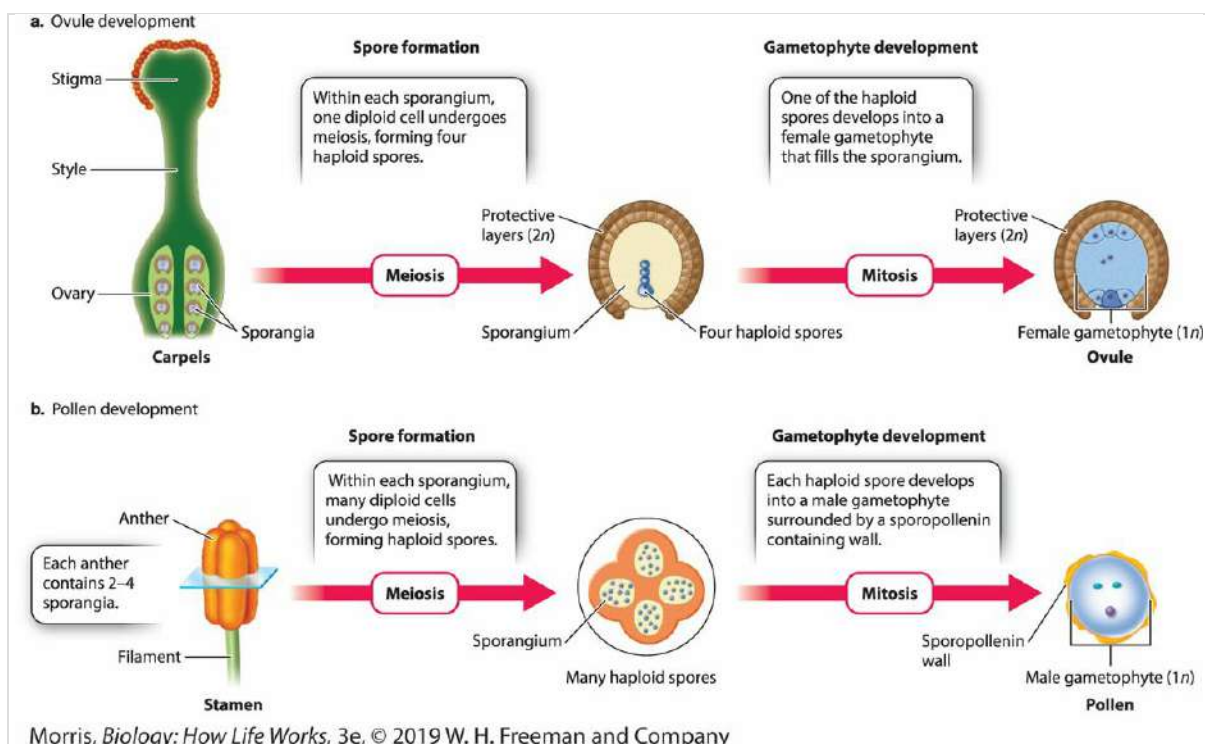

FIG. 28.13 Spore formation and gametophyte development in (a) carpels and (b) stamens.

Each flower produces one or more carpels (typically 3 to 5, but sometimes more than 20). Because the carpels are often fused, however, there may be only a single structure at the center of the

flower. At the base is the [ovary](#), in which one to many ovules develop. The ovary protects the ovules from being eaten or damaged by animals, but also makes it impossible for pollen to land directly on the surface of the ovule. Instead, to reach the ovules, pollen must land on the [stigma](#), a sticky or feathery surface at the top of the carpel(s), and germinate to produce a pollen tube that grows down through the stalk-like [style](#). The female gametophytes produce chemicals that guide the pollen tubes toward unfertilized ovules. Because animal pollinators can deposit many pollen grains at once, the fastest-growing pollen tubes are the most likely to deliver sperm to an egg. In some plants, the style can be more than 10 cm long—corn silks, for instance, are styles—creating the opportunity for competition, and thus natural selection, between genetically distinct male gametophytes.

Immediately surrounding the carpels are the pollen-[anther](#), which contains several sporangia ([Fig. 28.13b](#)). Within each sporangium, many cells undergo meiosis to form haploid spores. The male gametophyte then develops within the spore wall, forming pollen. In most flowers, the anther splits open, exposing the pollen grains. Once exposed, the pollen can come into contact with the body of a visiting pollinator or, in the case of a wind-pollinated species, be carried off by the wind. In other plants, such as the tomato, small holes open at the top of anthers. To extract the pollen, bees land on the flower and vibrate at just the right frequency to shake loose the pollen inside. Orchids and milkweeds do not release individual pollen grains. Instead, they disperse their pollen all together in a package with a sticky tag that attaches to a visiting pollinator.

The outer whorls of the flower produce neither pollen nor ovules, but instead contribute to reproductive success in other ways. Most flowers have two outer whorls. The outermost is made up of sepals, often green but sometimes brightly colored. Sepals protect the flower during its development. In contrast, petals are frequently brightly colored and distinctively shaped. Their role is to attract and orient animal pollinators. In addition to serving as visual cues, petals in many flowers produce volatile oils. These are the source of the distinctive odors—some pleasant, some decidedly not—that many flowers use to advertise their presence to pollinators.

## The diversity of floral morphology is related to modes of pollination.

The evolutionary histories of the angiosperms and their animal pollinators are closely intertwined. A rapid increase in angiosperm diversity occurred between 100 and 65 million years ago, about the same time as bees (Hymenoptera) and butterflies (Lepidoptera) diversified. The evolution of flowers allowed animals to specialize on new food resources. At the same time, animal pollinators greatly assisted the movement of pollen between plants within the same population.

Flowers communicate their presence through both scent and color. For pollination to be reliable, however, it must be in the interest of the animal pollinator to move repeatedly between flowers of the same species. Flowers earn fidelity from their pollinators by providing rewards, frequently in the form of food ([Fig. 28.14](#)). Many insects consume some of the pollen itself, and many flowers also produce

nectar, a sugar-rich solution that is attractive to bats and birds as well as to insects.

Some species provide rewards other than food. For example, many orchids secrete chemicals that male bees need to make their own sexual pheromones. Other flowers provide an enclosed and sometimes heated chamber in which insects can aggregate. Still other flowers do not provide rewards at all; instead, they “trick” their pollinators into visiting. For example, flowers that look and smell like rotting flesh attract flies, and orchids that look like a female bee even emit

chemicals that mimic sex pheromones to attract male bees ([Fig. 28.15](#)). As male bees attempt to copulate with the flower, they deliver and receive pollen.

Source: José Antonio Jiménez/AGE Fotostock.

FIG. 28.15 *Ophrys speculum*, a Mediterranean orchid, which mimics the shape and color of female bees. These flowers induce males to attempt mating. Through repeated attempts on different flowers, the males transfer pollen.

Producing rewards and attractants such as nectar and petals requires resources. Thus, while animals can provide more efficient pollination than can the wind, the resources expended may be wasted if nonpollinating visitors “steal” pollen or nectar. For this reason, many flowers have mechanisms to protect their investments. For example, tubular cardinal flowers provide rewards only to hummingbirds able to probe their depths, and snapdragons provide rewards only to insects

that are strong enough to push apart their petals.

Many plants have evolved flowers that match rewards and attractants to the metabolic needs and sensory capabilities of their pollinators. For example, flowers pollinated by larger pollinators such as bats and birds produce copious amounts of nectar. Bat-pollinated flowers tend to be large, white or cream colored, and strongly scented; these traits are all good matches to the size and nocturnal habits of their pollinators. In addition, these flowers are positioned among branches and leaves in such a way that they can be found by echolocation. In contrast, bird-pollinated flowers are often red, a color most insects cannot see, and have no scent. Because interactions between plants and pollinators affect gene flow, they can affect rates of speciation. A recent radiation in columbine occurred as the plants shifted from bumblebees to hummingbirds to hawkmoths as their primary pollinator ([Fig. 28.16](#)).

#### HOW DO WE KNOW?

### FIG. 28.16

## How do long nectar spurs evolve?

#### BACKGROUND

Some flowers produce nectar in tubular outgrowths of their petals, called nectar spurs. Pollinators pick up and deliver pollen as they access nectar in the spur with their tongue. In some species, nectar spurs can be up to 40 cm long. Scientists have long wondered which processes led to the evolution of such long nectar spurs.

#### HYPOTHESIS 1

Charles Darwin proposed that long nectar spurs result from a

coevolutionary “race” between plants and pollinators that favors gradual increases in both spur and tongue lengths. Flowers with longer nectar spurs gain a reproductive advantage because pollinators must come into close contact with the flower if they are to reach the nectar. Such close contact increases the likelihood that pollen will be transferred from the body of the pollinator to the stigma and from the anthers to the pollinator. At the same time, pollinators with longer tongues are able to obtain a larger food reward. Thus, plants and pollinators coevolve toward increasingly longer nectar spurs and tongues.

#### HYPOTHESIS 2

An alternative hypothesis is that longer nectar spurs evolve as plants adapt to a series of unrelated pollinators, each with longer tongues. According to this “pollinator shift” model, nectar spur length evolves to match the tongue length of the new pollinator. Note that this model also predicts increases in nectar spur length because pollinators with short tongues will not visit plants that have nectar they cannot reach.

#### PREDICTIONS

The two hypotheses make different predictions. Hypothesis 1 predicts that increases in nectar spur length occur in species with the same pollinator type. Hypothesis 2 predicts that increases in nectar spur length are associated with a change in pollinator type.

#### METHOD

To determine which of these two hypotheses is correct, scientists studied columbines (members of the genus *Aquilegia*). Their visually striking flowers are pollinated by bumblebees (short tongues), hummingbirds (medium-length tongues), and hawkmoths (long tongues).

Justen Whittall of the University of California at Davis and Scott Hodges of the University of California at Santa Barbara mapped changes in pollinator type—specifically whether the flowers were adapted for

pollination by bumblebees, hummingbirds, or hawkmoths—onto a phylogenetic tree of columbines. To do so, they assigned each of 25 species examined to one of three groups based on length of nectar spur, flower color, and most common pollinator. The group is indicated by the color circle at the tip of each branch in the phylogenetic tree in the figure. The researchers then conducted a statistical analysis, whose results suggested the most likely pollinator type at each node representing an ancestor (also indicated by color circles in the figure).

From this information, the researchers inferred the history of pollinator shifts (indicated by an \*) during the radiation of this group. Next, they analyzed whether increases in nectar spur length occurred in species with the same pollinator type, as predicted by Darwin's coevolutionary race hypothesis, or instead were associated with a change in pollinator type, as predicted by the pollinator-shift hypothesis.

#### RESULTS

Within the recent radiation of columbines, there are multiple instances of shifts from a shorter-tongued pollinator to a longer-tongued pollinator. Most of the increases in nectar spur length are associated with changes in pollinator type, consistent with hypothesis 2, the pollinator-shift hypothesis.

#### CONCLUSION

Spur length in columbines evolves by rapid increases to match the tongue length of a new pollinator type, indicating a key role for pollinator shifts in adaptive radiation.

#### FOLLOW-UP WORK

Developmental studies show that the diversity of nectar spur length evolves as a result of changes in cell shape.

"Evolution of Spur Length Diversity in *Aquilegia* Petals Is Achieved Solely Through Cell Shape Anisotropy." *Proceedings of the Royal Society, London, Series B*, 279:1640–1645.

Angiosperms are thought to have evolved in tropical forests. Pollen cannot move freely through the air in the high density of foliage that is present year round in these forests, favoring the evolution of animal pollination. However, as angiosperms diversified and spread around the globe, some evolved wind pollination once again. The reversal to

wind pollination is associated with habitats where pollinators are not reliably abundant, such as dry regions.

Wind pollination is most effective in species that are locally abundant. For example, many grasses rely on wind for pollination. Wind pollination is also common in temperate-zone trees, which produce flowers in the early spring, before leaves expand and before pollinators are active. Wind-pollinated species produce large amounts of pollen, and their petals tend to be tiny. Hay fever is an allergic reaction to pollen, almost all of which comes from wind-pollinated species.

## Angiosperms have mechanisms to increase outcrossing.

When pollen is deposited onto a stigma, the pollen must germinate and form a pollen tube that grows down through the style before fertilization can occur ([Fig. 28.17](#)). Typically, only pollen from the same species will germinate and grow successfully, thereby preventing gametes from two different species from coming into contact.

Source: Courtesy Keun Chae.

FIG. 28.17 Germination and growth of pollen tubes. The pollen tubes of *Arabidopsis thaliana* can be seen here; they have been stained with a fluorescent dye.

Plants do not have the elaborate courtship rituals that many animal species use to select an appropriate mate. Nevertheless, angiosperms have a wide range of mating systems. At one extreme are **self-compatible** species, in which gametes from male (pollen) and female (ovules) gametophytes produced by flowers on the same plant can form viable offspring. Self-compatible plants can reproduce even when they are physically isolated from other individuals of the same species or when pollinators are rare. Many weedy species and the majority of crops are self-compatible.

At the other extreme are species in which pollen must be transferred between different plants. Approximately half of all of angiosperm species are **self-incompatible**, meaning that pollination by the same or a closely related individual does not lead to fertilization. Self-incompatible plants must be able to recognize that a gamete comes from a closely related individual. Specifically, these plants recognize proteins produced from self-incompatibility genes, or *S*-genes. If the pollen's proteins match those of the carpel, the pollen either fails to germinate or germinates but the pollen tube grows slowly and eventually stops elongating. *S*-genes may have originated as a defense against fungal invaders, then later evolved as a means of promoting outcrossing. Because dozens of *S*-gene alleles can be present in a population, only pollen transfers between closely related individuals are blocked. Apples are examples of self-incompatible plants: apple

orchards always contain a mixture of different varieties to ensure fertilization occurs.

## Angiosperms delay provisioning their ovules until after fertilization.

As we have seen, a major trend in the evolution of plants is the decreasing size and independence of the gametophyte generation and the increasing prominence of the sporophyte generation. In angiosperms, this trend is taken even further ([Fig. 28.18](#)). The male gametophyte has only three cells: one cell controls the growth of the pollen tube, while the other two are male gametes or sperm. In most angiosperms, the female gametophyte contains only eight nuclei, arranged as six haploid cells (one of which gives rise to the egg) plus a central cell containing two nuclei. Thus, the female gametophyte of angiosperms is too small to support the growth of the embryo, as it does in gymnosperms. How, then, do flowering plants provide nutrition for the embryo to grow?

FIG. 28.18 The life cycle of an angiosperm.

This is where the central cell of the female gametophyte, which contains two haploid nuclei, comes into play. During pollination, the two sperm travel down the pollen tube and enter the ovule ([Fig. 28.19](#)). One of the sperm fuses with the egg to form a zygote, just as occurs in all plants. The other sperm unites with the two haploid nuclei in the central cell to form a triploid ( $3n$ ) cell. This triploid cell undergoes many mitotic divisions, forming a new tissue called [endosperm](#). In angiosperm seeds, this endosperm supplies nutrition to the embryo. The process in which two sperm from a single pollen tube fuse with the egg and the two haploid nuclei in the central cell is called [double](#)

## fertilization.

FIG. 28.19 Double fertilization. In double fertilization, one sperm fuses with the egg to form a zygote, while a second sperm fuses with the two haploid nuclei in the central cell of the female gametophyte, leading to the formation of triploid endosperm.

Double fertilization and endosperm formation offer a distinct advantage in terms of plant reproduction. In pines and other gymnosperms, the female gametophyte provides food for the embryo. This provisioning occurs whether or not the egg is successfully fertilized, so it is potentially a significant waste of resources. In contrast, in angiosperms, the endosperm develops only when fertilization has occurred. In many flowering plants, including corn, wheat, and rice, the mature seed consists largely of endosperm ([Fig. 28.20](#)); the embryo itself is quite small. As the seeds germinate, the embryo draws resources from the endosperm to help it become established. It is no overstatement to suggest that the human population is sustained mostly by endosperm produced in the seeds of cereal crops.

In other angiosperms, the growing embryo consumes all the endosperm before the seed leaves the parent plant. For example, a peanut has virtually no endosperm left at the time it is dispersed. Almost all the resources that were previously held within the endosperm have been transferred into two large embryonic leaves, called cotyledons, that form the two halves of the part of the peanut we eat. Thus, the embryo itself contains all of the stored resources that will nourish the growth of the seedling at germination.

## Fruits enhance the dispersal of seeds.

The transformation of a flower into a **fruit** is as remarkable as the metamorphosis of a caterpillar into a butterfly (**Fig. 28.21**). As the embryo develops and the endosperm proliferates around it, the ovary

wall develops into a fruit, stimulated by signaling molecules produced by the endosperm. For example, the fleshy fruit of a tomato is a mature ovary that encloses the seeds. In some plants, other parts of the flower may also become incorporated into the fruit. For instance, the fleshy part of an apple is formed from the outer part of the ovary combined with the base of the petals and sepals. Other fruits, such as pineapple, develop from multiple flowers. Fruits serve two functions: they enhance dispersal once the seeds are mature, and they protect immature seeds from being preyed on by animals.

Sources: (left to right) Gert Tabak The Netherlands/Getty Images; Trevor Sims/AGE Fotostock; McPHOTO/AGE Fotostock.

FIG. 28.21 Transition from flower to fruit. Fruits, in this case a plum, develop from ovaries and provide a means of dispersing seed.

The tremendous diversity of form seen in fruits reflects the many ways in which angiosperm seeds are dispersed ([Fig. 28.22](#)). The winged fruit of an ash tree is carried away on the wind, and a coconut can float on ocean currents for many months, protected from exposure to salt water by its thick outer husk. The burdock fruit has small hooks that attach to fur (or clothing): this small hitchhiker was the inspiration for Velcro. Other fruits are not dispersed, but instead open to expose their seeds. For example, as milkweed fruits mature and dry out, they split apart to release hundreds of seeds, each with a tuft of silky hairs

that helps them float away on even a light breeze. Still others, such as *Impatiens* (jewelweed), produce fruits that forcibly eject their seeds.

(a) The seeds of the milkweed *Asclepias syriaca* are dispersed by wind; (b) a robin is eating berries of mountain ash (*Sorbus americana*); (c) cocklebur (*Xanthium strumarium*) fruits are hitching a ride on the fur of a cow; (d) a squirrel carries a fruit it will bury for later use.

---

Animals are important agents of seed transport, in many cases being attracted by the nutritious flesh of the fruit. In fleshy fruits, the seeds are protected by a hard seed coat and pass unharmed through the animals' digestive tract. In some species, this passage actually speeds up germination. In many other cases, the seed is consumed, and successful dispersal occurs only when the animals gather more seeds than they eat. Squirrels are a good example, storing many acorns that never get eaten. Humans are also an important dispersal agent: we can transport seeds long distances, sometimes far outside their usual range. In some cases, these kinds of accidentally introduced plant species can disrupt native plant communities.

It is essential that the fruits dispersed by animals not be consumed before the seeds are able to withstand a trip through their disperser's digestive tract. Thus, immature fleshy fruits are physically tough and their tissues highly astringent. As they ripen, the fruits are rapidly transformed in texture, palatability, and color. Ripening converts starches to sugars and loosens the connections between cell walls so that the fruit becomes softer.

In a number of species, including apples, bananas, and tomatoes, a gaseous hormone called ethylene triggers fruit ripening. It is the production of ethylene that explains why a banana ripens faster when placed with a ripe apple. Tomatoes and bananas are usually picked in an immature state and later ripened by exposure to ethylene. As a consequence, the fruits can be transported while they are still hard and less prone to damage. Because ethylene synthesis requires oxygen, the

unripe fruits are typically stored in a low-oxygen environment. Without this precaution, the ethylene produced by the ripening of even a single fruit could set off a chain reaction in which all the stored fruit would ripen at once.

---

## CASE 6 AGRICULTURE: FEEDING A GROWING POPULATION

# How did scientists increase crop yields during the Green Revolution?

Human civilization and plant reproduction are closely intertwined. Not only do seeds and fruits make up much of our diet, but the direct manipulation of plant reproduction also plays a critical role in agriculture. Plant breeding began as the artificial selection for plants with seeds that were easy to harvest. Today it has become a highly quantitative field in which controlled crosses between plants are used to combine a number of favorable traits into a single variety. The spectacular increases in productivity that are often referred to as the Green Revolution resulted, in part, from controlling the movement of pollen between plants.

Norman Borlaug, an American agronomist, has been called “the father of the Green Revolution” and “the man who saved a billion lives.” In the mid-twentieth century, Borlaug led a project to make Mexico self-sufficient in bread wheat. Borlaug’s aim was to breed wheat that could resist infection by a devastating class of fungal

pathogens known as rusts. To do this, he and his group hand-pollinated plants that exhibited resistance to rusts with pollen from plants that grew well under field conditions in Mexico or had seeds that produced good flour.

Under natural conditions, wheat usually self-pollinates. To introduce new sources of pollen, Borlaug and his coworkers removed the anthers of each flower with tweezers before the flowers opened. Then they had to cover each flower to prevent unwanted pollen from coming into contact with the stigma. Finally, when the stigma was receptive, they dusted it with pollen collected from a plant with the desired characteristics. Under the hot sun, this is backbreaking work, but over a series of years the pollinations carried out by Borlaug and his coworkers achieved their goal of breeding disease-resistant wheat varieties.

Yet another problem remained to be solved. To obtain high yields requires large amounts of fertilizer ([Chapter 27](#)). Unfortunately, under these conditions, the new wheat varieties produced so many seeds that stalks became top heavy and fell over in the wind. Borlaug knew that an answer to this problem was to cross his plants with wheat varieties that had shorter, sturdier stems. Finding such a plant might be difficult, however, given the selective advantage of height in natural populations. Fortunately, Japanese wheat breeders had identified and preserved a mutant dwarf plant that had arisen spontaneously, and Borlaug obtained seeds of this dwarf variety.

Much hard work and many thousands of hand pollinations lay

ahead. Even so, by 1963, more than 95% of Mexican wheat under cultivation was one of Borlaug's high-yielding semi-dwarf wheat varieties, and wheat yields were six times greater than they had been in 1944, the year he began work in Mexico. In 1965, the seeds were exported in large numbers, first to India and Pakistan and soon to the rest of the world. Used in combination with greater investments in fertilizer and irrigation, these varieties prevented the famines that many had predicted would result from growing human populations. For his work in alleviating world hunger, Borlaug was awarded the Nobel Peace Prize in 1970.

#### Self-Assessment Questions

6. Diagram the relationship between the sporophyte and gametophyte generations in bryophytes, ferns, gymnosperms, and angiosperms. Show the relative sizes and physical interactions (if any) of the two generations.
7. What are the names and functions of the structures in each whorl of a flower?
8. Contrast the investments that angiosperms and gymnosperms make and the structures that they produce to enhance pollination.
9. Diagram the structure of a mature angiosperm and a mature gymnosperm seed, indicating the ploidy ( $1n$ ,  $2n$ ,  $3n$ ) of each tissue and its role in seed development and germination.
10. From which flower structure(s) is a fruit derived?

## 28.4 ASEXUAL REPRODUCTION

Many plants can also reproduce asexually, producing new individuals without the formation and fusion of gametes. While asexual reproduction avoids the challenges associated with fertilization, asexually formed plants must still disperse if they are to avoid competition for resources with the parent plant. Sexual reproduction relies on spores and seeds for dispersal. But how do asexually produced individuals move across the landscape?

### Asexually produced plants disperse with and without seeds.

Some species of flowering plants are able to use seeds to disperse asexually formed individuals. In these species, seeds can develop even in the absence of fertilization, a process called [apomixis](#). A variety of underlying mechanisms can result in “seeds without sex”; for example, an embryo can form directly from a diploid sporophyte cell.

Dandelions are an example of plant species that produce seeds in the absence of sex. Apomixis would be of tremendous utility in agriculture if it could be turned on or off at will. The reason is that, once a desirable variety was developed, additional seeds could be produced without introducing new genetic variation. This ability to breed true would be useful in self-incompatible species such as apple and blueberry.

Most plants that reproduce asexually do so without producing seeds; instead, a new plant grows out of part of the parent plant. In these

cases, offspring are dispersed in one of several ways. In mosses and liverworts, for example, tiny tissue discs form by mitosis at the base of shallow cups. Raindrops landing in this cup can dislodge the tiny discs, splashing some away from the parent plant. If a disc lands in a suitable site, it can grow to produce a new individual.

Most plants that reproduce asexually do so by growing to a new location. You need look no further than the front lawn to find evidence of such [vegetative reproduction](#). Grass forms horizontal stems underground from which new upright grass shoots are produced at a distance from the site where the parent plant originally germinated. Strawberries, bamboo, and spider plants (a common houseplant) also spread vegetatively by forming horizontal stems. In many cases, the connections that were needed initially to produce a new plant become severed. When this happens, genetic evidence is needed to determine whether a plant is the result of sexual or asexual reproduction.

Vegetative reproduction also occurs in woody plants. For example, when a redwood tree falls over, new upright stems can form along the now-horizontal trunk. Perhaps the most impressive example of the ability to spread vegetatively is the quaking aspen (*Populus tremuloides*), a common tree of the Rocky Mountains that produces brilliant yellow foliage in autumn ([Fig. 28.23](#)). Aspens produce upright stems from a spreading root system. Although each shoot lives for less than 200 years, a single individual can persist for tens of thousands of years by continuing to produce new stems. The current record holder is an aspen clone in Utah consisting of nearly 50,000 stems; it is estimated to be 80,000 years old.

Source: Scott Smith/Getty Images.

FIG. 28.23 Vegetative growth of aspen trees. Each distinct group of trees, distinguished by leaf color, is a group of genetically identical individuals produced by vegetative reproduction.

Plants can reproduce vegetatively because of the way they build their bodies. As we will see in the next chapter, a plant continues to grow and develop throughout its life, and this is the plant characteristic that allows plants to produce new upright “individuals” from roots or horizontal stems.

#### Self-Assessment Question

11. Describe two ways that plants can reproduce asexually. How does each of these methods help to disperse offspring?

## CORE CONCEPTS SUMMARY

**28.1 ALTERNATION OF GENERATIONS:** Alternation of generations evolved by the addition of a diploid sporophyte generation that allows plants to disperse spores through the air.

The life cycle of the algal sister groups of land plants has one multicellular haploid generation. [page 618](#)

The life cycle of all land plants is characterized by an alternation of haploid and diploid generations. [page 619](#)

Spores are produced by meiosis in the multicellular diploid generation, which is referred to as the sporophyte. [page 619](#)

Gametes are produced by mitosis in the multicellular haploid generation, which is referred to as the gametophyte. [page 619](#)

Bryophytes have a free-living haploid gametophyte that makes gametes and a dependent diploid sporophyte that makes spores that are released into the air. [page 619](#)

In spore-dispersing vascular plants, both the gametophyte generation and the sporophyte generation can survive on their own. [page 621](#)

Bryophytes and spore-dispersing vascular plants rely for fertilization on swimming sperm released into the environment. [page 621](#)

**28.2 SEED PLANTS:** Pollen allows the male gametophyte to be transported through the air, while resources stored in seeds support the

development of the embryo.

Pollen is the male gametophyte that develops within the spore wall, a structure that enables it to be transported through the air. [page 622](#)

The female gametophyte of seed plants is retained and nourished by the sporophyte. The female gametophyte, together with the surrounding layers of protective tissues, is called an ovule. [page 622](#)

Pollination is the transport of pollen to the ovule, where fertilization takes place. [page 622](#)

Ovules, when fertilized, develop into seeds. Seeds contain the diploid embryo, stored resources that support the growth of the embryo, and a protective seed coat. In gymnosperm seeds, it is the female gametophyte that provides nourishment to the embryo. [page 624](#)

A trend in the evolution of plants is the progressive reduction in size and independence of the gametophyte and the increasing size and persistence of the sporophyte. [page 624](#)

**28.3 FLOWERING PLANTS:** Angiosperms produce flowers and fruits that increase the efficiency of pollination and seed dispersal, and provide resources for seeds after fertilization.

The pollen and ovules of gymnosperms are produced in separate structures, whereas the pollen and ovules of angiosperms often form in one structure, the flower. [page 626](#)

Flowers consist of four whorls of organs: ovule-bearing carpels,

pollen-producing stamens, petals, and sepals. [page 626](#)

Many flowers attract animals because they provide a reward, such as food, shelter, or chemicals. Animals, in turn, transfer pollen. [page 629](#)

Many flowering plants have genetic and structural mechanisms to prevent self-fertilization. [page 630](#)

Double fertilization leading to the formation of a diploid zygote and triploid endosperm is unique to angiosperms. The endosperm nourishes the embryo that develops from the zygote. [page 633](#)

The fertilization of an ovule triggers the ovary to develop into a fruit, a structure that enhances seed dispersal. [page 633](#)

**28.4 ASEXUAL REPRODUCTION:** Many plants can reproduce asexually.

Asexual reproduction produces new individuals without the need for uniting gametes. Dispersal of offspring, however, remains important. [page 635](#)

Apomixis is the formation of seeds from diploid cells, in the absence of fertilization. Seeds formed by apomixis are therefore genetically identical to the parent plant. [page 635](#)

Vegetative reproduction can occur when a plant stem or root spreads horizontally and develops new upright shoots. [page 636](#)

## CHAPTER 29 Plant Growth and Development

Dietrich Rose/Getty Images

---

### CORE CONCEPTS

**29.1 SHOOT GROWTH AND DEVELOPMENT:** In plants, upward growth by stems occurs at shoot apical meristems, populations of totipotent cells that produce new cells for the lifetime of the plant.

**29.2 PLANT HORMONES:** Plant hormones are chemical signals that influence the growth and differentiation of plant cells.

**29.3 SECONDARY GROWTH:** Lateral meristems allow plants to grow in diameter, increasing their mechanical stability and the transport capacity of their vascular system.

**29.4 ROOT GROWTH AND DEVELOPMENT:** The root apical meristem produces new cells that allow roots to grow downward into the soil, enabling plants to obtain water and nutrients.

**29.5 THE ENVIRONMENTAL CONTEXT OF GROWTH AND DEVELOPMENT:** Plants respond to light, gravity, and wind through changes in internode elongation and the development of leaves, roots, and branches.

**29.6 TIMING OF DEVELOPMENTAL EVENTS:** Plants have sensory systems that control the timing of growth and development.

---

Plants build their bodies in ways that are fundamentally different from what occurs in animals. Consider briefly how our own bodies develop from fertilized eggs ([Chapter 19](#)). Animals grow by the repeated division of cells throughout the body. The first divisions of the fertilized egg form stem cells that are totipotent: each cell has the potential to give rise to all of the cell types found in a plant's body. As development proceeds, cells lose this totipotency and proceed down a specific developmental pathway. Once the body is mature, growth essentially stops.

In contrast to animals, cell division in plants persists in populations of totipotent cells called [meristems](#), and growth commonly lasts throughout the life of the plant. A bristlecone pine in western North America may be several thousand years old, but it continues to sprout new branches, new leaves, and new cones every year.

Plants respond to the world around them not by moving about, but rather by modifying their size and shape. Plants acquire resources by growing to them, and they compete with neighboring plants by growing beyond them. Because development in plants can be modified in response to local environmental conditions, growth fulfills many of the same roles in plants that behavior does in animals ([Chapter 43](#)). And although plants can't move out of the way of danger, plants can rebuild their bodies if they become damaged by fire or frost, or if they are struck by a falling tree. Even reproduction requires the continuing formation of new organs.

This chapter considers how vascular plants build their bodies. We focus on the sporophyte generation because of its greater size and persistence. However, many of the principles of cell growth and differentiation discussed here also pertain to how gametophytes build their bodies. We begin by asking how the shoot system, consisting of leaves, stems, and reproductive structures, is formed. We then turn to the development of root systems, exploring how plants grow belowground. Finally, we consider how plants sense the environment and how they respond to what they sense by modifying their growth and development.

# 29.1 SHOOT GROWTH AND DEVELOPMENT

In tropical forests, vines weave their way upward through the branches of trees. Many of these vines have long, thin stems with widely spaced leaves ([Fig. 29.1a](#)). In contrast, a barrel cactus, living in the desert, has thick stems and leaves modified to form sharp spines ([Fig. 29.1b](#)).

Although they look nothing alike, these two plants are constructed in the same way. Plant shoots are modular, meaning that they are formed of repeating units. Each unit consists of a [node](#), the point where one or more leaves are attached, and an [internode](#), the segment between two nodes ([Fig. 29.1c](#)). In vines, the internodes are long and the leaves large; by contrast, in cacti, the internodes are short and the leaves thin and sharp. The modular structure of plants helps us understand how the capacity for continued growth gives rise to the tremendous variation in plant form that we see around us.

FIG. 29.1 Shoot organization. (a) A tropical vine and (b) barrel cacti look very different, but their shoot systems are built from (c) the same repeating units of nodes and internodes.

# Stems grow by adding new cells at their tips.

At the tip of each stem lies a tiny dome of cells called the shoot apical meristem ([Fig. 29.2](#)). The **shoot apical meristem** is a group of totipotent cells that, like embryonic stem cells in animals, gives rise to new tissues. As we will see, plants have meristems in several parts of their bodies, but stem growth occurs exclusively at the shoot tip. This is where cell division occurs, generating all the new cells that elongate stems. The shoot apical meristem also initiates leaves and produces new meristems, which allow plants to branch.

FIG. 29.2 The shoot apical meristem. The shoot apical meristem consists of undifferentiated cells that divide rapidly, giving rise to all the cells in stems and

leaves. (a) The seedling is rowan (*Sorbus acuparia*). (b) The photo shows a longitudinal section of the shoot apical meristem of coleus (*Solenostemon scutellariodes*). (c) This scanning electron micrograph shows the shoot apical meristem of tomato (*Solanum lycopersicum*).

The shoot meristem maintains a constant size even as its cells actively divide. As new cells are added near the shoot tip, cells that are farther from the shoot tip cease to divide. Cells near the shoot tip maintain their ability to divide through the expression of [meristem identity genes](#). The expression of these genes is controlled by a network of chemical signals produced by cells at the very tip of the stem. Because these signals can be transmitted over a fairly limited distance, only the cells close to the shoot tip express meristem identity genes.

## Stem elongation occurs just below the apical meristem.

In animals, cell division and cell enlargement typically go hand in hand. In plants, however, most of the increase in cell size occurs after cell division is complete. Cells that are too far from the shoot tip to express meristem identity genes cease to divide, yet they continue to grow. Most of the elongation of stems takes place in the internodes located immediately beneath the shoot apical meristem ([Fig. 29.3](#)). The increase in cell size is impressive. If all of the cells in the stem of a 100-m redwood tree remained the size they were when they left the shoot apical meristem, the tree would be less than 5 m tall.

FIG. 29.3 Stem elongation. Elongation of the internodes results from cells increasing many times in length, but only a small amount in width.

Each elongating cell grows many times more in length than in width. The reason is the orientation of the cellulose molecules, which are primarily wrapped around the cell perpendicular to the axis of the stem rather than parallel with it. Because cellulose is very strong, having a tensile strength similar to that of steel, cells expand more easily in length than in girth. A large central vacuole forms during cell elongation. In fact, most of the increase in cell volume is due to the uptake of water and solutes that fill the vacuole. This explains in part why plant growth is markedly reduced during periods of drought.

As we move even farther from the shoot tip, cells reach their final size and complete their differentiation into mature cell types. This organization into successive zones of cell division, cell elongation, and cell maturation allows stems to grow without any predetermined limit to their length.

Once cells have matured, they no longer expand. Thus, during the upward growth of the shoot, it is the production and elongation of cells at the shoot tip that lift the meristem ever higher into the air. Imagine that, as a 10-year-old, you carved your initials into a tree. Twenty years later, your initials will be exactly the same distance from the ground as they were on the day you inscribed them. But the letters will be noticeably wider—a phenomenon we discuss later in this chapter.

## Stems branch by producing new apical meristems.

Vascular plants evolved the ability to branch even before they evolved roots or leaves. Branching was important to these first plants because it allowed them to produce more sporangia. In present-day plants, branching enables them to support greater numbers of both reproductive structures and leaves.

In most spore-dispersing vascular plants, branches form when the shoot apical meristem divides in two, giving rise to two stems, each with its own shoot apical meristem. In seed plants, branches grow out from **axillary buds**, which are meristems that form at the base of each leaf (**Fig. 29.4**). Axillary buds have the same structure and developmental potential as the apical meristem and express the same meristem identity genes.

FIG. 29.4 Axillary buds. In seed plants, branches grow out from axillary buds that are produced at nodes.

When a branch develops, the axillary bud becomes the shoot apical meristem of the new branch. Most plants have many shoot apical meristems: one at the tip of each branch. Axillary buds form at the same time as leaves do, but they remain dormant until triggered to grow, and they persist even after leaves are shed. Axillary buds provide seed plants with many points along their stem where new branches can form.

## The shoot apical meristem controls the production and arrangement of leaves.

The earliest vascular plants were simple branching stems, and photosynthesis took place along the length of the stem. As evolution proceeded, some branch systems became flattened, an arrangement that

allows the plant to capture more light. These planar branches lost the capacity for continued growth. By about 380 million years ago, the planar branches became modified into structures recognizable as leaves ([Fig. 29.5](#)).

Early vascular plants lacked leaves. Their shoots consisted of photosynthetic stems.

In some of these early vascular plants, side branches lost their apical meristems and became flattened into a single plane.

The development of new meristems allowed tissues to form between these side branches, leading to the development of leaves.

FIG. 29.5 The evolution of leaves. Fossils show that leaves evolved from

branches that (1) lost the ability for continued growth, (2) developed in a plane, and (3) expanded the photosynthetic surface to fill the area between veins. The photo shows *Archaeopteris*, one of the earliest plants with flattened leaves.

The evolution of leaves required several changes in plant development. Apical meristem identity genes were down-regulated and leaf identity genes up-regulated, resulting in an organ specialized for photosynthesis. New meristems evolved, enabling leaves to expand into flattened structures for capturing sunlight. In fern leaves, these regions of cell division are located along the leaf margin. In pine needles, they occur at the base of each needle. In most flowering plants, meristem cells are distributed throughout the developing leaf, making possible a diversity of leaf shapes. In contrast to cells in the shoot apical meristems, leaf meristem cells divide only for a relatively short period of time. This explains why, at a certain point, leaves stop growing.

Leaves begin as small bumps, called **primordia** (singular, **primordium**). These bumps form on the sides of the shoot apical meristem in a highly regular pattern (see [Fig. 29.2](#)). Each species has a characteristic number of leaves attached at each node along the stem. Some species have only a single leaf at each node, whereas others have two or more leaves at each site ([Fig. 29.6](#)). The regular placement of leaves reduces the shading of one leaf by another, thereby enhancing plants' ability to obtain sunlight.

FIG. 29.6 Diversity of leaf arrangements.

When we think of leaves, it is the green photosynthetic ones that first come to mind. In reality, many plants produce leaves that are specialized for functions other than photosynthesis, including climbing, trapping insects, and attracting pollinators ([Fig. 29.7](#)). Most plants that overwinter produce small, hard [bud scales](#) that protect shoot apical meristems from water loss and damage due to cold. Bud scales may not look like leaves, but they form from leaf primordia and are arranged in the same way around the stem as the green leaves produced in spring.

## Young leaves develop vascular connections to the stem.

During the initial growth of leaf primordia, cells rely on diffusion to

obtain the resources needed to divide and expand. As the young leaves increase in size, their demand for water and carbohydrates quickly exceeds the amounts that diffusion can supply. If they are to grow to even a fraction of their full size, leaves must establish vascular connections with the xylem and phloem in the stem. As we saw in [Chapter 27](#), the ability of leaves to carry out photosynthesis requires both a supply of water through the xylem and the ability to export carbohydrates to the rest of the plant through the phloem.

When a developing leaf is still very small, sets of cells within the leaf begin to elongate. These elongating cells form discrete strands of [procambial cells](#) that extend from near the tip of the leaf to the mature vascular tissues within the stem. Procambial cells ultimately give rise to both xylem and phloem within the leaf veins and in the vascular bundles in the stalk (petiole) attaching the leaf to the stem. The common origin of xylem and phloem from procambial cells explains why these two tissues are always found in close association throughout the length of the plant.

Spore-dispersing vascular plants typically have one or several vascular bundles in the center of their stems. Most commonly in seed plants, the vascular bundles form a ring near the outside of the stem. The xylem conduits of each bundle are located toward the center of the stem, while the phloem is found nearer the outside of the stem ([Fig. 29.8](#)). Typically, each leaf develops vascular connections with several of the stem's vascular bundles. The ground tissue between the epidermis and the vascular bundles is the [cortex](#), and the ground tissue inside the ring of vascular bundles is the [pith](#). The placement of the

vascular bundles, which contain the stiff xylem conduits, near the outside of the stem increases the stem's ability to support its leaves without bending over.

## Flower development terminates the growth of shoot meristems.

In vascular plants, sporangia are produced on the surfaces of leaves. In some plants, including many ferns, sporangia are located on leaves that

also carry out photosynthesis. In conifers and some other plants, sporangia form on the surfaces of highly modified leaves and branches that form compact cones. In both cases, the arrangement of the sporangia-bearing leaves is the same as that of the leaves that do not bear sporangia.

Flowers develop from floral meristems formed by the conversion of shoot meristems. As a consequence, flowers can be produced at the tip of a shoot or at the base of leaves as the products of axillary buds. Floral meristems differ from shoot meristems in several ways. First, all of the cells within a floral meristem differentiate, so floral meristems lose the capacity for continued growth. Second, although floral organs (sepals, petals, stamens, and carpels) develop from primordia and are thought to be modified leaves, their arrangement differs from the placement of leaves along the stem. Floral organs occur in whorls, with each whorl consisting of only a single organ type (see [Fig. 28.12](#)).

Flowering is triggered by florigen, a protein produced in leaves and transported through the phloem to apical meristems and axillary buds. Florigen triggers the transition to floral meristems by initiating the down-regulation of meristem identity genes and the up-regulation of genes that govern floral identity. Once the meristem is launched along the trajectory for flower development, the identity of each whorl is controlled by the expression of homeotic genes ([Chapter 19](#)).

#### Self-Assessment Questions

1. What are three functions of the shoot apical meristem?

2. Diagram the zones of cell division, elongation, and maturation for plant stems. Why does this organization allow stems to grow without a predetermined limit to their length?

## 29.2 PLANT HORMONES

A key question in the development of multicellular organisms is what controls the identity, or “fate,” of individual cells. In plants, each cell is bound to its neighbor by the cell wall and, therefore, is fixed in place. As a consequence, cell identity is determined by where a cell is located within the plant. For cells at the surface, the absence of neighboring cells on one side can be the signal to become an epidermal cell. For cells in the interior, chemical signals determine which sort of cell is formed. These signals provide information about both the identity of neighboring cells and the cell’s position in the plant. In contrast, animal cells are not fixed in place and cell migration plays an important role in development ([Chapter 19](#)). For this reason, cell lineage, rather than position, often controls the identity of animal cells.

Some of the chemical signals that guide plant development affect only a small area. For example, as mentioned in [section 29.1](#), the signals that cause cells to express meristem identity genes are restricted to the region close to the shoot tip. Other signaling molecules, or their precursors, enter the vascular system and are transported along the entire length of the plant. Because plants grow and develop in many places at once, signaling molecules that can move from one part of the plant to another play an important role in coordinating growth and development.

### Hormones affect the growth and differentiation of plant cells.

**Hormones** are chemical signals that influence growth and

development. The term “growth” refers to irreversible increases in size, whereas “development” encompasses the formation of new tissues and organs, as well as the differentiation of specific cell types. Hormones play two roles in plant growth and development. First, they help establish and maintain basic patterns of the plant body plan. For example, hormones determine how leaves are arranged, where branches form, and how much internodes elongate. Second, they coordinate growth in different parts of the plant in response to both internal and external environmental factors. For example, hormones control which axillary buds grow into branches and guide the growth of a stem toward sunlight. Hormones affect plant growth and development both by influencing physiological processes, such as the activity of membrane transport proteins, and by altering patterns of gene expression.

Traditionally, plant biologists have recognized five major plant hormones: auxin, gibberellic acid, cytokinins, ethylene, and abscisic acid ([Table 29.1](#)). How are such a small number of hormones able to shape the continuing growth and development of plants? Each of these hormones triggers a wide range of developmental effects. For example, ethylene can lead to fruit ripening ([Chapter 28](#)), but it also slows the elongation of roots and stems. How a cell responds to a particular hormone depends on both its developmental stage and its position within the plant. In addition, the effect of any one hormone is often influenced by the presence of one or more other hormones.

**TABLE 29.1 The Five Major Hormones**

|---------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------|

Several additional chemicals with hormone-like properties have recently been discovered. Some of these have broad effects on plant development (for example, strigolactone). Others appear to be more specific (for example, florigen, whose only role is to stimulate flower development).

To illustrate how hormones influence plant growth and development, we consider the role of three hormones—auxin, gibberellic acid, and cytokinins—in establishing the basic patterns of shoot development. Later in the chapter, we consider the role of hormones in root development ([section 29.4](#)) and plant growth in response to light and gravity ([section 29.5](#)).

**Polar transport of auxin guides the placement of leaf primordia and the development of vascular connections with the stem.**

The plant hormone [auxin](#) was first identified when it was observed to

cause shoots to elongate. As we will see in [section 29.5](#), auxin's ability to trigger cell elongation underlies how shoots bend and grow toward light. Auxin also plays an important role in establishing spatial patterns of development. In shoots, auxin influences the spacing and placement of leaf primordia and the formation of the vascular bundles connecting young leaves to the mature vascular system of the stem.

Auxin's role in patterning results from the fact that its movement across a group of cells can be controlled. The net movement of this hormone in a single direction creates regions of high and low concentrations of auxin. These gradients can guide the growth and development of individual cells.

Let's consider first how auxin movement influences the placement of new leaf primordia. Auxin is synthesized in rapidly dividing cells within the shoot meristem and is transported in the outermost cell layer toward the shoot tip. High levels of auxin in the outermost layer of cells trigger the growth of new leaf primordia. Once a primordium begins to form, it becomes a sink for auxin. The movement of auxin into leaf primordia depletes this hormone from surrounding regions, which prevents new leaf primordia from forming nearby. As the shoot continues to grow, already formed leaf primordia become spread farther and farther apart. This creates spaces where auxin moving upward in the outermost cell layer can accumulate to the levels needed to trigger new leaf primordia.

Let's now consider how auxin transport guides the formation of vascular bundles that connect the leaf to the stem. As auxin is

transported into leaf primordia, it promotes cell expansion, so that the young leaves grow. Auxin does not remain in the developing leaf, however. Instead, auxin that has accumulated at the tip of the young leaf is transported back toward the stem, but this time through cells in the interior of the leaf. As auxin moves through these cells, it causes the cells both to elongate and to produce more of the membrane transport proteins needed for auxin to exit the cell. The cells that initially, by chance, have the highest auxin levels become highly efficient at transporting this hormone toward the stem. This, in turn, creates distinct “channels” through which auxin drains from the leaf. These continuous strands of elongate procambial cells eventually develop into veins and vascular bundles containing mature xylem and phloem.

These two examples illustrate how the movement of auxin in a single direction establishes spatial patterns that can guide further differentiation and development. Nevertheless, they leave open the question of how undifferentiated cells control the movement of auxin in the first place.

The coordinated movement of auxin across many cells in a single direction is referred to as **polar transport** ([Fig. 29.9](#)). By means of polar transport, auxin can move independently of gravity at rates faster than the hormone could move by diffusion alone. Polar transport, however, requires an input of energy.

FIG. 29.9 Polar transport of auxin. Auxin moves from the tip of each developing leaf to the base of the plant by polar transport.

Polar transport depends on the difference in pH between the cell wall and the cytoplasm. In the cell wall, auxin carries no net charge, so it can enter surrounding cells by diffusing across the plasma membrane. Because the pH of the cytoplasm is higher than the pH of the cell wall, auxin loses a proton once it enters the cytoplasm. As a result, auxin has a net negative charge when inside the cell and cannot move easily across the plasma membrane. For auxin to leave the cell, an auxin-specific plasma membrane transport protein, known as PIN, is required. By restricting the placement of PIN proteins to only one face of each cell, plants can control the direction of auxin movement across an otherwise undifferentiated group of cells. For example, if PIN proteins are inserted only on those cell sides farthest away from the shoot tip, auxin will move toward the roots.

## CASE 6 AGRICULTURE: FEEDING A GROWING POPULATION

### What is the developmental basis for the shorter stems of high-yielding rice and wheat?

In natural ecosystems, competition for sunlight creates a strong selective advantage for growing tall. Compare the slender vine in Fig. 29.1, which grows in a dense forest, with the compact barrel cactus that grows where there is little danger of being shaded by a neighboring plant. Whereas the ancestors of today's crops competed for sunlight by growing taller, a key property of the high-yielding rice and wheat varieties developed during the Green Revolution is their shorter stems. These shorter-stemmed plants can support the much-larger seed mass induced by high rates of fertilizer application ([Chapter 27](#)). Moreover, by investing less in stems, these plants can allocate more resources to the production of seeds. But what happens inside these plants to make the stems shorter?

**[Gibberellic acid](#)** was first identified as a chemical produced by fungal pathogens that caused the stems of young rice plants to grow to many times their normal length. We now know that this hormone is produced naturally in plants, particularly in growing regions such as developing leaves and elongating stems. Gibberellic acid increases internode elongation by reducing the force needed to cause cell walls to expand. This raises the possibility that the high-yielding crop

varieties with shorter stems might produce less gibberellic acid or be less sensitive to it.

At the time that the semidwarf varieties were developed, the developmental basis for their reduced stem growth was not known. Since then, the genes responsible for reduced stem growth have been identified in both wheat and rice. The semidwarf wheats are less sensitive to gibberellic acid, while the shorter rice varieties are deficient in the enzymes needed to synthesize this hormone. In both cases, the result is shorter but sturdier plants.

## Cytokinins, in combination with other hormones, control the outgrowth of branches.

Plants with multiple branches can support more leaves, but if branches are too close together, leaves will overlap and shade one another. Seed plants have the potential to produce a new branch at each node. To avoid overlap, only a small number of axillary buds actually develop into branches. Which ones become branches is determined by the interaction of several hormones, including both cytokinins and auxin.

Cytokinins were discovered when they were seen to stimulate cell division in tissues grown in the laboratory. Not surprisingly, these hormones are produced in plant meristems, including the meristems within axillary buds. Cytokinins have many effects. Notably, when applied directly to axillary buds by researchers, they can stimulate these buds to develop into branches. This finding suggests that

cytokinins could stimulate branching in nature as well, but leaves open the question of what determines whether an axillary bud remains dormant or begins to grow.

Removing the shoot tip provides a clue. With the shoot tip gone, branches begin growing from axillary buds along that branch or stem ([Fig. 29.10](#)). Evidently, the shoot apical meristem somehow suppresses the growth of axillary buds, a phenomenon called [apical dominance](#). Apical dominance prevents branches from being formed too close to the shoot tip, yet new branches can still be formed if the shoot meristem is damaged.

*Source: Nigel Cattlin/Alamy.*

FIG. 29.10 Apical dominance. In the intact plant (left), the axillary buds are

suppressed. Removal of the apical meristem (right) results in the outgrowth of two axillary buds.

Apical dominance occurs when chemical signals moving down from the shoot tip suppress the growth of axillary buds by inhibiting the synthesis of cytokinins. When the apical meristem is removed, cytokinin synthesis increases in the stem nodes, triggering the growth of axillary buds ([Table 29.1](#)).

The chemical that suppresses branching is auxin. Researchers have shown that if the shoot tip is cut off and a paste containing auxin is applied to the cut end of the stem, the axillary buds remain dormant. If instead the shoot tip is treated with a substance that inhibits auxin transport, branching is induced.

Recent studies indicate that this top-down control is complemented by the action of another hormone, [strigolactone](#). This hormone is made in roots and transported upward in the xylem. Strigolactone inhibits the outgrowth of axillary buds: plants that are unable to synthesize this chemical produce many more branches than do wild-type plants. One hypothesis is that strigolactone is transported to the shoot when either water or nutrients limit growth. Thus, the plant would stop growing new branches whenever the root system is unable to supply the water and nutrients they require.

#### Self-Assessment Question

3. Name one role of the plant hormone auxin. How is auxin transported within a plant?

|  |

## 29.3 SECONDARY GROWTH

Shoot apical meristems enable plants to grow in length and to branch. Even so, a plant unable to grow in diameter would not become very tall before buckling under its own weight. Moreover, a plant unable to add vascular tissue could not supply its ever-increasing number of leaves with water. Growth in diameter thus serves two functions: it strengthens the stem, and it increases the capacity of the vascular system.

Primary growth is the increase in length made possible by apical meristems. Secondary growth is an increase in diameter. It results from a new type of meristem, one that forms only after elongation is complete. The fossil record shows that the ability to grow in diameter evolved millions of years after primary growth, and it did so independently in several groups of plants, testimony to the benefits of being able to compete for sunlight by growing tall. Today, secondary growth occurs almost exclusively in seed plants, although this was not always the case in Earth's history.

### Shoots produce two types of lateral meristem.

New cells must be added as a plant grows in diameter. The sources of these new cells are lateral meristems, which form along the length of a stem. Lateral meristems are similar to shoot apical meristems in their ability to produce new cells that grow and differentiate.

Lateral meristems differ from their apical counterparts in several

ways. First, they surround the stem, rather than occur at its tip. Second, because lateral meristems form only after elongation is complete, the new cells they produce grow in diameter but not in length. Finally, as a stem becomes thicker, the number of meristem cells needed to encircle the stem also increases. Thus, lateral meristems become larger over time.

Plants produce two distinct lateral meristems that together result in secondary growth. One of these, the [vascular cambium](#) (plural, [cambium](#)), accounts for most of the increase in diameter. The vascular cambium is the source of new xylem and phloem. The xylem produced by secondary growth is familiar to you: it's wood. Plants with secondary growth are often described as woody, whereas plants that lack secondary growth are described as herbaceous. Most of the mass of a large tree consists of wood, generated from the vascular cambium.

As a plant's diameter increases, the epidermis formed during primary growth eventually ruptures. A second lateral meristem, the [cork cambium](#), renews and maintains a protective outer layer. This outer layer protects the stem against herbivores, mechanical damage, desiccation, and, in some species, fire.

## The vascular cambium produces secondary xylem and phloem.

The vascular cambium forms at the interface between the xylem and the phloem. In stems, the vascular cambium derives from procambial cells within each vascular bundle and parenchymal cells in between the bundles. In forming vascular cambium, both types of cell take on a new

identity, becoming meristem cells.

The vascular cambium produces new cells on both its sides. Those to the inside of the vascular cambium become [secondary xylem](#), while those on the outside become [secondary phloem](#) ([Fig. 29.11](#)). The vascular cambium forms a continuous layer that surrounds the xylem and runs nearly the entire length of the plant. The undifferentiated and actively dividing cells of the vascular cambium are weak and easily pulled apart. Thus, when you peel the bark off a stem, it separates from the wood at the vascular cambium. All of the material produced to the outside of the vascular cambium, including the secondary phloem, makes up the bark.

As the vascular cambium forms new secondary xylem cells along its inner face, the newly formed cells push the vascular cambium outward,

much in the same way that the elongation of newly formed cells pushes the shoot apical meristem upward. The vascular cambium accommodates this outward movement by adding new cells that increase its circumference.

In contrast, secondary phloem is unable to produce any additional cells. As the vascular cambium is pushed outward, the phloem becomes stretched and, eventually, damaged. Consequently, the vascular cambium must continually produce new secondary phloem.

Over time, xylem conduits lose their ability to transport water. In long-lived trees, the xylem that is still active is located in a [sapwood](#) layer adjacent to the vascular cambium. The [heartwood](#), in the center of the stem, does not conduct water. Heartwood is often darker in color than sapwood because it contains large amounts of chemicals such as resins. For this reason, heartwood is typically more resistant to decay than sapwood.

In many plants growing in seasonal climates, secondary xylem cells produced at the end of the growing season are smaller than ones produced earlier. If you cut down a tree and inspect the top surface of the stump, the layer of smaller cells is visible as the dark edge of a [growth ring](#). Counting growth rings makes it possible to determine a tree's age.

Growth rings provide a window into the past. By measuring the width of each ring, it is possible to determine how much wood was laid down in a given year ([Fig. 29.12](#)). A tree produces more wood when moisture and temperature levels are favorable for photosynthesis. Thus,

annual growth rings provide a record of past climatic conditions, as well as events such as fire.

## The cork cambium produces an outer protective layer.

The cork cambium maintains a protective layer around a stem that is actively increasing in diameter (see [Fig. 29.11](#)). It forms initially from cortex cells that de-differentiate—that is, regress to their earlier state—to become meristem cells. With time, this layer of actively dividing cells becomes increasingly distant from its source of carbohydrates, the phloem. As the cork cambium becomes cut off from its carbohydrate supply, a new cork cambium forms within the secondary phloem. Thus, each cork cambium layer is relatively short-lived. Indeed, in

many cases, the new cork cambia form in patches rather than as continuous layers, causing the bark of the tree to have a patchy and fissured appearance ([Fig. 29.13](#)).

FIG. 29.13 Outer bark. (a) Outside and (b and c) inside, showing how successive cork cambia are produced. The growth of many, discontinuous cork cambia layers results in the patchy bark of pine and walnut trees.

The cells produced by the cork cambium are called cork. As cork cells mature, they become coated with [suberin](#), a waxy compound that protects the cells against mechanical damage and the entry of pathogens, while also forming a barrier to water loss. However, this layer of waxy, nonliving cells impedes the inward diffusion of oxygen needed for cellular respiration. The outer bark cells are less tightly packed in regions called [lenticels](#). Oxygen diffuses through lenticels into the stem ([Fig. 29.14](#)).

## Wood has both support and transport functions.

We have seen that as a tree grows, its secondary xylem fulfills the two roles of secondary growth: to provide trees with the strength and stability to stand upright and support large crowns, and to transport water and nutrients from the roots to the leaves. In most gymnosperms, a single cell type, the tracheid, fulfills both of these functions ([Fig. 29.15a](#)). As discussed in [Chapter 27](#), tracheids are single-celled xylem conduits that have thick lignified cell walls. They are nonliving and empty at maturity. The wood of a pine tree, for example, is relatively uniform in structure, consisting almost entirely of tracheids. This type of wood does not vary dramatically from species to species.

In contrast, the wood of angiosperms is diverse in structure. Xylem cells mature into several distinct types that separate the functions of water conduction and mechanical support ([Fig. 29.15b](#)). **Fibers** are narrow cells with extremely thick walls and almost no lumen; their primary function is support the plant as it grows taller. In contrast, **vessel elements** can be extremely wide cells; their primary function is water transport ([Chapter 27](#)). The largest vessel elements are nearly 0.5 mm in diameter and visible to the naked eye. Vessel elements can be much wider than tracheids because the fibers provide support. Because vessel elements develop open connections that link them end to end with other vessel elements, creating multicellular xylem vessels, angiosperms can produce wood that transports water more efficiently than does the wood of gymnosperms.

The ability to form xylem vessels has a number of important consequences. For example, angiosperms can have higher rates of

water flow through their stems than is possible with wood that contains only tracheids. As a result, angiosperms sustain higher rates of CO<sub>2</sub> uptake and, therefore, higher growth rates.

In addition, because vessels can transport water much more efficiently than do tracheids, angiosperms can devote a smaller fraction of their wood to cells for water conduction, and a larger fraction to other cell types. The wood of some angiosperms contains many fibers. In fact, in extreme cases, the fiber-heavy wood is so dense that it sinks. These dense woods are extremely strong, allowing trees to create spreading crowns with outstretched branches. Such “hardwoods” are useful as flooring materials and furniture. The wood of other angiosperms contains a high percentage of living cells instead of fibers, so it has a very low density. Balsa trees, whose wood is used in building model airplanes, are a good example.

#### Self-Assessment Questions

4. Why do plants have two types of lateral meristem?
5. Why does a plant that has a vascular cambium also have a cork cambium?
6. Why does the vascular cambium form a continuous sheath that runs from near the tips of the branches to near the tips of the roots, whereas the cork cambium is discontinuous in both space and time?

## 29.4 ROOT GROWTH AND DEVELOPMENT

Roots enable vascular plants to obtain water and nutrients from the soil and provide an anchor for plants capable of growing tall. As in the case of leaves and wood, the fossil record shows that the first vascular plants lacked roots. These plants survived only in extremely wet environments, where they absorbed water through horizontal, and possibly submerged, stems. Once roots evolved, vascular plants expanded into drier habitats and became able to support taller stems.

The fossil record indicates that roots evolved at least twice. Nevertheless, the roots of all vascular plants share many features. These commonalities suggest that the physical challenges of growing through dense soil and the demands of obtaining water and nutrients from that soil place strong constraints on root structure.

### Roots grow by producing new cells at their tips.

In [Chapter 27](#), we saw that plants produce large numbers of thin roots to obtain sufficient nutrients from the soil. Also, to obtain water during periods without rain, plants produce roots that penetrate deep into the soil. Growing roots into the soil presents new challenges. Although the dangers of drying out are much reduced belowground, the density of deeper soil layers can approach that of concrete. How are the thin and permeable roots needed for water and nutrient uptake able to penetrate and grow through the soil?

In one respect, roots grow in the same way as shoots: new cells are produced at their tip. The **root apical meristem** is the source of new cells. After cell division, these cells elongate and become differentiated. They complete their differentiation only after elongation has ceased (**Fig. 29.16**). Thus, as we move back from the tip of the elongating root, we encounter successive regions of cell division, elongation, and maturation, just as we saw in stems.

FIG. 29.16 The structure of a typical root, including the root apical meristem and root cap.

Roots also differ from stems in several important ways. One difference is that roots are much thinner than stems. Plants with thin roots can more efficiently produce the large surface area needed for uptake of water and nutrients from the soil. Thin roots can also more easily bend around soil particles and make use of channels burrowed through the soil by invertebrate animals.

A second difference is that the root apical meristem is covered by a [root cap](#) that protects the meristem. As the root elongates through the soil, root cap cells are rubbed off or damaged, while the meristem remains intact. The root cap is continually supplied with new cells produced by the root apical meristem.

A third difference between roots and stems, and one that can be seen without a microscope, is that the root apical meristem does not produce any lateral organs, whereas the shoot apical meristem makes leaves. Root hairs, the single-celled outgrowths of root epidermal cells that greatly increase the roots' surface area ([Chapter 27](#)), form only after elongation has ceased.

## Root elongation and vascular development are coordinated.

A cross section taken through the zone of cell maturation shows a series of concentric tissue layers: the epidermis is on the outside, followed by the root cortex, and then the endodermis ([Fig. 29.16](#)). Recall that the endodermis plays a key role in the selective uptake of nutrients ([Chapter 27](#)). The Casparian strip, a waxy band surrounding each endodermal cell, forces all materials that will enter the xylem to

cross a plasma membrane. At the center of the root is a single vascular bundle in which the xylem is arranged as a fluted cylinder, with phloem nestled in each groove. In cross section, the xylem is arranged in a star shape; the number of points of the star varies among different plant species.

As in stems, the hormone auxin plays a central role in specifying which cells differentiate into vascular tissues. Auxin produced in shoot meristems is transported downward through the mature stem and into the roots by the phloem. At the end of the fully formed phloem, auxin moves by polar transport from cell to cell until it reaches the root apical meristem and the root cap. As auxin moves through the elongation zone, it triggers the formation of procambial cells that become phloem and xylem.

In this way, the production of auxin by developing leaves and the polar transport of auxin from cell to cell ensures that the vascular system is continuous between roots and leaves. Phloem extends closer to the root tip than do fully lignified xylem conduits. The root apical meristem does not need direct access to the xylem because it can obtain water and nutrients directly from the soil, but it depends entirely on the phloem for carbohydrates needed for growth.

So far, we have described only the primary growth of roots. Roots can undergo secondary growth as well: they increase in diameter and add new xylem and phloem. As in stems, the vascular cambium forms at the interface between the xylem and the phloem. Indeed, the vascular cambium must be continuous from the shoot to the roots to

ensure that the secondary xylem and phloem provide an unbroken connection between the roots and the leaves.

In older roots with extensive secondary growth, a cork cambium also forms. As in stems, the cork cambium renews the outer layers of cells that protect the living tissues from damage and predation.

## The formation of new root apical meristems allows roots to branch.

Compared to stems, roots have extensive branching. Even a plant that has just a single stem aboveground will have many tens of thousands of elongating root tips. A major reason that roots branch so much is that most of the water and nutrients are taken up in a zone near the root tip where root hairs are most abundant. Branching is necessary to create enough root surface area to supply the water and nutrient needs of the shoot.

For a root to branch, it must form a new apical meristem. These new root meristems develop from the [pericycle](#), a single layer of cells just inside the endodermis ([Fig. 29.17](#)). The pericycle is immediately adjacent to the vascular bundle, so the new root is connected to the vascular system from the beginning. Because the new root meristem develops internally, the new root must grow through the endodermis, cortex, and epidermis before it reaches the soil.

FIG. 29.17 Branching in roots. New root meristems develop from the pericycle and must grow through the root cortex before reaching the soil. The light micrographs show willow (*Salix*) roots.

One consequence of initiating new root meristems from the pericycle is that new roots can form anywhere along the root. As a result, roots can proliferate locally where nutrients are abundant. For example, the presence of nitrate, the most common form of nitrogen in soil, triggers the formation of new roots.

Most new roots are active for only a short time, after which they die and are shed. Although this turnover of fine roots allows the root system to respond to changes in the availability of water and nutrients, it represents a major expenditure of carbon and energy.

Up to this point, we have described how new roots form from existing roots. New roots can also be produced by stems. Many plants that lack secondary growth produce horizontal stems that grow on or beneath the soil surface. In these plants, new roots form at each successive node, so the uptake capacity of the root system increases as the stem elongates.

When the stem of a plant is severed, new roots often form at the cut end. The formation of new root meristems is stimulated by auxin,

which is produced by the young leaves and accumulates by polar transport at the cut end. Because their cut stems can form new roots, plants are able to survive damage and in some cases even proliferate afterward. Many commercially important plants are propagated from cut stems.

## The structures and functions of root systems are diverse.

How a plant's roots are distributed in the soil has a tremendous impact on the ability of the root system to supply the shoot with water. Some plants produce very deep roots that provide access to groundwater that is independent of the variability of rainfall. For example, roots have been observed in mine shafts and caves more than 50 m below the soil surface. Producing and maintaining these non-photosynthetic structures is costly for the plant.

At the other extreme are plants that produce shallow and spreading root systems. For example, barrel cacti produce roots that penetrate less than 10 cm into the soil but extend out several meters from the base of the plant. These roots cast a wide but shallow net to capture as much water as possible from the intermittent rain showers that fall in desert environments.

Some plants produce distinctive roots whose principal role is *not* the absorption of water and nutrients from the soil ([Fig. 29.18](#)). For example, climbing plants such as poison ivy produce roots along their stems that adhere to the sides of trees ([Fig. 29.18a](#)). The conspicuous prop roots produced by some tropical trees provide mechanical

stability that allows these plants to grow tall despite their slender stems ([Fig. 29.18b](#)).

FIG. 29.18 Root diversity. (a) Climbing roots of poison ivy; (b) prop roots of a *Pandanus* tree; (c) storage roots of yams; and (d) breathing roots of black mangrove (shown at low tide).

Many plants produce swollen roots that store resources such as starch ([Fig. 29.18c](#)). Plants with belowground storage can produce new leaves and shoots quickly following either damage or a period of

drought or cold that has killed the shoots. Cassava and sweet potato are examples of economically important species with storage roots.

Perhaps the most unusual rooting structures are the “breathing” roots produced by trees that grow in water. For example, black mangroves produce pencil-sized roots that extend vertically upward out of the sandy soil ([Fig. 29.18d](#)). Breathing roots do not actually breathe; instead, they contain internal air spaces that provide an easier pathway for oxygen to diffuse into the roots than through the waterlogged soil. For this reason, breathing roots must extend above the surface of the water.

#### Self-Assessment Questions

7. How is root development similar to and different from stem development?
8. What are three structural differences between roots and shoots that allow roots to grow through the soil?
9. How would you tell whether an isolated piece of a plant came from the shoot or from the root?

## 29.5 THE ENVIRONMENTAL CONTEXT OF GROWTH AND DEVELOPMENT

Using their capacity for continued growth, plants often respond to changes in their environment by growing more in one direction than another. To respond in a manner that enhances fitness, however, plants must first gain information about the world around them. Plants rely on three types of sensory receptors to provide that information.

Photoreceptors sense the availability of light needed to drive photosynthesis; mechanical receptors sense physical influences such as gravity and wind; and chemical receptors detect the presence of specific chemicals, as well as chemical gradients.

We saw in [Chapter 9](#) how a signal can be conveyed to a cell by a change in the shape of a receptor molecule on the cell surface or within the cell. Sensory receptors in plants work in a similar manner. For example, the absorption of light by a photoreceptor changes the chemical properties of the photoreceptor, similar to what happens with the photoreceptors in your eye. When a plant's sensory receptor is activated, it produces a signal that triggers changes in the cell's metabolism or alters patterns of gene expression. Hormones play a key role in translating information gained by the plant's sensory receptors into an appropriate response.

**Plants orient the growth of their stems and roots by light and gravity.**

If you lay a plant on its side, its stems will turn upward and its roots will bend downward. Similarly, if you place a houseplant near a window, the shoot will grow toward the light. **Tropism** is the bending or turning of an organism in response to an external signal such as light or gravity. Plant stems are positively **phototropic**, meaning they bend toward the light. Plant stems are also negatively **gravitropic**, meaning they grow upward against the force of gravity. In contrast, plant roots grow down and away from the light. Thus, roots are positively gravitropic and negatively phototropic.

Observing that grass seedlings bend toward light, Charles Darwin and his son Francis conducted experiments to determine which part of the plant detects light. When they covered just the tip of the young plants, the plants no longer grew toward the light; in contrast, when the Darwins buried the plants in fine black sand so that only their tips were exposed, they did. This experiment established the shoot tip as the site where the light is perceived, but left open the question of which kind of signal caused the plants to bend (**Fig. 29.19**).

#### HOW DO WE KNOW?

### FIG. 29.19

## How do plants grow toward light?

#### BACKGROUND

In 1926, Frits Went, a Dutch graduate student, followed up on the experiments of Charles and Francis Darwin. Went sought to understand how the perception of light by the tip of the plant led to a growth response farther down the stem. He reasoned that if the signal from the shoot tip was a chemical, he could isolate the chemical signal by cutting the tip off

of a growing plant and putting the tip on a block of gelatin. The gelatin would act like a trap, capturing any chemical that moved out of the shoot tip.

#### HYPOTHESIS

A chemical signal links the perception of light by the shoot tip with the growth of the stem toward light.

#### EXPERIMENT

Went cut off the tips of young oat plants (*Avena sativa*) and placed them on gelatin blocks for periods of 1 to 4 hours. Removing the tip of the plant caused the plants to stop elongating. When the gelatin block was placed on top of the cut plant (Experiment 1), growth resumed. This experiment demonstrated that a growth-inducing chemical was exported from the tip of the young oat plants to the gelatin block.

Interestingly, Went found that if the block of gelatin was not centered on the tip but instead was a bit off center, the plant bent away from the side of the gelatin block (Experiment 2). The side of the plant exposed to the gelatin block grew faster, causing bending, because it received more of the chemical signal.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

## CONCLUSION

A signal is produced in the tip of the plant and travels downward through the stem, toward the roots. This signal stimulates growth. Light causes the signal to move to the opposite side, stimulating growth on that side, which in turn causes the plant to bend toward the light. This signal is now known to be a plant hormone, called auxin from the Latin word *augere*, “to increase.”

## FOLLOW-UP WORK

Went followed up his experiments by determining how the level of auxin relates to the degree of curvature. Other experiments showed that auxin moves in a directed fashion by polar transport. Later, auxin was shown to be indole-3-acetic acid (IAA).

SOURCES Darwin, C., and F. Darwin. 1880. *The Power of Movement in Plants*. London,

UK: John Murray; Went, F. W. 1926. "On Growth-Accelerating Substances in the Coleoptile of *Avena sativa*." *Proceedings of the Royal Academy of Amsterdam* 30:10–19.

A plant's photoreceptors detect light and set off a response. The photoreceptors that trigger phototropism absorb blue wavelengths of light. If a plant is exposed to light from only one side, only the photoreceptors on the illuminated side are activated. Their absorption of blue light is thought to trigger a change in the placement of PIN proteins so that auxin is transported to the shaded side of the stem. As a result, concentrations of auxin are higher on the shaded side and lower on the illuminated side. Because auxin stimulates cell expansion in stems, the shoot grows faster on the shaded side than it does on the illuminated side, causing the plant to bend toward the light ([Fig. 29.20](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 29.20 Phototropism in shoots. Bending toward the light is controlled by the redistribution of the hormone auxin to one side of the shoot.

Phototropism in roots is similar, in that illuminating a root from the side causes auxin to be redistributed toward the shaded side. In this

case, auxin is transported to the shaded side within the root cap, and then moves upward in the outermost layer of cells into the zone of cell elongation. In contrast to what happens in shoots, higher auxin concentrations *decrease* the rate of cell elongation in roots, causing roots to bend *away* from light. In roots, high concentrations of auxin reduce cell elongation and trigger the production of ethylene, a hormone that also reduces cell elongation.

A similar mechanism orients plants with respect to gravity. Moving a plant to a horizontal position results in the transport of auxin to the lower side. The accumulation of auxin on the lower surface causes stems to bend up and roots to turn down. How is the plant able to detect which way is up and which way is down? Recall that plants store carbohydrates as starch. Starch is a large molecule that has a density greater than water. As a consequence, starch-filled organelles sink to the bottom of the cell. The weight of these organelles pressing on the cytoskeleton or membranes is thought to be the signal that causes auxin to move toward the lower side of the plant. In roots, gravity is a critical source of information regarding orientation. Specialized gravity-sensing cells in the root cap contain large starch-filled organelles known as [statoliths](#) ([Fig. 29.21](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Photo source: Courtesy Dr. Christophe Jourdan.

FIG. 29.21 Root orientation with respect to gravity. Starch-filled statoliths settle to the bottom of cells, triggering a redistribution of auxin to the lower side of the root. Auxin slows elongation on that side, causing the root to bend downward.

**Seeds can delay germination if they detect the presence of plants overhead.**

For a small seed that has few stored reserves, germinating in the shade of another plant could be fatal. But how can a seed detect the presence

of plants overhead?

As sunlight passes through leaves, the red wavelengths are absorbed by chlorophyll but the far-red wavelengths are not. For this reason, the ratio of red to far-red light is much higher under an open sky than in the shade of another plant. When scientists first began to study the effects of light on seed germination, they found that red light is particularly good at stimulating germination, while far-red light inhibits germination. A simple “flip-flop” experiment by H. A. Borthwick and colleagues showed that the inhibitory effect of far-red light could be overcome by a subsequent exposure to red light ([Fig. 29.22](#)). Ultimately, it was shown that only a single photoreceptor was needed to detect both far-red and red light.

#### HOW DO WE KNOW?

### FIG. 29.22

## How do seeds detect the presence of plants growing overhead?

#### BACKGROUND

To study the effects of light on seed germination, American researchers Harry Borthwick and Sterling Hendricks exposed lettuce seeds to different wavelengths of light and then counted what fraction of the seeds germinated. Red light had the greatest ability to stimulate germination but, surprisingly, far-red light inhibited germination. That is, fewer of the seeds exposed to far-red light germinated than even control seeds kept in darkness. In the rush to conduct more experiments, petri dishes with the light-treated seeds piled up by the sink until someone noticed that the seeds that had been experimentally treated with far-red light were now

germinating.

#### HYPOTHESIS

This observation suggested that the inhibitory effect of far-red light can be overcome by a subsequent exposure to red light.

#### EXPERIMENT

The scientists exposed lettuce seeds to red and far-red light in an alternating pattern, ending with either red light or far-red light. They then placed the seeds in the dark for two days and afterward counted the number of seeds that had germinated.

#### RESULTS

When the lettuce seeds were exposed to red light last, approximately 75% of the seeds germinated. By contrast, when the lettuce seeds were exposed to far-red light last, the percentage of seeds that germinated was dramatically reduced.

### Lettuce Seeds Germinating After Exposure to Red and Far-Red Light in Sequence

| SEQUENCE OF LIGHT EXPOSURE                             | SEED GERMINATION (%) |
|--------------------------------------------------------|----------------------|
| Red                                                    | 70                   |
| Red, far-red                                           | 6                    |
| Red, far-red, red                                      | 74                   |
| Red, far-red, red, far-red                             | 6                    |

| Red, far-red, red, far-red, red, far-red               | 7                    |
| Red, far-red, red, far-red, red, far-red, red          | 81                   |
| Red, far-red, red, far-red, red, far-red, red, far-red | 7                    |
| Time →                                                 |                      |

#### CONCLUSION

Seed germination in lettuce is triggered by exposure to red light and is

inhibited by exposure to far-red light in a reversible fashion. This finding indicates that plants are able to track changes in the relative amounts of red and far-red light, obtaining information on the presence or absence of plants overhead (see [Fig. 29.23](#)).

#### FOLLOW-UP WORK

Additional studies showed that this result was due to a single photoreceptor, now known as phytochrome, that is converted into an active form by red light and reversibly converted into an inactive form by far-red light.

SOURCE Borthwick, H. A., et al. 1952. "A Reversible Photoreaction Controlling Seed Germination." *Proceedings of the National Academy of Sciences* 38:662–666 and Borthwick, H. A., et al. 1954 "Action of Light on Lettuce-Seed Germination." *Botanical Gazette* 115:205–225.

**Phytochrome** is a photoreceptor that switches back and forth between two stable forms depending on its exposure to light ([Fig. 29.23a](#)). Red light causes phytochrome to change into a form that absorbs primarily far-red light ( $P_{fr}$ ); far-red light causes phytochrome to change back into the form that absorbs red light ( $P_r$ ). Because red light stimulates seed germination, we know that  $P_{fr}$  is the active form of phytochrome. That is, red light causes phytochrome to change into its  $P_{fr}$  form.  $P_{fr}$  then moves from the cytoplasm to the nucleus, where it alters patterns of gene expression, leading to seed germination.

FIG. 29.23 Detection of shading. Phytochrome detects the depletion of red light under the canopy.

Phytochrome allows dormant seeds to detect the presence of plants

overhead ([Fig. 29.23b](#)). Because the proportion of phytochrome that is in the active  $P_{fr}$  form depends on the ratio of red to far-red light, more  $P_{fr}$  will be produced in open environments than in the forest understory. Furthermore, because the ratio of red to far-red light is independent of light intensity, it provides a reliable signal that leaves are overhead, even when seeds are covered by a thin layer of soil. Independent of whether light is present,  $P_{fr}$  slowly converts back into the inactive  $P_r$  form, which allows the phytochrome system to reset itself overnight.

## Plants grow taller and branch less when growing in the shade of other plants.

A newly germinated seedling must reach the soil surface before using up its stored resources; otherwise, it will die. Seeds that germinate in the dark produce completely white seedlings with thin, highly elongated internodes and small leaves ([Fig. 29.24](#)). By putting all their resources into elongation, seedlings grown in the dark maximize their chances of reaching the light. If and when they do, internodal elongation slows markedly and green leaves expand. These dramatic changes are triggered by photoreceptors that signal the presence of light. The seedling receives signals from several types of photoreceptors, including one type that absorbs blue wavelengths and another type, phytochrome, that absorbs both red and far-red wavelengths.

FIG. 29.24 Seedlings grown in the light and the dark (left) or in full sun and shade (right).

Even after a plant emerges above the soil, its ability to sense and respond to light can enhance its chances for survival. Some species are adapted for shade, producing thin leaves that efficiently use low levels of light; others grow best in direct sunlight. When such sun-adapted species are grown in the shade of another plant, they direct their resources primarily into growing tall. When shaded, these plant species produce stems that have long, thin internodes and fewer branches, and they invest less in root growth.

Interestingly, the effect is much less if the shade is produced by anything other than another plant. Plants can sense when shade is produced by neighboring plants because chlorophyll absorbs red, but not far-red, wavelengths of light. Thus, as light passes through leaves, it becomes depleted in red wavelengths. As a result, phytochrome is

converted from the  $P_{fr}$  form to the  $P_r$  form. Furthermore, light reflected off the leaves of a plant's neighbors is also depleted in red wavelengths, so phytochrome allows a plant to detect not only when it is underneath another plant, but also when it is surrounded by other plants that could grow to shade it in the future. Thus, phytochrome provides an early-warning system that competitors are nearby.

## Roots elongate more and branch less when water is scarce.

The sensitivity of plant shoots to their environment is mirrored underground. When a plant experiences drought, it produces more roots, and these roots penetrate farther into the soil, in part because they produce fewer branches. Deeper roots increase a plant's chances of reaching moister soil.

Cells in the root sense and respond to the amount of water in the soil. Because the root cap is not well connected to the plant's vascular system, the water status of its cells provides a good indication of the moisture content of the soil. As soils dry out, root cap cells produce a hormone called **abscisic acid**, abbreviated as ABA ([Table 29.1](#)). ABA both stimulates root elongation and triggers stomata to close, reducing the demand for water.

Abscisic acid stimulates root elongation by suppressing ethylene synthesis. Ethylene slows root elongation by influencing the orientation of cellulose in the cell wall. Cells treated with ethylene expand in diameter, rather than in length. Thus, by inhibiting the production of ethylene, the production of ABA in drought-exposed

roots leads to roots that penetrate deeper into the soil.

## Exposure to wind results in shorter and stronger stems.

In the 1980s, scientists studied the model plant *Arabidopsis thaliana* to learn which genes are expressed in response to different hormones. The experimental treatment involved spraying plants with a variety of solutions containing different hormones; control plants were sprayed with water. The hormone treatments were successful, in that several genes were strongly up-regulated. Surprisingly, though, the same genes were turned on in the plants sprayed with water. Further experiments showed that the plants were responding to neither the hormones nor the water, but to their stems bending back and forth when the plants were sprayed. This finding led to the discovery of touch-sensitive genes in plants, which are activated by mechanical perturbation.

This discovery confirmed what foresters and horticulturists had long known. Plants exposed to wind produce stems that are shorter and wider than plants grown in more protected sites. In fact, commercial greenhouses often install fans, in part so that their plants will produce stems robust enough that the plants can thrive when moved outdoors. Flexing a stem back and forth triggers an increase in the synthesis of ethylene. As already noted, cells treated with ethylene expand more in diameter and less in length, resulting in shorter and thicker stems.

### Self-Assessment Questions

10. What are the similarities and differences in the ways stems and

roots respond to gravity and light?

11. Diagram how the amount of red light versus far-red light allows plants to determine whether they are in the open or in the forest understory.
12. What is an example of how a plant's ability to sense its environment improves the plant's chances for survival and reproduction?

## 29.6 TIMING OF DEVELOPMENTAL EVENTS

As plants colonized the land, they encountered environments with distinct seasons. In temperate regions, temperatures vary from summer to winter; in most tropical habitats, wet seasons alternate with dry ones. Thus, plants evolved mechanisms to control the timing of developmental transitions such as the production of flowers and other reproductive organs, the germination of spores or seeds, or the formation of overwintering buds. To time these events appropriately, plants need reliable information that tells them which season it is. While temperature tends to be unreliable—think of unusually warm or cold summers—day length is a dependable source of information about the seasons that works everywhere except close to the equator.

### Flowering time is affected by day length.

In the 1910s, Wightman Garner and Henry Allard, scientists at the U.S. Department of Agriculture, set out to understand the unusual flowering schedule of Maryland Mammoth, a variety of tobacco. This plant does not produce flowers during the summer like other tobacco plants. Instead, these plants continue to grow throughout the summer, reaching heights several times that of a typical tobacco plant and producing many more leaves. Only in autumn does the Maryland Mammoth tobacco plant finally produce flowers, too late in the year for seeds to mature.

One possible explanation for the variety's delay in flowering time is

that Maryland Mammoth must achieve a greater size before it produces flowers. However, when Garner and Allard grew Maryland Mammoth plants in a heated greenhouse during the winter, the plants flowered at the same time and size as other tobacco plants. Therefore, size does not determine when Maryland Mammoth flowers. Because the heated greenhouse was set to typical summer temperatures, temperature could also be eliminated as a factor. Garner and Allard were left with only one environmental variable that was different between the summer and the winter: the length of the day.

In a series of experiments, Garner and Allen artificially shortened the day length during summer and extended it during winter. Their results showed that in Maryland Mammoth, as well as in many other plants, flowering is controlled by day length. They coined the term **photoperiodism** to describe the effect of the “photo period,” or day length, on flowering (**Fig. 29.25**). **Short-day plants**, like Maryland Mammoth, flower only when the day length is less than a critical value. When the light period exceeds this threshold, a short-day plant continues to produce new leaves, but no flowers are formed. In contrast, **long-day plants**, which include radish, lettuce, and some varieties of wheat, flower only when the light period exceeds a certain length. Flowering of **day-neutral plants** is independent of any change in day length.

Sensitivity to day length ensures that plants flower only when they are large enough to support the development of a large number of seeds *and* there is enough time for those seeds to mature before the onset of winter. A short-day plant that germinates in the spring will not flower until late summer, when the decreasing day length falls below the critical value for that species ([Fig. 29.26a](#)). This flowering strategy allows short-day plants to grow as large as possible and switch from producing leaves to producing flowers in time to complete seed development before winter. In contrast, many long-day plants produce flowers during midsummer. These plants germinate in spring and are triggered to flower when the day length exceeds a critical value ([Fig. 29.26b](#)).

FIG. 29.26 Flowering strategies for short-day and long-day plants. (a) A short-day plant that germinates in the spring flowers in the late summer, when day length falls below a critical value. (b) A long-day plant flowers in the summer after a critical day length is reached. (c) A long-day plant that requires vernalization does not flower until the critical day length is reached in the second summer.

## Plants use their internal circadian clock and photoreceptors to determine day length.

To determine day length, one first needs to know what time it is, specifically how long it has been since the sun came up, and then whether it is light or dark outside. Plants, like all organisms, have an

internal circadian clock. Circadian clocks are biochemical mechanisms that oscillate with a 24-hour period and are coordinated with the day–night cycle. Phytochrome is the photoreceptor responsible for synchronizing the plant’s internal oscillator with the first light of dawn. The circadian clock tells the plant how long it has been since the sun came up, while phytochrome tells the plant whether it is light or dark during a specific phase of the circadian cycle.

The actual mechanism used by plants to determine day length relies on the fact that the plant’s circadian clock affects the transcription of many genes. For example, in *Arabidopsis thaliana*, a long-day plant, a gene whose protein product is critical for triggering flowering is transcribed at increasingly higher rates throughout the day, peaking approximately 16 hours after dawn. After that, the rate of transcription declines. The protein product of this gene is targeted for rapid degradation unless light is present. Thus, whether the protein builds up to a level sufficient to trigger flowering depends on day length. During long days, the protein reaches levels needed to trigger flowering because peak production occurs during daylight, when the protein is not targeted for destruction. During short days, the protein product does not reach levels needed to trigger flowering because the gene is transcribed at high rates only after the sun has gone down, so the protein is rapidly degraded.

Other experiments have demonstrated that day length is sensed by the leaves, but not by the buds where the flowers will form. When conditions are right for flowering, the protein florigen is synthesized in leaves and transported through the phloem to the growing points of a

plant. In this way, florigen acts as a chemical signal or hormone that converts shoot meristems into floral meristems.

## Vernalization prevents plants from flowering until winter has passed.

In some species, flowering is induced only if the plant has experienced a prolonged period of cold temperatures, a process known as [vernalization](#). A requirement for vernalization prevents long-day plants from flowering during their first summer, instead forcing them to wait until the following spring to flower, when the chances for successful pollination and seed development are much better ([Fig. 29.26c](#)). Even parts of the plant that form long after the cold stimulus is past seem to “remember” that they received the required cold treatment. This “memory” of winter is important because many plants that overwinter grow rapidly in the spring. But what is the basis of this “memory”?

One common mechanism acts through chromatin remodeling. The DNA of all eukaryotic organisms is bound with proteins to form chromatin. As discussed in [Chapter 18](#), modifications to chromatin, such as DNA methylation, can change gene expression. In *Arabidopsis*, for example, vernalization results in chromatin remodeling that turns off a gene whose protein product inhibits flowering. Chromatin remodeling is stable through mitotic divisions, which explains why newly formed parts of a plant “remember” winter. However, the slate is wiped clean during meiosis, and the requirement for vernalization is reinstated with each generation.

## Plants use day length as a cue to prepare for winter.

We have seen how plants use day length to control when flowers are produced. Day length also triggers other developmental events, particularly ones that allow plants that persist for more than a year to prepare for winter. For example, as the days shorten, these plants form storage organs, often in their roots. Carbohydrates that accumulate in these structures can support the growth of new leaves and stems the following spring.

These plants also form overwintering buds to prepare for winter. As the days begin to shorten, plants stop producing photosynthetic leaves and begin forming bud scales. Bud scales surround and protect the meristem from ice and water loss. The formation of bud scales accompanies a series of metabolic changes that allow meristems to remain in a dormant state throughout the winter. For example, plugs are produced that block the plasmodesmata between the meristem and the rest of the plant. These plugs, which prevent any growth-stimulating compounds from reaching the meristem over the winter, are removed in the spring.

### Self-Assessment Questions

13. Why will a short-day plant that germinates in the spring not flower until late summer? Why will a long-day plant that germinates at the end of summer not flower until late the following spring?
14. How does vernalization have an effect in cells that were not

formed at the time of the cold treatment?

## CORE CONCEPTS SUMMARY

**29.1 SHOOT GROWTH AND DEVELOPMENT:** In plants, upward growth by stems occurs at shoot apical meristems, populations of totipotent cells that produce new cells for the lifetime of the plant.

Stems are built from repeating modules consisting of nodes, where one or more leaves are attached, and internodes, which are the regions of stem between the nodes. [page 639](#)

The shoot apical meristem, located at the tip of each stem, is the source of new cells from which the stem and the leaves are formed. [page 639](#)

Stems contain zones of cell division, elongation, and maturation. Most of the increase in size occurs in the zone of cell elongation. [page 641](#)

In seed plants, branching occurs at axillary buds at the base of each leaf. [page 642](#)

Leaves differ from stems in two major ways: all cells differentiate fully, and leaves in most species have no capacity for continued growth. [page 642](#)

Leaves develop from leaf primordia produced by the shoot apical meristem. [page 643](#)

In most seed plants, the stem's vascular bundles are organized as a ring. [page 643](#)

Shoot apical meristems and axillary buds can be transformed into

floral meristems, at which point they lose their capacity for continued growth. [page 644](#)

**29.2 PLANT HORMONES:** Plant hormones are chemical signals that influence the growth and differentiation of plant cells.

Traditionally, five plant hormones have been identified: auxin, gibberellic acid, cytokinins, ethylene, and abscisic acid. [page 645](#)

The transport of auxin guides the placement of leaf primordia and the development of vascular channels (xylem and phloem) that connect leaves and stems. [page 646](#)

The polar transport of auxin depends on a difference in pH between the cytoplasm and the cell walls, as well as the effect of this difference on the ionization of auxin. [page 646](#)

The polar transport of auxin through PIN proteins ensures the movement of auxin in a specific direction to establish the patterning of leaf primordia and the continuity of vascular channels. [page 646](#)

Gibberellic acid causes shoot internodes to elongate. [page 647](#)

The control of axillary bud growth by hormone interactions illustrates how growth and development are often regulated by interactions between two or more hormones. [Page 647](#)

**29.3 SECONDARY GROWTH:** Lateral meristems allow plants to grow in diameter, increasing their mechanical stability and the transport capacity of their vascular system.

The formation of two lateral meristems, the vascular cambium and

the cork cambium, allows plants to grow in diameter. [page 648](#)

The vascular cambium produces secondary xylem toward the center and phloem toward the outside. [page 649](#)

The cork cambium produces a protective outer layer. [page 650](#)

Gymnosperm tracheids provide both mechanical support and water transport. Angiosperm xylem produces fibers that influence the strength of wood and vessel elements that function in water transport. [page 650](#)

**29.4 ROOT GROWTH AND DEVELOPMENT:** The root apical meristem produces new cells that allow roots to grow downward into the soil, enabling plants to obtain water and nutrients.

The root apical meristem is the source of new cells that allow roots to elongate. [page 651](#)

The root cap protects the root apical meristem from damage as the root grows through the soil. [page 652](#)

The root's vascular tissues are located in the center of the root, surrounded by the pericycle, the endodermis, the cortex, and the epidermis. [page 652](#)

Lateral roots develop from new root apical meristems that form in the pericycle. [page 653](#)

Roots alter their development in response to conditions in the soil. [page 653](#)

Some roots are involved in adhesion, storage, or gas diffusion. [page](#)

## **29.5 THE ENVIRONMENTAL CONTEXT OF GROWTH AND**

**DEVELOPMENT:** Plants respond to light, gravity, and wind through changes in internode elongation and the development of leaves, roots, and branches.

Plant stems grow toward the light and away from gravity as a result of redistribution of auxin. [page 655](#)

Roots grow away from light and toward gravity as a result of redistribution of auxin. [page 655](#)

Starch-filled statoliths allow roots to sense and respond to gravity. [page 656](#)

Seedlings germinating in the dark produce elongated internodes and suppress leaf expansion to increase their ability to reach the soil surface before their stored resources are depleted. [page 657](#)

Phytochrome is a photoreceptor that allows plants to determine the amount of red light versus far-red light. Because light filtered through leaves has lower levels of red wavelengths, phytochrome enables plants to detect the presence of plants overhead. [page 658](#)

Some plants respond to the presence of neighboring plants by elongating more rapidly and suppressing branching, thereby maximizing their height growth. [page 657](#)

Stems that experience mechanical stress, such as bending in the wind, become short and wide. [page 659](#)

**29.6 TIMING OF DEVELOPMENTAL EVENTS:** Plants have sensory systems that control the timing of developmental events.

Many plants are photoperiodic, meaning that their flowering is controlled by day length. [page 660](#)

Plants measure day length through an interaction between photoreceptors and their internal circadian clock. [page 661](#)

Vernalization is a prolonged period of exposure to cold temperatures necessary in some temperate-zone species before flowering can be induced. [page 662](#)

Decreases in the photoperiod trigger plants to prepare their meristems for winter by producing bud scales and reducing internode elongation. [page 662](#)

## CHAPTER 30 Plant Defense

Don Johnston/Getty Images

---

### CORE CONCEPTS

**30.1 PROTECTION AGAINST PATHOGENS:** Plants have mechanisms to protect themselves from infection by pathogens.

**30.2 DEFENSE AGAINST HERBIVORES:** Plants use chemical, mechanical, and ecological defenses to protect themselves from being eaten by herbivores.

**30.3 ALLOCATING RESOURCES TO DEFENSE:** The production of defenses is costly, resulting in trade-offs between protection and growth.

**30.4 DEFENSE AND PLANT DIVERSITY:** Interactions among plants, pathogens, and herbivores contribute to the origin and maintenance of plant diversity.

---

Plants have complicated interactions with animals. As we saw in [Chapter 28](#), many plants rely on animals for pollination or seed dispersal. In return, plant seeds provide a rich source of food for animals, and leaves furnish a vast, but lower-quality, food resource. The plant body also provides habitats for an array of viruses, bacteria, and protists, not to mention other plants. How do plants defend themselves against the animals that would eat them? How do they defend against pathogens? The answers to these questions help us understand how plant populations are distributed in nature, and they help us solve practical problems as well. In the United States alone, crop damage by herbivores and pathogens costs farmers more than \$2 billion every year.

Plants can't run away and hide as animals can. Nonetheless, they can sense danger and are able to respond by deploying a diverse and powerful defensive arsenal. Their defenses include physical and

chemical deterrents as well as aerial surveillance, armed guards, and sticky traps.

Plants produce a wide array of chemicals that alter the metabolism and influence the behavior of animals that seek to consume them. These molecules also interact with our own biochemistry, which explains why compounds derived from plants have been used since antiquity as sources of medicine. Our early ancestors turned to the leaves and bark of willow trees in much the same way that we rely on aspirin—and for good reason. Willows produce a compound that deters herbivores but in humans relieves aches and pain; this compound provides the chemical basis of aspirin. Quinine, derived from the tropical cinchona tree, is used in the treatment of malaria. Belladonna, a relative of the tomato, produces toxins that the ancient Romans used to eliminate rivals but in very low doses relieve gastrointestinal disorders. In fact, nearly 30% of all medicines used today are based on chemicals that plants produce to defend themselves.

## 30.1 PROTECTION AGAINST PATHOGENS

In September 1845, potato plants across Ireland began to die. Their leaves turned black and entire plants began to rot. When the potatoes were dug up, those that were not already rotten soon shriveled and decayed into a foul-smelling and inedible mush. The biological agent that had destroyed the potato crop looked like a fungus, but in fact was an oomycete called *Phytophthora infestans*, a type of protist ([Chapter 25](#)).

*Phytophthora infestans* is one example of the diverse pathogens that infect plants. Plant pathogens include viruses, bacteria, fungi, nematode worms, and even other plants. What all of these organisms have in common is the ability to grow on and in the tissues of plants, extracting resources to support their own growth. The outcome for the plant is often disease and death ([Fig. 30.1](#)). Most plants appear disease free only because they are able to defend themselves. Plants have an immune system that allows them to recognize and respond to pathogens that would otherwise exploit them. In the Irish potato famine, which lasted from 1845 to 1852, these defenses were breached. *P. infestans* devastated the potato crop, and many members of the Irish population starved to death.

## Plant pathogens infect and exploit host plants by a variety of mechanisms.

The epidermis, with its thick walls and waxy cuticle, is a plant's first line of defense against pathogens. Viruses and bacteria cannot penetrate the cuticle, but instead commonly enter plants through wounds or on the piercing mouthparts of insects and nematodes.

Stomata form a natural entry point for bacteria, oomycetes, and fungi ([Fig. 30.2](#)). Other pathogens, notably parasitic plants and some species of fungi, secrete enzymes that weaken epidermal cell walls. These invaders then force their way through the weakened epidermis. Crop plants damaged by farm machinery also contain entry points for

pathogens.

Source: Clouds Hill Imaging Ltd./Science Source.

FIG. 30.2 Entry points for pathogens. A scanning electron micrograph shows *Phytophthora infestans* gaining access to the leaf interior by growing through stomata.

Once inside the plant, fungi and bacteria can spread by secreting enzymes that degrade plant cell walls. In contrast, viruses move from one plant cell to another through plasmodesmata. The plant vascular system provides a highway that allows pathogens to move over long distances. Viruses and some bacteria are transported within the phloem, whereas fungi and other bacteria move through the xylem. During the 1950s, commercial banana production in Mesoamerica was nearly wiped out by *Fusarium oxysporum*, a fungal pathogen whose

spores are carried in the xylem. More recently, the Florida citrus industry has been threatened by citrus greening disease, which is thought to result from infection by *Liberibacter*, a bacterium that moves through the phloem.

**Biotrophic pathogens** obtain resources from living cells, whereas **necrotrophic pathogens** kill cells before exploiting them. Most biotrophic pathogens do not enter into the host plant's cells. Instead, they produce chemicals that stimulate the host cells to secrete compounds that the pathogen can use as food. Viruses, however, are biotrophic pathogens that do enter the cell, where they hijack the living cell's machinery so that the virus can reproduce. Necrotrophic pathogens produce toxins that kill cells; the pathogens feed on compounds that leak from the dead and dying cells. Bacteria and fungal pathogens can be either biotrophic or necrotrophic. For example, wheat leaf rust (*Puccinia* species) is a biotrophic fungus that significantly reduces wheat yields ([Chapter 32](#)). Rice blast (*Magnaporthe grisea*) is a necrotrophic fungus that each year reduces rice production by an amount that would feed 60 million people.

Parasitic plants obtain resources by infecting other plants ([Fig. 30.3](#)). These plants produce structures that penetrate into the stems or roots of other plants, eventually tapping into the host plant's vascular system. Some, like some mistletoe ([Fig. 30.3a](#)), are xylem parasites: they obtain water and nutrients from the xylem of the host plant without expending the costs of producing roots themselves. Other plant pathogens target both the xylem and the phloem. In the most extreme cases, the parasite receives all of its carbohydrates from its host and

carries out no photosynthesis of its own. *Rafflesia* ([Fig. 30.3b](#)), for example, grows entirely within the tissues of its host. It emerges only when it produces its giant flowers, the largest in the world. The ability to parasitize other plants has evolved independently multiple times. Currently, more than 4000 species of parasitic plants have been identified.

FIG. 30.3 Parasitic plants. (a) Mistletoe carries out photosynthesis, but relies on its host plant for water and nutrients. (b) *Rafflesia* produces the world's largest flower. It does not photosynthesize, but instead obtains everything it needs from its host. (c) *Cuscuta*, or dodder, parasitizes the stems of many plants. It also obtains everything it needs from its host.

## Plants are able to detect and respond to pathogens.

Most plants are at risk of infection by only a small subset of the many known plant pathogens. [Host plants](#) of a particular pathogen are the species that can be infected by that pathogen. Not all infections significantly damage the host plant. [Virulent](#) pathogens can overcome the host plant's defenses and lead to disease. In contrast, [avirulent](#) pathogens damage only a small part of the plant because the host plant

is able to contain the infection. Whether an interaction is virulent or avirulent depends on the genotypes of both the pathogen and the host plant.

In the human body, the innate immune system provides a first line of defense against pathogens ([Chapter 41](#)). Plants, too, have an immune system that detects pathogens and mounts an appropriate response. A key feature of the immune system is that plants, like animals, can recognize a cell or virus as foreign. How do they accomplish this?

Plant cells have protein receptors ([Chapter 9](#)) that bind to molecules produced by pathogens and recognize them as foreign to the plant body. Binding changes the conformation of the receptor, triggering a cascade of reactions that enhance the plant's ability to resist infection.

The plant immune system has two components ([Fig. 30.4](#)). Both rely on receptors, but these receptors are in different locations. The first component, known as basal resistance, consists of receptors located on the plasma membrane ([Fig 30.4a](#)). These receptors recognize highly conserved molecules generated by broad classes of pathogens. Examples of such molecules include flagellins, which are present in the flagella of bacteria, and chitin, which is a component of the fungal cell wall. When one of these molecules binds to the plant's receptor, an array of defense mechanisms is triggered that help protect the plant from infection.

FIG. 30.4 The plant immune system. (a) In basal resistance, plasma membrane receptors recognize molecules produced by broad classes of pathogens. (b) Specific resistance depends on *R* genes that allow plant cells to identify and deactivate AVR proteins produced by specific pathogens.

Some pathogens have evolved a means of overcoming basal resistance. These pathogens produce proteins called AVR proteins that enter into plant cells and enable infection (“AVR” stands for “avirulence”). Some AVR proteins block defense responses triggered by the basal resistance of plants; others cause the cell to secrete molecules that the pathogen needs to support its own growth.

The second component of the plant immune system, known as specific resistance, targets these AVR proteins. In this case, the receptors are located inside the cell rather than on the plasma membrane (Fig. 31.4b). Plants harbor hundreds of these receptors, called **R proteins**. Each is expressed by a different gene, with the various genes being collectively called **R genes** (“R” stands for “resistance”). Each R protein recognizes a specific AVR protein. When an R protein binds with a pathogen-derived AVR protein, it both

prevents the AVR protein from blocking the plant's defenses and activates additional defenses.

The large number of *R* genes is the result of an evolutionary arms race. Pathogens improve their success rate when mutation results in an AVR protein that does not bind with any of the *R* proteins produced by the host plant. For example, *P. infestans*, the pathogen responsible for the Irish potato famine, produces many more AVR proteins than related *Phytophthora* species. This large number of AVR proteins increases the probability that at least one of the proteins will escape detection by the infected plant. Conversely, when pathogens are successful, natural selection favors plant populations that produce new *R* proteins capable of binding to the AVR proteins of the invader.

## Plants respond to infections by isolating infected regions.

Once a plant has detected a pathogen, how does it protect itself? One way is by reinforcing its natural barriers against pathogens. For example, plants under attack commonly strengthen their cell walls, close their stomata, and plug their xylem. Alternatively, the plant may counterattack. Plants produce a variety of antimicrobial compounds, including ones that attack bacterial or fungal cell walls. In a third type of defense, known as the [hypersensitive response](#), uninfected cells surrounding the site of infection rapidly produce large numbers of reactive oxygen species. These species trigger cell wall reinforcement and cause the cells to die ([Fig. 30.5](#)). The resulting barrier of dead tissue prevents the spread of biotrophic pathogens.

Site of initial infection

Source: Norm Thomas/Science Source.

**FIG. 30.5 Hypersensitive response.** A tobacco plant infected with tobacco mosaic virus produces a region of dead tissue that surrounds the site of infection and prevents the virus from spreading to other parts of the plant.

Plants can isolate infected regions to a far greater degree than is possible in most animals. For example, plants infected by xylem-transported pathogens often plug their xylem conduits. If the infection is caught in time, the pathogen is prevented from spreading throughout the plant. But if containment fails and the pathogen spreads, the plant may contribute to its own death by blocking its entire vascular system. Virulent pathogens that move through the xylem cause a variety of disorders collectively called vascular wilt diseases ([Fig. 30.6](#)). The widespread death of native elm trees in both Europe and North America is the result of a vascular wilt disease caused by a fungus introduced from Asia. This pathogen was first identified in the

Netherlands, so it is commonly called Dutch elm disease.

Sources: a. Guy Blomme/Bioversity International; b. Bruce Fleming/Cephas Picture Library.

FIG. 30.6 Vascular wilt diseases. Pathogens that are transmitted through the xylem can kill their host if plant defenses block water transport to the leaves. (a) Panama disease, which affects bananas, is caused by a fungal pathogen. (b) Pierce's disease, which affects grapes, is caused by a pathogenic bacterium.

## Mobile signals trigger defenses in uninfected tissues.

In 1961, American plant pathologist A. F. Ross reported that when individual tobacco leaves were infected with the tobacco mosaic virus (TMV), they developed dead patches characteristic of a hypersensitive response. However, when uninfected leaves of the same plant were subsequently exposed to the virus, they suffered little or no damage ([Fig. 30.7](#)). Ross called this ability to resist future infections **systemic acquired resistance (SAR)**. Initially reported for viral infections, SAR is now known to occur in response to a wide range of pathogens, including bacteria and fungi.

#### HOW DO WE KNOW?

### FIG. 30.7

## Can plants develop immunity to specific pathogens?

#### BACKGROUND

Tobacco is susceptible to an infectious disease that causes its leaves to turn a mottled yellow; hence the name “tobacco mosaic disease.” In the 1890s, experiments with filters showed that the infectious agent was smaller than a bacterium, a finding that led to the discovery of viruses. Some plants succumb to the disease, but others do not. Are the plants that survive the initial infection immune from further attacks?

#### HYPOTHESIS

Plants that survive infection with tobacco mosaic virus (TMV) have acquired immunity and, therefore, resist further attack.

#### EXPERIMENT

American plant pathologist A. F. Ross infected one leaf on a tobacco plant with TMV. One week later, he exposed another leaf on the same plant to the virus.

#### RESULTS

Plants that had been previously exposed to TMV showed only minor signs of infection when exposed to the virus a second time.

### CONCLUSION

Tobacco leaves that have never been exposed to TMV can acquire resistance to the pathogen if another leaf on the same plant has been previously exposed to the virus. This result indicates that a signal has been transmitted from the infected leaf to the undamaged parts of the plant, and that the transmitted signal subsequently triggers an immune response that protects the plant from further infection.

### FOLLOW-UP WORK

Plants are now known to acquire immunity to a wide range of pathogens in addition to viruses.

SOURCE Ross, A. F. 1961. "Systemic Acquired Resistance Induced by Localized Virus Infections in Plants." *Virology* 14:340–358.

How do uninfected leaves acquire resistance to pathogens? One hypothesis is that a chemical signal is transported from the infected

region through the phloem. This chemical signal then triggers the expression of genes encoding many of the same proteins that defend against the pathogen in infected cells. The identity of the mobile signal has proved elusive, but experiments show that salicylic acid (the chemical basis of aspirin) is required for SAR.

A plant steps up its production of salicylic acid when it is infected by a biotrophic pathogen that triggers a hypersensitive response. Plants produce different signaling molecules in response to necrotrophic pathogens, notably jasmonic acid and the plant hormone ethylene. Both of these chemicals activate defenses effective against broad classes of pathogens. Only in the case of viral infections, discussed next, is the response targeted to a specific pathogen.

## Plants defend against viral infections by producing siRNA.

Viruses can be potent infectious agents. To defend against them, plants have evolved multiple responses to viral infection, including a hypersensitive response, that are much like those mounted against other pathogens. In addition, plants have a form of defense that targets the virus itself ([Fig. 30.8](#)).

Most plant viruses have genomes made of single-stranded RNA (ssRNA). During the replication of the viral genome inside the plant cell, double-stranded RNA molecules (dsRNA) are formed. Because plant cells do not normally make double-stranded RNA, the replicating viral genomes are readily identified as foreign. Enzymes produced by the plant cell cleave these double-stranded RNA molecules into small pieces of 20 to 25 nucleotides, forming fragments called **small interfering RNA (siRNA)** ([Chapter 3](#)). The siRNA fragments then bind with protein complexes in the cell. The RNA–protein complexes subsequently play a role in targeting and destroying ssRNA molecules that have a complementary sequence—that is, the viral genome

([Chapter 18](#)). The damaged virus is unable to replicate and, therefore, cannot spread.

When a cell is attacked by a virus, the siRNA molecules that are produced in response to the initial infection can move through plasmodesmata, enter the phloem, and then spread throughout the plant. This movement allows the plant to acquire systemic immunity against specific viruses. Thus, the response to viral infection consists of both general defenses triggered by salicylic acid and the transport of highly specific RNA molecules that target and destroy viral genomes throughout the plant.

## A pathogenic bacterium provides a way to modify plant genomes.

Some pathogenic bacteria alter their host plant's biology by inserting their own genes into the host's genome. One such pathogen, *Rhizobium radiobacter* (formerly known as *Agrobacterium tumefaciens*), is useful to humans, even though it can cause widespread damage to crops such as apples and grapes. The reason? This bacterium's naturally evolved ability to incorporate its DNA into the genome of its host plant provides a surprisingly easy way to genetically modify plants.

*Rhizobium radiobacter* is a soil bacterium with virulent strains that infect the roots and stems of many plants ([Fig. 30.9](#)). Virulent bacteria enter a plant through wounds and move through the plant's cell walls, propelled by flagella. A tumor, or gall, forms at the point of infection, often where the stem emerges from the soil. For this reason *R. radiobacter* infection is called crown gall disease.

FIG. 30.9 The formation of a crown gall tumor. *Rhizobium radiobacter*, a soil bacterium, can insert its genes into the plant genome, altering the growth and metabolism of the plant in ways that enhance the growth of *R. radiobacter*.

Virulent strains of *R. radiobacter* contain a plasmid, called the **Ti plasmid**, which is a small (approximately 200 kb), circular DNA molecule. This plasmid contains genes that will become integrated into the host cell's genome, as well as all the genes needed to make this transfer. The integrated genes alter the growth and metabolism of infected cells. Some of the transferred genes—including ones that result in the synthesis of the two plant hormones auxin and cytokinin ([Chapter 29](#))—cause infected cells to proliferate and form a gall. Other transferred genes induce cells in the gall to produce specialized compounds that the bacteria use as sources of carbon and nitrogen for growth. Note that because plant cells do not move (in contrast to animal cells), there is no possibility that the tumor-forming cells will spread to other parts of the plant.

Biologists make use of *R. radiobacter*'s ability to insert genes into the host genome to genetically modify crops and other plants. The first

step is to replace the genes in the Ti plasmid that are inserted into the plant genome. Genes for gall formation are removed, and genes of interest are inserted. These genes may have products that increase the plant's nutritional value or confer resistance against disease. In addition, researchers need a way to identify which cells have taken up the genes, so a marker gene, such as one conferring antibiotic resistance, is typically included. Cells that survive an application of the antibiotic are known to have successfully incorporated the Ti plasmid into their genome.

#### Self-Assessment Questions

1. How do pathogens enter and move within the plant body?
2. What is the difference between biotrophic and necrotrophic plant pathogens?
3. What are the two components of the plant immune system? Describe them.
4. How does the plant hypersensitive response differ from systemic acquired resistance, and how are they alike?
5. What is a feature of *Rhizobium radiobacter* that makes it a useful tool in biotechnology?

## 30.2 DEFENSE AGAINST HERBIVORES

The first land plants were followed closely in time by the ancestors of spiders and scorpions. Fossils show that these earliest land animals soon began to feed on plant fluids and tissues. As plants diversified, so did herbivores, and the pressure on plants to defend themselves against organisms from caterpillars to cows only increased.

Given that they are unable to run away, plants would seem to be the ideal food. Plants, however, have evolved a diversity of mechanisms that deter would-be consumers. Because these mechanisms deplete resources that could otherwise be directed toward growth and reproduction, plants have also evolved means of deploying their defenses in a cost-effective manner. In this section, we explore the mechanical, chemical, developmental, and even ecological means by which plants protect themselves in a world teeming with hungry herbivores.

### Plants use mechanical and chemical defenses to avoid being eaten.

Milkweeds (*Asclepias* species) are common in open fields and roadsides across North America. They illustrate well how plants protect themselves from herbivorous animals. In fact, most generalist herbivores, referring to those herbivores that eat a diversity of plants, do not use milkweeds as a food source. Only specialists, such as caterpillars of the monarch butterfly (*Danaus plexippus*), can feed on these well-defended plants.

In part, milkweed's defenses are mechanical. Dense hairs cover the leaves of many milkweed species. An insect crawling on a leaf must make its way through as many as 3000 hairs per square centimeter, a journey likely more daunting to an insect than wading into a blackberry thicket is to a human. Monarch caterpillars may spend as much as an hour mowing off these hairs before they begin to feed. This long handling time represents a significant cost. To understand why monarch caterpillars make this investment, let's look at milkweed's other defenses.

A network of extracellular canals filled with a white, sticky liquid called **latex** runs through the milkweed leaf, both within the major veins and extending into the regions between veins (**Fig. 30.10**). Latex canals are under pressure in the intact leaf. When the leaf is damaged, the latex flows out, sticking to everything it comes into contact with and rapidly congealing on exposure to air. In particular, the tiny mouthparts of a feeding insect may become glued together by the latex, with potentially fatal consequences. Small monarch caterpillars cut trenches into the leaf that prevent latex from flowing onto the region where they are feeding. Larger caterpillars sever the midvein, relieving the pressure within the latex canals downstream of the cut. The caterpillars can then feed without risk on the part of the leaf that lies beyond the severed midvein.

FIG. 30.10 How monarch caterpillars feed on milkweed. Young monarch caterpillars disarm milkweed defenses by digging trenches, while older, larger caterpillars sever major veins. Both methods prevent the sticky latex from flowing into the feeding area.

Milkweed latex is not only sticky but toxic. In particular, it contains high concentrations of cardenolides, steroid compounds that cause heart arrest in animals. (In small doses, these compounds are used to treat irregular heart rhythms in humans.) Monarch caterpillars do not metabolize the cardenolides that they consume. Instead, they sequester them within specific regions of their bodies as a chemical defense against their own predators. As a consequence of this buildup of cardenolides, monarch caterpillars and even the adult butterflies are highly toxic to most birds and other animals that would otherwise eat them. The protection conferred by these chemicals helps explain why monarch caterpillars have evolved to feed on leaves that are time-consuming to eat.

Most plant species have mechanical or chemical defenses against

herbivores, or even both. Mechanical defenses vary. Hairs are common on leaves, and, as anyone who has ever rubbed against a stinging nettle knows, these hairs are sometimes armed with chemical irritants. Hard silica ( $\text{SiO}_2$ ) plates form within the epidermal cells of grasses and some other plants. Silica wears down insect mouthparts, so the insects feed less efficiently and grow more slowly. On a larger scale, some trees have prickles, spines, or thorns ([Fig. 30.11](#)). Even something as simple as how tough a leaf is can have a large impact on the probability of the leaf's being eaten. In fact, leaves are most likely to be eaten while they are still growing and their tissues not fully hardened. Nonetheless, the most spectacular diversity in plant defenses lies in the realm of chemistry.

FIG. 30.11 Mechanical defenses. (a) Spines on the peach palm (*Bactris gasipaes*)

make it hard for animals to climb or penetrate its stem. Hairs on the leaves of (b) nettle (*Urtica dioica*) and (c) *Arabidopsis thaliana* deter much smaller herbivores.

## Diverse chemical compounds deter herbivores.

The cardenolides produced by milkweeds are just one example from the vast chemical arsenal available to plants for protection. Some plants produce [alkaloids](#), nitrogen-bearing compounds that damage the nervous system of animals. Commonly bitter tasting, alkaloids include such well-known compounds as nicotine, caffeine, morphine, theobromine (found in chocolate), quinine (a treatment for malaria), strychnine, and atropine. Alkaloids are a costly defense because they are rich in nitrogen, an essential and often limiting element that plants need to build proteins for photosynthesis. However, even very small concentrations of alkaloids can deter herbivores. One of the first chemotherapy drugs ([Table 30.1](#)), vincristine, is an alkaloid extracted from the Madagascar periwinkle. It inhibits microtubule polymerization, thereby preventing cell division ([Chapter 11](#)). Vincristine does not harm the plant's own cells because it is stored within an extracellular system of latex-containing canals.

TABLE 30.1 A Sampling of Plant Compounds Used in M

| CLASS | EXAMPLE     | PLANT SOURCE          |
|-------|-------------|-----------------------|
|       | Atropine    | Deadly nightshade     |
|       | Vincristine | Madagascar periwinkle |

## Alkaloids

|                     |                             |
|---------------------|-----------------------------|
| Codeine             | Opium poppy                 |
| Morphine            | Opium poppy                 |
| Quinine             | Cinchona tree               |
| Ephedrine           | <i>Ephedra</i> (Mormon tea) |
| Turocurare (curare) | <i>Strychnos toxifera</i>   |
| Digitoxin           | Foxglove                    |
| Berberine           | <i>Berberis</i> (barberry)  |

## Terpenoids

|             |                            |
|-------------|----------------------------|
| Menthol     | Peppermint                 |
| Camphor     | Camphor laurel             |
| Eucalyptol  | <i>Eucalyptus speciosa</i> |
| Taxol       | Pacific yew                |
| Artemisinin | <i>Artemisia annua</i>     |

|                |             |
|----------------|-------------|
| Salicylic acid | Willow tree |
|----------------|-------------|

A second group of defensive compounds, the **terpenes**, do not contain nitrogen. As a result, plants can produce them for defense without having to make use of nitrogen that could otherwise be devoted to protein synthesis. Small terpenes are volatile and vaporize easily, so they make up many of the essential oils associated with plants. The distinctive smells of lemon peel, mint, sage, menthol, pine resins, and geranium leaves are all due to terpenes. These odors, while pleasant to us, are feeding deterrents to mammals such as squirrels and moose. In addition, terpenes obstruct the growth and metabolism of both fungi and insects. For this reason, pyrethrin, a terpene derivative extracted from chrysanthemums, is marketed commercially as an insecticide.

**Phenols** form the third main class of defensive compounds. Examples are the **tannins** found widely in plant tissues. Tannins bind with proteins, reducing their digestibility. Because plants store tannins in cell vacuoles, these compounds come into contact with the protein-rich cytoplasm only when cells are damaged. Herbivores attempting to feed on tannin-producing plants obtain a poor reward for their efforts. For this reason, natural selection favors individuals that avoid tannin-

rich plants. Many unripe fruits are high in tannins: the unpleasant experience of biting into an unripe banana illustrates how tannins deter consumers. For thousands of years, humans have taken advantage of the protein-binding properties of tannins, using extracts from tree bark to process animal skins by “tanning” to produce leather.

Some chemical defenses found in plants are protein based. Plants and animals use the same 20 amino acids to construct proteins, but some plants produce additional amino acids as well. Plants do not incorporate these additional amino acids into their proteins, but herbivores that ingest them do. The resulting proteins can no longer fulfill their function. As a consequence, the insect herbivores that consume nonprotein amino acids grow slowly and often die early.

Another protein-based defense is the production of antidiigestive proteins called [protease inhibitors](#). These proteins bind to the active site of enzymes that break down proteins in the herbivore’s digestive system. As a result, the enzymes can no longer break down proteins into their individual amino acids. Insects that feed on plants that produce protease inhibitors have reduced growth rates.

## Some plants provide food and shelter for ants, which actively defend them.

While many plants have mechanical defenses against herbivores and nearly all have at least one form of chemical defense, a smaller number of species have evolved ecological defenses against herbivory. These plants “employ” animals as bodyguards in exchange for shelter or nourishment, much the way that many plants provide food or other

rewards to animals that transfer pollen and disperse seeds ([Chapter 28](#)).

Nectar is typically associated with flowers, but many plants produce nectar in glands located on their leaves ([Fig. 30.12](#)). These extrafloral nectaries attract ants. As ants move actively throughout the plant in search of nectar, they may encounter the eggs or larvae of other insects, and they consume these as well. The value of this relationship to the plant is easily demonstrated: when ants are prevented experimentally from patrolling certain branches, those branches suffer higher rates of herbivore damage.

Source: Alex Wild/alexanderwild.com.

FIG. 30.12 Ants attracted by an extrafloral nectary. These ants receive a food reward and also consume any insect eggs or larvae they encounter on the plant.

A small number of plants, several hundred in total, have evolved a much closer relationship with ants. These so-called ant-plants provide both food and shelter for an entire colony of ants, which then defend their host. The bullhorn acacia (*Acacia cornigera*), which grows in dry areas of Mexico and Central America, produces hollow spines at the

base of each leaf, as well as protein- and lipid-rich food bodies on the tips of its expanding leaves. Symbiotic ants (*Pseudomyrmex ferruginea*) live in the spines and feed on the food bodies ([Fig. 30.13](#)). To protect this source of food and shelter, the ants actively defend the plant. When the ants detect an invader, they produce an alarm pheromone that causes the entire colony to swarm over the plant, attacking any insects or vertebrates (including scientists) that they encounter. The ants will attack the growing tip of a vine that might climb up the host. They even destroy plants growing in the soil beneath the host *Acacia*.

Source: Dan L. Perlman/EcoLibrary.org.

FIG. 30.13 The symbiosis between ants and the bullhorn acacia. (a) Ants live in the plant's thorns, and (b) the plant provides food (the yellow food bodies). The ants vigorously defend their home against animals and plants alike.

This system works well until it comes time to reproduce. Without some mechanism to control the hypervigilant ants, they would attack any visiting pollinator as though it were a truly unwanted guest. But the bullhorn acacia has found a solution to this dilemma: to ensure that pollinators may visit its flowers unharmed, those flowers release a chemical that repels the resident ants.

The interactions between ant-plants and their ants are highly coevolved. The ant species are found only in association with their host plants. While ant-plants can be grown without ants, herbivores would rapidly consume an undefended plant in nature because ant-plants lack the chemical defenses present in related species that do not host ants.

## Grasses can regrow quickly following grazing by mammals.

By far, the most important vertebrate herbivores are the bison, zebra, antelope, and their relatives that populate the great plains of East Africa and North America. Studies of herbivore damage in an East African savanna indicate that vertebrates annually consume approximately the same amount of leaf biomass as do insects.

Grasses are well adapted to cope with grazing mammals ([Fig. 30.14](#)). The vertically oriented leaves grow from stems with limited internodal elongation. The shoot apical meristem remains close to the

ground, where it is less likely to be damaged. Grasses have persistent zones of cell division and elongation at the base of each leaf. Because grass leaves elongate from their base, grasses can quickly replace leaf tissues removed by a grazing mammal, fire, or a lawn mower. Only when grasses produce their flowering stalks does the apical meristem emerge above the leaves.

Grasses are thought to have evolved in forest environments. In fact, grass-dominated ecosystems have become widespread only during the

past 25 million years. The fossil record shows that as grasslands expanded, grazing mammals evolved along with them. Horses, for example, originated as small browsers that fed on the leaves of small trees and shrubs. As grasslands expanded, larger horse species with teeth adapted to eating grass evolved. Grasses have small plates of silica in their cell walls that increase their strength and may provide a mechanical defense against herbivores. Horses and other grazers that feed on these grasses wear down their tooth enamel grinding against the silica, so teeth with a thick enamel layer are favored by natural selection. It is not clear whether grasses evolved in response to grazing or to disturbances such as fire, but without question, their distinctive pattern of meristem activity minimizes the damage caused by grazing mammals.

#### Self-Assessment Question

6. What are three ways that plants protect themselves from being eaten by herbivores?

## 30.3 ALLOCATING RESOURCES TO DEFENSE

By now, it should be clear that plants invest substantial resources in defense, resources that might otherwise be used for growth and reproduction. Given the considerable cost of plant defenses, their benefits must be correspondingly large. If a commonly encountered pathogen or herbivore is lethal, the resources invested in defense provide a clear reproductive advantage. But what if the pathogen or herbivore usually damages only half of a plant's leaves? Or 10%? Or encounters the plant only infrequently?

**Some defenses are always present, whereas others are turned on in response to a threat.**

In nature, a balance between cost and benefit is achieved in several different ways. When a threat is common, plants produce constitutive defenses—defenses that are always present. When a threat is uncommon, however, there is an advantage to mounting a defense only when the threat is encountered. A defense that is activated only when the plant senses the threat is called an inducible defense. An inducible defense can consist of either an increase in the level of an already present (constitutive) defense or the production of a new type of defense. The ability to sense and respond to the presence of herbivores allows plants to use resources efficiently.

When a plant is attacked by herbivores, it begins to express a new

set of genes. Many of these genes increase the production of chemical defenses, while others stimulate the reinforcement of cell walls. In addition, herbivore damage triggers the synthesis of jasmonic acid, a signal that is transmitted through the phloem. Exposure to jasmonic acid induces the transcription of defensive genes even in parts of the plant untouched by herbivores.

Scientists are working to determine how information about herbivore damage is transmitted to distant parts of the plant. Chemical signals transported in the phloem may be the primary means of communicating with organs such as roots that are actively importing sugars. However, mature leaves export rather than import sugars, yet they also respond when a distant leaf is damaged. New research suggests that electrical signals transmitted within the plant vascular system may play an important role in alerting the plant to the presence of herbivores.

## Plants can sense and respond to herbivores.

For more than 15 years, biologists have studied how coyote tobacco (*Nicotiana attenuata*), a relative of tobacco native to dry open habitats of the American West ([Fig. 30.15](#)), defends itself against herbivores. These studies provide a fascinating window into how plants allocate their resources toward defense under natural conditions.

Sources: a. Danny Kessler, Max Planck Institute for Chemical Ecology, Jena, Germany; b. Celia Diezel, Max Planck Institute for Chemical Ecology, Jena, Germany.

FIG. 30.15 *Nicotiana attenuata*, the coyote tobacco. This species has been developed as a model organism for studying how plants protect themselves against herbivores. (a) *Nicotiana attenuata* in a Utah desert; (b) *Manduca sexta*, a specialist herbivore, feeding on *N. attenuata*.

*Nicotiana attenuata* is attacked by a wide variety of herbivores, both generalists and specialists. One of its major defenses against being eaten is the production of the alkaloid nicotine. Nicotine is an effective defense against many generalist herbivores, but it is expensive to produce because it diverts nitrogen away from the synthesis of proteins. Thus, *N. attenuata* plants that have not been exposed to herbivores produce only low levels of nicotine as a constitutive defense. When *N. attenuata* is attacked by a generalist herbivore, however, nicotine concentrations in leaves increase dramatically—typically fourfold, but in some cases as much as tenfold. Because nicotine is synthesized in roots and transported to leaves in the xylem, this inducible defense must be activated by signaling molecules transported in the phloem from the sites of insect damage to the roots.

*Nicotiana attenuata* is also attacked by a specialist herbivore, the tobacco hornworm caterpillar, *Manduca sexta*. These caterpillars, which can reach 7 cm in length, have evolved the ability to sequester and secrete nicotine. By this means, these caterpillars are able to consume leaves with high levels of nicotine. Since nicotine is not an effective defense against this voracious herbivore, how can *N. attenuata* protect itself?

It turns out that *N. attenuata* can recognize specific chemicals in the saliva of *M. sexta*. When attacked by *M. sexta*, *N. attenuata* does not waste time and resources synthesizing nicotine. Instead, it protects itself in an entirely different way: it attracts other insects that will attack the herbivore, as we discuss next.

# Plants produce volatile signals that attract insects that prey upon herbivores.

How does *N. attenuata* attract its insect allies? A hint comes from the smell of a newly mown lawn. This distinctive smell originates from chemicals released from the cut blades of grass. Some of the chemicals released when plants are damaged are produced specifically in response to that damage. When *N. attenuata* is attacked by *M. sexta* caterpillars, it produces volatile signals that attract insects that prey on the caterpillar's eggs and larvae. The adage "The enemy of my enemy is my friend" seems to hold true when it comes to protecting plants from herbivore damage.

Studies first conducted in the 1980s showed that undamaged plants increase their synthesis of chemical defenses when neighboring plants are attacked by herbivores ([Fig. 30.16](#)). Although these plants were described in the popular press as "talking trees," the plants under attack are not altruistically warning their neighbors. Instead, subsequent studies suggested that the undamaged plants detect signals released by their neighbors that are directed at other insects, then ramp up their own defenses.

HOW DO WE KNOW?

FIG. 30.16

Can plants communicate?

BACKGROUND

When damaged by herbivores, plants produce chemicals that make their tissues less palatable. Field experiments in which caterpillars were added to target plants suggested that undamaged neighboring plants increased their production of defensive chemicals, whereas plants farther away did not.

#### HYPOTHESIS

Volatile chemicals released from plants that have been attacked by herbivores elicit a defensive response in undamaged plants.

#### EXPERIMENT

One set of plants was placed downwind of other plants in which two leaves were torn, simulating herbivore damage, and a set of control plants was placed downwind of an empty chamber. The concentrations of defensive compounds in all sets of plants were measured and compared.

#### RESULTS

When measured 52 hours after the initial damage, both the damaged plants and the undamaged plants downwind of them had elevated levels of defensive compounds in their leaves compared to control plants.

Morris, *Biology: How Life Works*, 3e, ©  
2019 W. H. Freeman and Company

#### CONCLUSION

Volatile chemicals released from damaged plant tissues can trigger the production of defensive chemicals in undamaged plants.

#### FOLLOW-UP WORK

The volatile chemicals released from damaged plants have been identified and shown to attract predatory animals that feed on the herbivores, parasitize their eggs, or both. Thus, when plants respond to damaged neighbors, they are “eavesdropping” on signals that likely evolved to attract predatory insects, rather than to warn neighboring plants.

SOURCE Baldwin, I. T., and J. C. Schulze. 1983. “Rapid Changes in Tree Leaf Chemistry Induced by Damage: Evidence for Communication Between Plants.” *Science* 221:277–279.

## Nutrient-rich environments select for plants that allocate more resources to growth than to defense.

Some plant species allocate far more resources to defense than others. Because defenses are costly to produce, you might think that plants growing in nutrient-rich habitats should be the best defended. But consider the counterargument: plants growing in nutrient-poor soils might invest heavily in defense because they cannot afford to replace

tissues lost to herbivores. Such plants would grow relatively slowly because their resources are being used to build defenses rather than to produce new leaves and roots. By contrast, plants from nutrient-rich habitats would favor growth over defense because they can more readily replace lost or damaged tissues.

This situation is an example of a **trade-off**: something is gained and, at the same time, something is lost. You can't have your cake and eat it, too; you have to make a choice. With plants, there can be a trade-off between growth and defense: allocating resources for one means that those resources cannot be allocated for the other.

A recent study in the Amazon rain forest focused on a possible trade-off between growth and defense. Researchers compared plant species found growing in nutrient-rich clay soils with closely related species growing in nutrient-poor sandy soils. They found that species from the nutrient-rich clay soils invested less heavily in defenses than did species from the sandy sites. Because the clay-soil species divert fewer resources to defense, they grow faster in either soil type compared to sandy-soil species—as long as they are grown under a net that excludes herbivores (**Fig. 30.17**). When grown out in the open, each species grows best in the soil type in which it is naturally found.

FIG. 30.17 A trade-off between growth and defense. Plants from nutrient-rich clay habitats can overcome herbivory by growing fast, whereas plants from low-nutrient sandy habitats grow slowly and invest more in defense. The photos show that, without defenses, clay-soil plants are prone to being eaten by herbivores.

The clay-soil species grow poorly in sandy soils when not protected by a net because, without ample soil nutrients available, they are unable to replace tissues consumed by herbivores. Conversely, when

grown in the nutrient-rich soils, species from the sandy habitats are poor competitors because they allocate resources that could have been used for growth to defensive compounds and structures. What we see is a classic example of a trade-off.

## Exposure to multiple threats can lead to trade-offs.

In the real world, plants are routinely confronted with more than one threat. A plant may be attacked simultaneously by both a pathogen and an herbivore, or it might be in danger of being shaded by a fast-growing neighbor at the same time that it must defend its leaves from being eaten. Given that the resources a plant can draw on are limited, how do plants respond to multiple threats?

Often, the response to multiple threats suggests a trade-off. For example, a plant exposed to a pathogen may be less able to respond to a later herbivore attack. If tobacco plants are exposed to tobacco mosaic virus and systemic acquired resistance is activated, they become more susceptible to the hornworm caterpillar, *Manduca sexta*. Studies indicate that plants do not defend themselves as vigorously against subsequent herbivore attacks because of cross talk between the signaling pathways for responding to biotrophic pathogens and those for responding to herbivores.

There can also be trade-offs between the threat of competition with neighboring plants and the threat of attack by herbivores. For example, when the phytochrome receptor in plants detects the presence of neighboring plants ([Chapter 29](#)), plants allocate more resources to

growing tall, but they also produce fewer defensive chemicals in response to herbivore damage. Interactions among the signaling molecules associated with each of these processes underlie this trade-off.

#### Self-Assessment Questions

7. What would happen to a plant in which jasmonic acid synthesis is blocked?
8. Why are there often trade-offs between plant growth and plant defense?
9. Does the trade-off between growth and defense favor a single species that dominates in all soil types or different species specialized for each habitat?

## 30.4 DEFENSE AND PLANT DIVERSITY

Many plants spend a significant fraction of their resource and energy budgets on defenses. Despite this commitment, insects consume approximately 20% of all new plant growth each year, while pathogens destroy a substantial additional amount. The magnitude of this loss means that pathogens and herbivores must be a potent force in both ecology and evolution, limiting the success of some species while allowing some of their competitors to prosper. In nature, plant fitness may be strongly influenced by the capacity to deter herbivores and resist pathogens.

Interactions between plants and their consumers are thought to have influenced patterns of plant diversification. Just like pollinating insects, plant-eating insects diversified along with angiosperms (the flowering plants). The coincidence of timing is consistent with an important role for plant–insect coevolution in generating diversity. Further evidence that defense has influenced plant diversification comes from plant genes and secondary compounds. For example, the *R* genes that are instrumental in pathogen recognition form one of the largest gene families in plants, while chemical defenses against herbivores include about 6000 alkaloids and more than 10,000 terpenoid compounds. Such observations suggest that plants are locked in an evolutionary arms race with herbivores and pathogens.

**The evolution of new defenses may allow plants to diversify.**

American scientists Paul Ehrlich and Peter Raven observed that closely related species of plants were fed upon by closely related species of butterflies. In 1964, they cited this observation as evidence that plants and their herbivores are caught up in an evolutionary arms race: plants evolve new forms of defense, and herbivores evolve mechanisms to overcome these defenses. In particular, Ehrlich and Raven hypothesized that the evolution of novel defenses has been an important force in the diversification of both plants and herbivorous insects.

A novel form of defense may allow a plant population to expand into new areas. If the population in a new area remains separated from the original population, it may evolve into a new species. Similarly, a novel means of overcoming plant defenses may allow an insect or pathogen population access to new plant resources. If these insects or pathogens became separated from their original population, then they might also evolve into new species. Thus, Ehrlich and Raven's "escape and radiate" hypothesis predicts a burst of diversification following the evolution of novel defenses.

This hypothesis makes intuitive sense, but it could be tested only with the advent of phylogenetic trees based on DNA sequence comparisons ([Chapter 22](#)). Biologists knew that latex or resin canals evolved independently in more than 40 different groups of plants. Reasoning that these features represent a novel defense, they asked whether the groups that evolved latex or resin canals were more diverse than closely related groups that lacked these forms of defense. In 14 of the 16 groups examined, the groups with the protective canals

were significantly more diverse than their closest relatives that lacked the canals. This pattern supports the hypothesis that the evolution of latex and resin canals provided plants with the freedom to expand into new habitats.

Escalation of defenses is not the only possible evolutionary outcome. Phylogenetic research shows that, as milkweeds diversified, many of the newly evolved species produced *fewer* chemical defenses such as latex canals and cardenolides. Instead, these species grow in resource-rich habitats and replace tissues by growing quickly following damage. The presence of specialized herbivores such as monarch caterpillars that can disarm milkweeds' defenses may help explain why these more recent plant species reduce investments in defense in favor of more rapid growth.

## Pathogens, herbivores, and seed predators can increase plant diversity.

The lowland rain forests of eastern Ecuador have the highest diversity of tree species recorded anywhere: more than 1000 species of trees were identified in a 500 m × 500 m plot. Because trees compete for sunlight, water, and nutrients, the species best able to acquire resources would be expected, over time, to outcompete all others. What allows so many tree species to coexist is one of the great questions of modern biology. In the 1970s, two ecologists, Daniel Janzen and Joseph Connell, independently proposed that interactions with host-specific pathogens, herbivores, or seed predators provide at least a partial answer.

The Janzen–Connell hypothesis, as it is now known, is based on the observation that seeds or seedlings often suffer high rates of mortality when the new plants grow directly beneath an adult tree of the same species ([Fig. 30.18](#)). Seed predators often gather in higher densities near trees with mature fruit, so seeds that disperse far from their maternal plant may escape notice by these predators. By a similar argument, pathogens are more common in the soil underneath an adult tree, so seedlings that grow farther away have a better chance of escaping these invaders. In both cases, high-density populations of seeds and seedlings are more at risk.

FIG. 30.18 Density-dependent mortality promotes tree diversity. Seedlings of rare species have a greater probability of surviving because they are more likely to escape infection by species-specific pathogens.

Rare species have an advantage over more common species: the offspring of a rare species are more likely to survive because their seeds are more likely to be dispersed into a location where there are no neighboring adult plants of the same species. By favoring the survival of less common species, density-dependent mortality prevents one species from outcompeting all others.

In the tropical rain forests of Ecuador and elsewhere, only a small number of tree species are common; the majority of tree species are rare. These rare species are able to escape herbivore and pathogen damage, but they need reliable ways of getting pollen from one plant to another. Thus, animal pollination ([Chapter 28](#)) and the threats of herbivory and infection by pathogens are thought to play complementary roles in promoting angiosperm diversity.

## CASE 6 AGRICULTURE: FEEDING A GROWING POPULATION

### Can modifying plants genetically protect crops from herbivores and pathogens?

The density-dependence of herbivore and pathogen damage is a particular challenge for agriculture as practiced in most countries. When acre after acre is covered by a single crop species, successful invaders are not slowed by low target density. On the contrary, pest populations build up to high levels, and the tendency to plant

genetically uniform varieties, which play to the pests' strengths, increases the losses in yield. Not surprisingly, herbivores and pathogens exact a large toll on agricultural crops, and protecting crops from damage is a high priority for farmers.

The production of pesticides and herbicides increased dramatically in the second half of the twentieth century. Together with irrigation and fertilizers, these chemicals are important contributors to the increased yields of the Green Revolution. Unfortunately, large-scale application of pesticides has risks. In addition to the potential for toxic effects, widespread chemical treatments provide a strong selective force for the evolution of resistance. As pests become resistant to pesticides, one response is to apply more or stronger chemicals. A population of resistant pests can spiral out of control as chemical applications indiscriminately kill off their natural predators.

During the 1980s, farmers applied ever more pesticides to rice paddies in South Asia, yet crop losses continued to increase. This dangerous course was reversed by the introduction of a program that had originally been developed in the 1950s. Farmers in this program carefully determine which pests are actually present, whether they are at damaging levels, and whether there are natural predators of the pests. Only after understanding the ecology of the farm do farmers remove pests, starting with physical removal by hand or machine, followed by biological control using natural predators, and, only as a last resort, application of industrial pesticides. Farmers using this approach, called integrated pest management, can minimize routine pesticide use, thereby preventing pest species from evolving resistance.

Another approach is to improve crop defenses through breeding and genetic modification. Crop breeders must emulate, albeit on a faster timescale, the role played by evolution in selecting for resistance to newly evolving pests. For example, Norman Borlaug's original task was to develop wheat varieties for Mexico that were resistant to fungal pathogens. To do this, he obtained seeds of wheat varieties from around the world that showed evidence of pathogen resistance. He then crossed these disease-resistant varieties with varieties adapted to the local conditions. Although it took thousands of hand-pollinations, Borlaug successfully introduced resistance genes into wheat varieties that grew well in Mexico.

Crop breeding is a powerful way to alter the genetic makeup of cultivated species. However, because it relies on sexual reproduction, crop breeding is limited to the genetic diversity that exists within varieties that can interbreed. In contrast, *Rhizobium radiobacter* allows scientists to introduce specific genes found in distantly related organisms into cultivated species. One of the first commercial uses of this technology was to introduce chemical defenses from a bacterium into crop plants.

*Bacillus thuringiensis* (*Bt*) is a soil-dwelling bacterium that produces proteins toxic to insects. It has been used to control insect outbreaks in agriculture since the 1920s. At first, farmers applied spores containing the toxins or the toxins themselves directly to plants. In 1985, the genes that encode the toxins from *B. thuringiensis* were inserted into tobacco, where their expression conferred substantial protection against insects. Today, *Bt*-modified crops are some of the

most widely planted genetically modified plants.

The introduction of *Bt* crops markedly reduced the application of pesticides, to the benefit of both farmworkers and the environment. Nevertheless, planting *Bt*-expressing crops widely has its own risk: constant exposure to *Bt* toxins increases the probability that pest populations will evolve resistance. Organic farmers are particularly concerned because they continue to use traditional application of *B. thuringiensis* spores to control insect outbreaks.

To prevent the evolution of resistance, U.S. farmers are required by law to plant a fraction of their fields, known as a refuge, with non-*Bt*-expressing plants ([Fig. 30.19](#)). Pests that are not resistant to *Bt* toxins survive by feeding on the non-*Bt*-expressing plants. These non-resistant pests interbreed with individuals feeding on the *Bt*-expressing plants, slowing the evolution of *Bt*-resistance. The efficacy of this practice has been called into question by reports of *Bt*-resistant pests and the need to apply increasing amounts of industrial pesticides to *Bt* crops.

Source: John L. Obermeyer, IPM Specialist Department of Entomology, Purdue University.

FIG. 30.19 *Bt*-crops co-planted with non-*Bt* varieties to prevent the development of resistance.

If there is one practical lesson to be learned from our experience with *Bt*, it is that pathogens and herbivores will continue to evolve new ways of circumventing the defenses of crop plants. Thus, agriculture will require the ongoing development of new forms of crop protection. While widespread use of chemical pesticides is likely to continue, the application of genetics to protecting crops will increase, through both crop breeding and biotechnology. In either case, success will depend on the availability of existing genes honed by natural selection.

In some cases, crop protection will rely on genes from distantly related organisms, as illustrated by *Bt*. More commonly, genes are taken from other plants, often ones that are closely related. For example, specific *R* genes typically are present only within a single species or closely related species. Thus, to develop potatoes that are resistant to the protist *Phytophthora infestans* that causes potato blight, scientists are transferring *R* genes from a wild relative of potato. We can continue these efforts if we commit to safeguarding the genetic diversity found in natural populations of crop species and their close relatives. Only by tapping into these natural genetic resources can breeders produce crops that stay one step ahead of the constantly evolving threats of pathogens and herbivores.

#### Self-Assessment Questions

10. Draw a phylogenetic tree that illustrates an “escape and radiate” pattern of diversification for plants that evolve novel defenses.

11. What is one benefit and one disadvantage of herbicide and pesticide use in agriculture?

---

## CORE CONCEPTS SUMMARY

**30.1 PROTECTION AGAINST PATHOGENS:** Plants have mechanisms to protect themselves from infection by pathogens.

Pathogens enter plants through damaged tissue or stomata and spread by growing or moving through the plant's vascular system. Viruses and some bacteria move in the phloem, whereas fungi and other bacteria move in the xylem. [page 665](#)

Biotrophic pathogens obtain resources from living cells; necrotrophic pathogens kill cells before exploiting them. [page 666](#)

Plants have an immune system that allows them to detect and respond to pathogens. One component of the plant immune system acts generally and recognizes highly conserved molecules produced by broad classes of pathogens. [page 667](#)

A second component of the plant immune system acts on specific pathogens. It consists of “resistance” or *R* genes that encode *R* proteins, which recognize pathogen-derived AVR proteins. [page 668](#)

Plants may respond to pathogens by actively killing the cells surrounding the infection (the hypersensitive response). [page 668](#)

Infected plants may send a signal to uninfected tissues so that they can mount a defense (systemic acquired resistance). [page 668](#)

When attacked by a virus, plants produce siRNA that targets the viral genome for destruction. Because siRNA can move between cells and in the phloem, plants can acquire systemic immunity

against specific viruses. [page 670](#)

The bacterium *Rhizobium radiobacter* infects plants by inserting some of its genes into the plant's genome, resulting in the formation of a tumor and providing a way to genetically engineer plants. [page 670](#)

**30.2 DEFENSE AGAINST HERBIVORES:** Plants use chemical, mechanical, and ecological defenses to protect themselves from being eaten by herbivores.

Plant defenses against herbivory include latex, chemicals, and mechanical defenses such as dense hairs. [page 672](#)

Plants produce a wide range of chemicals to deter herbivores, including alkaloids, terpenes, and tannins. [page 673](#)

Ant-plants, such as the bullhorn acacia, provide food and shelter for ants. The ants, in turn, defend their host plant. [page 675](#)

Grasses are well adapted to disturbances such as fire and grazing by mammals because their vertically oriented leaves can regrow from the base, while their apical meristems remain near the ground where they are less likely to be damaged. [page 675](#)

**30.3 ALLOCATING RESOURCES TO DEFENSE:** The production of defenses is costly, resulting in trade-offs between protection and growth.

Plants produce both constitutive defenses, which are produced whether or not a threat is present, as well as inducible defenses, which are triggered when a plant detects a specific attack. [page 676](#)

Plants produce volatile signals that attract insects that prey on herbivores. [page 677](#)

A trade-off is sometimes observed between plant growth and defense, in which allocating resources to defense results in slower growth rates. [page 678](#)

In nutrient-rich environments, species that allocate more resources to growth and less to defense can outcompete plants that invest more resources in defense and less in growth; the opposite is true in nutrient-poor soils. [page 678](#)

A trade-off can also occur when plants are confronted by multiple threats. For example, a plant attacked by a pathogen will allocate more resources to defend against this threat, but will also become more susceptible to a subsequent attack by a herbivore. [page 679](#)

**30.4 DEFENSE AND PLANT DIVERSITY:** Interactions among plants, pathogens, and herbivores contribute to the origin and maintenance of plant diversity.

The “escape and radiate” pattern of plant evolution suggests that plants undergo a burst of diversification following the evolution of a new form of defense against a pathogen or an herbivore. [page 680](#)

The Janzen–Connell hypothesis proposes that interactions with pathogens and herbivores increase plant diversity by favoring the survival of less common species. [page 680](#)

Herbivores and pathogens are a major concern for agriculture. [page 680](#)

Methods of crop protection include the use of chemical pesticides, integrated pest management, application of spores or toxins from *Bacillus thuringiensis* to plants, and insertion of genes that encode for toxins from *B. thuringiensis* to make *Bt*-modified plants. [page 681](#)

## CHAPTER 31 Plant Diversity

Alfredo Maiquez/Getty Images

### CORE CONCEPTS

#### 31.1 MAJOR THEMES IN THE EVOLUTION OF PLANT

**DIVERSITY:** The evolutionary history of plants has been shaped by the challenges of fertilization, dispersal, and photo-synthesis on land.

**31.2 BRYOPHYTES:** Bryophytes have a dominant gametophyte generation; they are small in stature and rely on surface moisture for hydration.

**31.3 SPORE-DISPERSING VASCULAR PLANTS:** Spore-dispersing vascular plants have small free-living gametophytes and much larger free-living sporophytes with xylem and phloem; they are most commonly found growing as epiphytes or in forest understories.

**31.4 GYMNOSPERMS:** Gymnosperms rely on pollen for fertilization and seeds for dispersal; they have woody stems and today are most common in seasonally cool or dry regions.

**31.5 ANGIOSPERMS:** Angiosperms are distinguished by flowers, fruits, double fertilization, and xylem vessels; they are the most diverse group of plants found today.

---

Five hundred million years ago, the land surface of Earth supported little more than a living crust made up of a mixture of photosynthetic and non-photosynthetic microbes. Then, through the process of natural selection, a group of freshwater green algae began to evolve new ways of surviving, reproducing, and carrying out photosynthesis on land. Their descendants are the organisms we call plants. Fast-forward 465 million years to the present time, and plants are everywhere. Much of what makes up plants, including roots, leaves, tree trunks, and seeds, evolved quickly. Within the first quarter of the time since plants diverged from their algal ancestors, all of these features were present. But one thing was missing: flowers. Flowering plants, also known as angiosperms, do not appear on the scene until the last quarter of this history, yet today they make up a remarkable 90% of all plant species.

Many of the plant groups that were present before angiosperms appeared are still present, but where they live and grow has been shaped by the evolution of flowering plants.

## 31.1 MAJOR THEMES IN THE EVOLUTION OF PLANT DIVERSITY

The closest living relatives of plants are green algae that primarily grow in streams and ponds ([Fig. 31.1](#)). Some features found in plants are also present in the close algal relatives, including cellular structures such as plasmodesmata and the enzymes used to reduce CO<sub>2</sub> loss during photorespiration. But for the most part, plants are quite distinct from their aquatic ancestors. The reason is that, as plants evolved on land, they had to survive in a new medium, air. Algae can rely on water for hydration, support, and protection from ultraviolet radiation and temperature fluctuations, and they can use water currents to transport sperm and disperse offspring. Surviving on land required the evolution of new ways of growing and reproducing. We have seen the key adaptations that allow plants to photosynthesize and reproduce on land in [Chapters 27–30](#). In this chapter, we bring these adaptations together to explore how plant diversity changed as new ways of growing and reproducing evolved.

FIG. 31.1 Phylogenetic tree of land plants. During the evolutionary history of land plants, there were four key innovations: alternation of generations, xylem and phloem, seeds and pollen, and flowers.

## Four major transformations in life cycle and structure characterize the evolutionary history of plants.

The phylogeny in [Fig. 31.1](#) shows four major events that transformed how plants grow and reproduce. The first was alternation of generations ([Chapter 28](#); [Fig. 31.2](#)). Every plant species alternates between two multicellular forms: a haploid gametophyte generation that makes gametes and a diploid sporophyte generation that makes spores ([Fig. 31.2b](#)). The green algae most closely related to plants have a life cycle in which there is only one multicellular form, which is made up entirely of haploid cells ([Fig. 31.2a](#)). It is thought that the addition of a second, diploid generation, extending upward above the ground-hugging gametophytes, gave newly evolving plants an advantage in dispersing their offspring through the air. Spores released

from sporangia on the tips of these taller structures were more likely to be carried away by air currents. Meanwhile, the gametophyte generation grew low to the ground, where it could release swimming sperm into surface moisture layers. Thus, the evolution of the alternation of generations in plants allowed the gametophyte generation to have features that enhance fertilization and the sporophyte generation to have features that enhance dispersal.

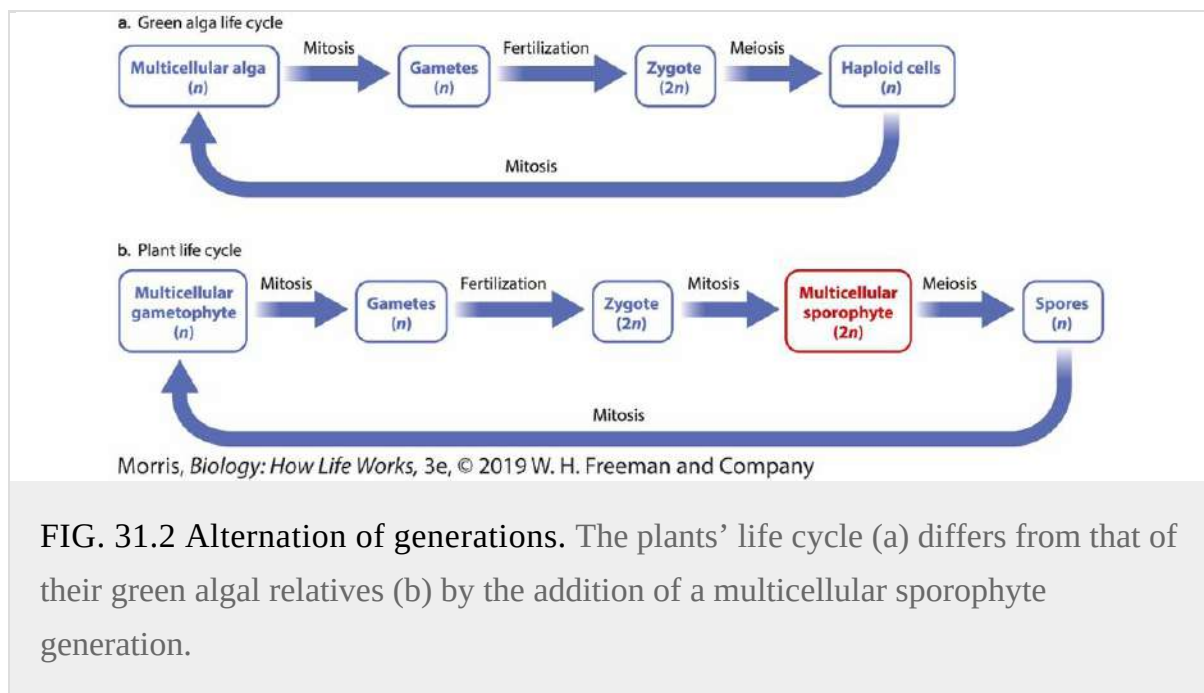

FIG. 31.2 Alternation of generations. The plants' life cycle (a) differs from that of their green algal relatives (b) by the addition of a multicellular sporophyte generation.

The second major event was the evolution of xylem and phloem in the sporophyte generation (see [Fig. 31.1](#)). These internal transport systems distinguish the vascular plants from the mosses, liverworts, and hornworts. Xylem transports water and dissolved nutrients, and phloem transports carbohydrates produced by photosynthesis ([Chapter 27](#)). Xylem and phloem transport water and carbohydrates efficiently over considerably longer distances than is possible with diffusion, and xylem allows vascular plants to pull water from the soil. Thus, these structures provided a competitive advantage in both height and

sustained hydration over plants that lacked xylem and phloem.

The third major event was the evolution of seeds and pollen (see [Fig. 31.1](#)). Fertilization could now take place without releasing swimming sperm into the external environment. Natural selection for fertilization without surface moisture led to the gametophyte generation being retained within the tissues of the much larger and more productive sporophytes. Male gametophytes packaged into small structures called pollen could deliver sperm to the female reproductive organs of another plant by traveling through the air.

The third major event also resulted in a new dispersal unit: multicellular seeds packed with stored resources and surrounded by protective layers. Seeds provide new ways of increasing the probability of the next sporophyte generation becoming successfully established as a free-living plant ([Chapter 28](#)). Plants that produce seeds and pollen are called “seed plants.” Their reliance on pollen for mating and seeds for dispersing offspring distinguishes them from all other plants, which release swimming sperm into the environment and disperse unicellular spores.

If we step back and look at these first three events, two major themes emerge ([Fig. 31.3](#)). The first theme is the transition from a gametophyte-dominated life cycle to a life cycle dominated in size and photosynthetic output by the sporophyte. It is hypothesized that the diploid sporophyte generation, when it first evolved, was physically and physiologically dependent on the gametophyte. That is still true today in mosses, liverworts, and hornworts. In seed plants, the reverse

is true: the gametophyte generation is physically and physiologically dependent on the sporophyte. The second theme is the increasing independence from the need for surface moisture for hydration and fertilization. With the evolution of lignified xylem, vascular plants gained the ability to pull water from the soil, meaning that they could engage in photosynthesis even when their surfaces were dry. Similarly, with the evolution of pollen, fertilization could occur without releasing swimming sperm into the environment.

FIG. 31.3 Life cycle features of plants.

The fourth major event was the evolution of flowering plants, the angiosperms (see [Fig. 31.1](#)). Flowers are the signature feature of this group, but other distinguishing characteristics include carpels, double fertilization leading to endosperm, xylem vessels, and fruits ([Chapter 28](#)). In [section 31.5](#), we discuss how these and other features increase the efficiency with which angiosperms build their bodies and complete their life cycles, contributing to the evolutionary success and diversification of flowering plants.

## Plant diversity has changed over time.

If we tabulate the numbers of species within each major branch on plant phylogenetic tree, one fact stands out: of the nearly 400,000 species of plants present today, approximately 90% are angiosperms ([Table 31.1](#)). Thus, the fourth major event in plant evolution gave rise to the most diverse group of plants.

TABLE 31.1 Diversity of Land Plants

| PHYLUM                                  | COMMON NAME          | APPROXIMATE NUMBER OF SPECIES |
|-----------------------------------------|----------------------|-------------------------------|
| <b>Bryophytes</b>                       |                      |                               |
| Marchantiophyta                         | Liverworts           | 8000                          |
| Bryophyta                               | Mosses               | 15,000                        |
| Anthocerophyta                          | Hornworts            | 100                           |
| <b>Spore-Dispersing Vascular Plants</b> |                      |                               |
| Lycopodiophyta                          | Lycophytes           | 1200                          |
| Monilophyta                             | Ferns and horsetails | 10,500                        |

|                    |                  |          |
|--------------------|------------------|----------|
| <b>Gymnosperms</b> |                  |          |
| Cycadophyta        | Cycads           | 300      |
| Ginkgophyta        | Ginkgo           | 1        |
| Coniferophyta      | Conifers         | 630      |
| Gnetophyta         | Gnetophytes      | 90       |
| <b>Angiosperms</b> |                  |          |
| Magnoliophyta      | Flowering plants | >380,000 |

Angiosperms are relative newcomers, first appearing in the fossil record approximately 140 million years ago ([Fig. 31.4](#)). By comparison, the oldest known evidence of land plants is found in rocks approximately 465 million years old. Thus, for more than 300 million years, terrestrial vegetation was made up of plants other than angiosperms. During this period, lycophytes, ferns and horsetails, and gymnosperms, as well as many groups of now-extinct plants, dominated the land, forming forests and landscapes unlike those that surround us today.

Source: Adapted from A. H. Knoll and K. J. Niklas, 1987, "Adaptation, Plant Evolution, and the Fossil Record," *Review of Palaeobotany and Palynology*, 50:127–149.

FIG. 31.4 The diversity of vascular plant groups through time. First appearing about 140 million years ago, angiosperms have come to dominate the fossil record.

Once the flowering plants gained an ecological foothold, however, the number of angiosperm species increased at an unprecedented rate. As the number of angiosperm species rose, the number of species in other groups fell. At the same time, the total number of plant species increased dramatically. Thus, angiosperms' hold on plant diversity is the result of both squeezing out other groups and increasing the number of species that can coexist.

One way that angiosperm evolution may have increased the overall number of plant species on Earth was by transforming the

environments into which they diversified. Climate models suggest that angiosperms may have been necessary for the formation of tropical rain forests as we know them today. Without the higher rates of transpiration exhibited by angiosperms, many tropical regions would have higher temperatures and lower rainfall amounts. The warmer, drier conditions would have been less conducive to the luxuriant plant growth found in tropical rain forests. The new tropical forests, with their dense shade and humid understories, provided new habitats into which both angiosperms and non-angiosperms could evolve. Thus, although early angiosperms outcompeted many species for space and light, their evolution also stimulated radiations of new species in at least some of the groups that preceded them.

#### Self-Assessment Questions

1. How did the addition of a sporophyte generation contribute to the success of plants on land?
2. Why did xylem and phloem evolve only in the sporophyte generation?
3. How was plant diversity affected by the evolution of angiosperms?

## 31.2 BRYOPHYTES

Liverworts, mosses, and hornworts share many features and are collectively referred to as bryophytes. Among their shared characteristics are a dependence on surface moisture for hydration and a life cycle dominated by a persistent, photosynthetic gametophyte. They are also united by the absence of key features of vascular plants, notably xylem and phloem.

The phylogenetic tree shown in [Fig. 31.1](#) indicates that the relationships among liverworts, mosses, and hornworts remain uncertain. As a consequence, we do not know which of the three is most closely related to the vascular plants (that is, shares a more recent common ancestor) or even if two or more of them might form a monophyletic group. We do, however, believe that their last common ancestor lived long ago and that liverworts, mosses, and hornworts have evolved independently for hundreds of millions of years.

### Bryophytes are small and tough.

Mosses are the most widely distributed of the bryophyte groups and the most diverse, encompassing approximately 15,000 species. You may have seen moss growing on a shady log or on top of rocks by a stream. In fact, mosses grow in all terrestrial environments, from deserts to tropical rain forests. Liverworts (about 8000 species) and hornworts (about 100 species) are less widespread and also less diverse. In considering the diversity of these three groups, let's start by reviewing some of their features that allow them to carry out photosynthesis on land.

A distinctive feature of bryophytes is the dominance of the gametophyte generation. Only the haploid gametophyte is free-living (capable of growing on its own). In contrast, the sporophyte remains attached to and dependent on the gametophyte. A second distinctive feature of bryophytes is their small stature. In most cases, the gametophyte is less than 5 cm tall ([Fig. 31.5](#)).

FIG. 31.5 Bryophyte diversity. Bryophytes include (a) mosses (*Polytrichum commune* is shown); (b) liverworts (*Pellia epiphylla*, a thalloid liverwort, is shown); and (c) hornworts (*Anthoceros* species).

Bryophyte gametophytes come in two forms. Some species produce only a flattened photosynthetic structure called a [thallus](#). Others have slender stalks with tiny leaf-like appendages. These leaf-like structures are quite different from the leaves of vascular plants, in that they are only one to several cells thick and lack internal air spaces. Liverworts can be either thalloid or leafy, whereas all mosses are of the leafy type and all hornworts are of the thalloid type.

Bryophytes produce neither roots nor xylem, so they are unable to pull water from the soil. Instead, these plants absorb moisture from

droplets of rainfall or dew that land on their surfaces or are pulled by surface tension into the spaces between their closely packed stalks and leaf-like structures. Bryophytes can produce cuticle, a waxy layer that restricts water loss, but many of their surface cells, especially those involved in photosynthesis, lack this protection. As a result, these surfaces are capable of absorbing water and nutrients. Although hair-like structures, only a single cell wide, grow from the lower surfaces of bryophytes, they anchor the gametophyte to the substrate rather than transport resources from the soil.

Bryophytes can absorb enough water to remain metabolically active when the environment is wet, but they lose water quickly when their surfaces are dry. Without the ability to regulate water loss, their water content fluctuates in tandem with the environmental moisture. Some bryophytes grow only in habitats that are continually moist; others live in habitats that frequently dry out. The latter species typically exhibit desiccation tolerance ([Chapter 27](#)), which allows them to survive a nearly complete loss of water. Thus, while some bryophytes are delicate, others are extremely tolerant of stressful conditions. As a result, bryophytes can be found from the equator to the highest latitudes at which vegetation exists, from lowlands to the highest altitudes of vegetation, and from swamps to deserts.

Before the evolution of vascular plants, bryophytes may have covered much of the land surface. Bryophytes remain common today, although in most habitats they are dwarfed by the presence of the much larger vascular plants. Because bryophytes are small, they are poor competitors for light and do poorly when closely overtopped by a

dense canopy of vascular plants or covered by a thick layer of fallen leaves. However, bryophytes can grow in places where plants with roots cannot—for example, on the surfaces of rocks. Many bryophytes found in rain forests live on the branches and trunks of trees rather than on the ground. Plants that grow on other plants are called [epiphytes](#) (from the Greek words *epi*, “on,” and *phyton*, “plant”). Bryophytes are well suited to growing on other plants because they do not depend on the soil as a source of water.

## The small gametophytes and unbranched sporophytes of bryophytes are adaptations for reproducing on land.

Bryophyte surfaces close to a solid substrate dry more slowly than those elevated in the air. Indeed, one reason that bryophytes are small is to sustain the hydration of their photosynthetic cells. A second reason for their diminutive stature is related to how they reproduce. Bryophytes release swimming sperm into the environment, and these sperm swim through films of surface water on their way to fertilize an egg or are transported by the splash of a raindrop. Sperm can travel in this manner only over a relatively limited distance and only if water is present. Consequently, the gametophyte generation tends to be small. A few mosses grow to be more than half a meter tall, but these giants of the bryophyte world are found only in the understory of very wet forests.

Following fertilization, the diploid zygote develops by mitosis into a

multicellular sporophyte, while remaining physically attached to and nutritionally dependent upon the gametophyte. Recall that the diploid, spore-producing generation represents a new component of the life cycle as plants evolved on land (see [Fig. 31.2](#)). This sporophyte generation addresses the challenges plants face in dispersing offspring through the air. In bryophytes, the sporophyte produces many haploid spores by meiosis, with these spores then being dispersed to promote spread of offspring.

In most bryophytes, the unbranched sporophyte extends several centimeters above the gametophyte ([Fig. 31.5](#)). In mosses and liverworts, a capsule-like sporangium forms at the tip; spores are produced in this structure. After the spores mature, the sporophyte dries out and the sporangia open. Drying prevents spores from sticking together, thereby increasing the chances that a gust of wind will carry off a spore. In hornworts, the spores form at the top of the sporophyte, albeit within the stalk itself. The spores are released as the sporophyte stalk dries from the top down and splits open.

In mosses and liverworts, the sporophyte is short-lived, falling off after the spores are dispersed. In hornworts, the sporophyte can live nearly as long as the gametophyte because it can produce new cells at its base, similar to the way grass blades elongate ([Chapter 29](#)).

**Bryophytes exhibit several cases of convergent evolution with the vascular plants.**

Bryophytes are interesting partly because they are so different from the more familiar vascular plants. However, given that they have long evolved in parallel with vascular plants, it is not surprising that bryophytes have developed similar solutions to environmental challenges, a process referred to as convergent evolution ([Chapter 22](#)). For example, some mosses depend on insects to transport their spores ([Fig. 31.6a](#)). The brightly colored sporangia of these mosses emit volatile chemicals that mimic compounds released by rotting flesh or herbivore dung. Attracted by these chemicals, insects land on the sporangia, and their legs become covered with spores. When the insects subsequently land on a real pile of dung, some of the spores fall off into this ideal site for supporting the growth of a new gametophyte.

Sources: a. Biopix: A Neumann; b. blickwinkel/Alamy.

FIG. 31.6 Moss specializations. (a) The yellow moose-dung moss, *Splachnum luteum*, attracts insects, which then transport its spores. (b) The internal transport tissues of *Dawsonia superba* allow it to grow more than 40 cm tall.

Another example of convergent evolution is the presence of cells

specialized for the internal transport of water and carbohydrates in some of the largest mosses and leafy liverworts ([Fig. 31.6b](#)). The structure of these cells indicates that they evolved independently from the xylem and phloem of vascular plants. In particular, the water-conducting cells in bryophytes do not have lignified cell walls. Nevertheless, water and carbohydrates can move efficiently from one part of the plant to the other through these elongated cells.

Stomata are present on the sporophytes of hornworts and some mosses, particularly in places where a waxy cuticle also develops. As discussed in [Chapter 27](#), stomata are pores in the epidermis of vascular plants that open and close, providing an active means of controlling water loss. Bryophyte stomata, however, may play a different role. Bryophyte stomata open only once during development of the sporophyte; once open, they are unable to close. What purpose might these stomata serve? A sporophyte with open stomata will dry out quickly, so its spores are more easily released into the air. Further study is needed to determine whether these stomata are the result of convergent evolution.

## Sphagnum moss plays an important role in the global carbon cycle.

In most ecosystems, bryophytes make only a small contribution to the total biomass. The major exception is in [peat bogs](#). In these wetlands, dead organic matter accumulates rather than decomposes. A major component of peat bogs is sphagnum moss, any of the several hundred species of the genus *Sphagnum* ([Fig. 31.7](#)). These mosses play a key role in creating the wet and acidic conditions that slow rates of

decomposition. They contain specialized cells that hold onto water, much like a sponge, and they secrete protons that acidify the surrounding water. Unlike many plants with roots, sphagnum moss thrives under wet, acidic conditions. In addition, these mosses produce phenols, organic compounds that slow decomposition under waterlogged conditions.

FIG. 31.7 Sphagnum moss. Peat bogs have low rates of organic decomposition due to the wet and acidic conditions created by sphagnum moss.

Peat bogs occupy only 2% to 3% of the total land surface, but they

store large amounts of organic carbon—on the order of 65 times the amount released each year from the combustion of fossil fuels. Thus, any increase in the decomposition rate of these naturally formed peats has the potential to increase significantly the CO<sub>2</sub> content of Earth's atmosphere.

What might cause an increase in the decomposition rate? Peat bogs are vulnerable to changes in the water table. As water levels fall, the peat becomes exposed to the air, allowing it to be broken down by microbes. Most peat bogs are located in northern latitudes, where the effects of climate change are predicted to be greatest. If rising summer temperatures result in higher rates of transpiration from surrounding forests, the result could be a lowering of the water table and a relatively rapid release of CO<sub>2</sub> from this moss-dominated ecosystem. Thus, destruction of peat bogs has the potential to accelerate rates of climate change over the next century.

#### Self-Assessment Questions

4. Which factor is thought to limit the stature and productivity of the gametophyte generation?
5. Which features of the sporophyte generation enhance the likelihood of successful spore dispersal?
6. Are there any habitats where a bryophyte might be more productive than a vascular plant?
7. If the stomata of bryophytes and of vascular plants are not the result of convergent evolution, what is an alternative explanation for their appearance in these groups?

## 31.3 SPORE-DISPERSING VASCULAR PLANTS

Vascular plants first appear in the fossil record approximately 425 million years ago. The evolution of xylem and phloem gave vascular plants advantages in size and the ability to keep their photosynthetic cells hydrated using water pulled from the soil. As a result, they were able to outcompete bryophytes for light and other resources and to become the dominant plants on land.

Vascular plants can be divided into two groups according to how they complete their life cycle. Lycophytes, as well as ferns and horsetails, disperse by spores and rely on swimming sperm for fertilization, just like bryophytes. Gymnosperms and angiosperms are seed plants: they disperse seeds and rely on the aerial transport of pollen for fertilization. In this section, we focus on the spore-dispersing vascular plants, which include lycophytes and the group composed of ferns and horsetails. In both groups, the sporophyte dominates in physical size. The gametophyte is small, only a few centimeters across, and thalloid in structure.

Unique to the spore-dispersing vascular plants is that both the sporophyte and the gametophyte are free-living, capable of surviving on their own (see [Fig. 31.3](#)). In many cases, the gametophytes of spore-dispersing vascular plants are capable of photosynthesis and tolerant of desiccation. Because of their size and fossil record, our discussion emphasizes the sporophytes of these plants.

## Rhynie chert fossils provide a window into the early evolution of vascular plants.

Fossils recovered from a single site in Scotland document key stages in the evolution of vascular plants. Four hundred million years ago, near the present-day village of Rhynie, a wetland community thrived in a volcanic landscape. Mineral-laden springs similar to those found today in Yellowstone National Park encased the newly deposited remains of local populations in chert, a mineral made of silica ( $\text{SiO}_2$ ). These fossils preserve plants, fungi, protists, and small animals in remarkable detail.

The fossils of Rhynie chert provide our best view of early vascular plants. These plants were small (maximum of 15 cm tall) and consisted primarily of photosynthetic stems that branched repeatedly, forming sporangia at the tips of short side branches ([Fig. 31.8](#)). They had no leaves, and their only root structures were small hairlike extensions on the lower parts of stems that ran along the ground. The stems had a cuticle with stomata, and a tiny cylinder of vascular tissue ran through the center. Many of the gametophytes also had erect cylindrical stems, not at all like the reduced gametophytes of living vascular plants.

FIG. 31.8 Rhynia, a fossil vascular plant from the 400-million-year-old Rhynie chert. All vascular plants are descended from these kinds of simple plants.

The fossils of Rhynie chert provide another important glimpse into early plant evolution: some fossils have a branched sporophyte that includes cell walls reinforced with lignin, but there is no evidence of vascular tissue. Evidently, plants evolved the upright stature we associate with living vascular plants before they evolved the differentiated tissues of the vascular system (xylem and phloem). Once vascular tissues evolved, they played a key role in shaping the

subsequent evolution of the plant sporophyte.

## Lycophytes evolved leaves and roots independently from all other vascular plants.

One of the fossil populations in Rhynie cherts is notably larger and more complex than the others. These fossil sporophytes show leaflike structures arranged on the stem in a spiral pattern, and a thick-lobed cylinder of xylem runs through the stem ([Fig. 31.9](#)). These are among the earliest fossils of lycophytes, a group of vascular plants that today can be found in environments ranging from tropical rain forests to Arctic tundra. Because lycophytes diverged before any of the other groups of vascular plants, they are the sister group to all other vascular plants (see [Fig. 31.1](#)).

FIG. 31.9 An early lycophyte preserved in the 400-million-year-old Rhynie chert. The fossil has helically arranged leaflike structures, adventitious roots (roots that arise from the shoot and not from the root system), and a central strand of xylem, features much like those of living lycophytes.

Fossils indicate that the leaves and roots of lycophytes evolved independently from those of ferns, horsetails, and seed plants. A distinctive feature of lycophyte leaves is that their small leaves have only a single vein. About 1200 species of lycophytes can be found today. Some grow low to the ground and produce branching stems covered by small leaves ([Fig. 31.10a](#)) or leaves in rows held in a single

plane ([Fig. 31.10b](#)), while others grow as epiphytes in tropical forests. The most distinctive living lycophytes are the quillworts (genus *Isoetes*), small plants that live along the margins of lakes and slow-moving streams ([Fig. 31.10c](#)). Seeing a quillwort today, you would never guess that its relatives once included enormous trees.

## Ancient lycophytes included giant trees that dominated coal swamps about 320 million years ago.

Fossils show that ancient lycophytes evolved additional features convergently with seed plants, including a vascular cambium and cork cambium that enabled them to form trees up to 40 m tall ([Fig. 31.11](#)). Swamps that formed widely about 320 million years ago were

dominated by tree-sized lycophytes. Unlike the vascular cambium of seed plants, the vascular cambium of these lycophytes produced relatively little secondary xylem and no secondary phloem. Instead, the giant lycophytes relied on their thick bark for mechanical support. Tree-sized lycophytes were markedly different from the trees familiar to us today ([Fig. 31.12](#)).

#### HOW DO WE KNOW?

### FIG. 31.12

## Did woody plants evolve more than once?

#### OBSERVATIONS

Today, the vascular cambium is present almost exclusively among seed plants, with only limited development of secondary xylem in some adder's

tongue ferns and quillwort lycophytes (*Isoetes* species). The fossil record, however, shows that other plants, now extinct, also had a vascular cambium.

#### HYPOTHESIS

The vascular cambium evolved independently in several different groups of vascular plants.

#### EXPERIMENT AND RESULTS

The vascular cambium is recorded in fossils by xylem cells in rows oriented radially in the stem or root. Thus, the giant tree lycophytes of Carboniferous coal swamps (the top photo) had a vascular cambium, as did extinct tree-sized relatives of the horsetails (the bottom photo) and other extinct horsetail relatives. Phylogenetic trees generated from morphological features preserved in fossils unambiguously show that woody lycophytes, woody horsetail relatives, and the group of seed plants and progymnosperms did not share a common ancestor that had a vascular cambium. Moreover, anatomical research shows that the vascular cambium of extinct woody lycophytes and the giant horsetails *Archaeocalamites* and *Calamites* generated secondary xylem but not secondary phloem, unlike the vascular cambium of seed plants. Living horsetails do not have a vascular cambium, but fossils show that they are descended from ancestors that did make secondary xylem and have lost this trait through evolution.

## CONCLUSION

Fossils and phylogeny support the hypothesis that the vascular cambium and, hence, wood evolved more than once, reflecting a strong and persistent selection for tall sporophytes among vascular plants.

SOURCE Taylor, T. N., E. L. Taylor, and M. Krings. 2009. *Paleobotany*. Amsterdam: Elsevier.

These forest giants were not outcompeted by early seed plants, but persisted alongside them for millions of years in swampy environments. Environmental change, however, spelled their doom. When changing climate dried out the swamps, the large lycophytes disappeared, along with their habitat. Little *Isoetes* was left as the only living reminder of this once-dominant group of plants.

These ancient forests left one other legacy: the coal deposits we mine today. As trees died and fell over into the swamp, their bodies decomposed slowly. Over time, as material accumulated and became buried, the combined action of high temperature and pressure converted the dead organic matter first into peat and then into the carbon-rich material we call coal. Thus, a major source of energy we use today derives originally from photosynthesis carried out by lycophtye trees.

## Ferns and horsetails are morphologically and ecologically diverse.

Ferns and horsetails form a monophyletic group that is the sister group to the seed plants ([Fig. 31.13](#)). Most ferns have distinctive leaves that uncoil during development from tightly wound “fiddleheads” ([Fig. 31.14a](#)). Horsetails, as well as whisk ferns and their relatives, lack this feature. In fact, horsetails and whisk ferns were once considered distinct groups because of their unique body organizations. Whisk ferns have photosynthetic stems without leaves and roots (see [Fig. 31.13b](#)), so they look similar to fossils of early vascular plants. Nevertheless, molecular sequence comparisons support the hypothesis that whisk ferns are the simplified descendants of plants that produced both leaves and roots.

FIG. 31.14 Fern leaves and stems. (a) A fern leaf uncoiling from a “fiddlehead.” (b) Silver tree ferns (*Cyathea meullaris*) grow 10 m tall or more.

The horsetails, represented by 15 living species of the genus *Equisetum*, produce tiny leaves arranged in whorls, giving the stem a jointed appearance (see [Fig. 31.13c](#)). Horsetail stems are hollow, and their cells accumulate high levels of silica, earning them the name “scouring rush.” Today, horsetails are small plants, most less than a meter tall. In earlier times, however, tree-sized versions grew side by side with the ancient lycophyte trees (see [Fig. 31.12](#)).

In contrast, most ferns produce large leaves—in some cases up to 5 m long, although typically the photosynthetic surfaces are divided into smaller units called **pinnae**. Yet, because most ferns are not capable of secondary growth, their stems remain slender and frequently grow underground. Only the leaves emerge into the air. Many ferns exhibit little stem elongation and produce their leaves in tight clumps. Other species, such as bracken fern, produce underground stems with widely spaced leaves. Because bracken is toxic to cattle and other livestock, its tendency to invade pastures is a serious problem for farmers.

Despite the absence of secondary growth, some ferns can grow quite tall ([Fig. 31.14b](#)). Tree ferns can reach heights of more than 10 m by producing thick roots near the base of each leaf that descend parallel to the stem to the ground. These roots increase the mechanical stability of the plant and allow it to transport more water. Other ferns grow tall by producing leaves that twine around the stems of other plants, using those stems for support. At the other extreme are tiny aquatic ferns such as *Salvinia* (see [Fig. 31.13e](#)) that float on the surface of the water.

## Fern diversity has been strongly

## affected by the evolution of angiosperms.

The fossil record shows that ferns and horsetails originated more than 360 million years ago, and between 300 and 100 million years ago they were the most diverse group of plants (see [Fig. 31.4](#)). Then, as angiosperms evolved, their diversity markedly decreased. It is not clear why angiosperm evolution should have so affected ferns and horsetails, which had coexisted with a variety of seed plant groups for more than 200 million years.

The most diverse group of ferns today, the polypod ferns (about 9300 species; see [Fig. 31.13f](#)), evolved after the rise of the angiosperms. Thus, many of the fern species present today are likely to have evolved in habitats newly created by the development of angiosperm forests. Approximately 40% of living ferns are epiphytes, many of them growing in tropical rain forests dominated by angiosperm trees.

Polypod ferns may owe some of their evolutionary success to an enhanced capacity for spore dispersal. Horsetails, whisk ferns, and a few other fern groups make large sporangia similar to those produced by early vascular plants. These sporangia break open to release spores, but lack a mechanism for ejecting the spores into the air. In contrast, most ferns have a distinctive sporangium (called a [leptosporangium](#)) whose wall is only a single cell thick. In the leptosporangia of polypod ferns, a line of thick-walled cells runs along the sporangium surface (see the photo on the first page of [Chapter 28](#)). When the spores mature, the sporangium dries out and these cells contract like a

catapult, forcibly flinging the spores into the air.

#### Self-Assessment Questions

8. Where are lycophytes found today?
9. What are three ways that ferns, which lack secondary growth, are able to elevate their leaves and thus access more sunlight?
10. How has fern diversity been affected by the evolution of the angiosperms?

## 31.4 GYMNOSPERMS

Gymnosperms are seed plants, as are angiosperms: both types of plants reproduce using pollen and seeds. Gymnosperms total only a bit more than 1000 species, whereas there are more than 380,000 species of angiosperms ([Table 31.1](#)). Despite their much lower diversity, gymnosperms are highly successful inhabitants of modern-day Earth. In cool or dry parts of the world, gymnosperms such as pine trees are often more common than angiosperms in the forest canopy.

The fossil record shows that there were once many more groups of gymnosperms than are found today. Taking these extinct groups into account, biologists hypothesize that gymnosperms are paraphyletic ([Fig. 31.15](#)). In this section, we examine the evolutionary history of living gymnosperms and explore how their diversity and distribution were affected by the rise of the angiosperms. First, though, we review some of the features of seed plants that may have contributed to their evolutionary and ecological success.

FIG. 31.15 Seed plant diversity. The phylogenetic tree shows a hypothesis of evolutionary relationships among gymnosperms.

## Seed plants have been the dominant plants on land for more than 200 million years.

Seed plants have come to dominate land environments since their first appearance about 370 million years ago. While the coal-forming swamps of 300 million years ago were populated by spore-producing giants, the understory of these strange forests included plants that produced pollen and seeds. By 200 million years ago, seed plants had become the largest and most widespread plants on Earth.

Which factors have contributed to the success of seed plants? Notably, they do not require external water for fertilization. Instead, a tiny, sperm-producing male gametophyte is transported through the air in pollen; the female gametophyte develops while remaining hidden inside the sporophyte. Thus, the sporophyte generation dominates the seed plant's life cycle. Gametophytes still grow from spores produced inside a sporangium, but the spores are not dispersed. In gymnosperms, the sporangia develop in cones, whereas in angiosperms, they develop in flowers.

Pollination, if successful, leads to fertilization and the formation of a seed. Seeds contain an embryonic sporophyte, surrounded by food resources and a protective outer layer. The resources stored with each seed support the growth of the embryo following dispersal. In this way, seeds increase the likelihood that the embryo will grow into a photosynthetically self-sufficient new sporophyte.

Before these innovations, the ancestors of seed plants evolved the ability to produce additional or “secondary” xylem and phloem through the formation of a vascular cambium. This layer of actively dividing and differentiating cells surrounds stems and allows them to increase in diameter ([Chapter 29](#)). A second layer of dividing cells, the cork cambium, maintains an intact layer of protective outer bark. Vascular and cork cambia provide the support and water transport capacity needed for plants to grow tall and to support increasing numbers of leaves. Woody stems and roots are the ancestral condition in seed plants and all gymnosperms exhibit secondary growth.

## Cycads and ginkgos were once both diverse and widespread.

Cycads typically have unbranched stems topped by a whorl of stiff leaves ([Fig. 31.16](#)). Although most cycads have thick stems, their vascular cambium produces little additional xylem, and most of their bulk is made up of unlignified (nonwoody) cells in the center of the stem (pith) and surrounding the vascular tissues (cortex). Cycads have low photosynthetic rates and, as a result, grow very slowly.

Sources: a. A. Laule/AGE Fotostock; b. & c. Andrew Knoll, Harvard University.

FIG. 31.16 Cycads. (a) Most living cycads have thick, unbranched stems that support large leaves and cones. Shown here is *Encephalartos friderici-guilielmi*. (b) Many cycads, such as *Encephalartos transvenosus*, have large cones. (c) Mature seeds are large (the seeds of *Cycas circinalis* are shown here) and contain a relatively large female gametophyte that provides nutrition for the embryo and germinating sporophyte.

In nutrient-poor environments, cycads are able to grow by forming

symbiotic associations with nitrogen-fixing cyanobacteria. They can survive wildfires because their vascular cambium is located far beneath the surface of their thick stems and their apical meristem is protected from heat by a dense covering of bud scales. Thus, cycads have traits that favor persistence, rather than high rates of photosynthesis.

Cycads are an ancient group, with fossils at least 280 million years old. During the time of the dinosaurs (about 230 to 66 million years ago), they were among the most common plants. As the angiosperms rose to ecological prominence, however, cycads' diversity and abundance declined markedly. The approximately 300 species of cycads found today occur most commonly in tropical and subtropical regions. Most species have a fragmented distribution, suggesting that they were much more widespread in the past.

Cycads may owe their persistence in part to their reliance on insects for pollination, as well as to their ability to live in nutrient-poor and fire-prone environments. Insects transfer pollen more efficiently than wind, so insect-pollinated species with small populations are able to reproduce successfully. Many cycads are pollinated by beetles attracted by chemical signals released from the cones. The large seed cones provide shelter for the insects, and the pollen cones provide them with food. Following fertilization, the brightly colored, fleshy seed coats attract a variety of birds and mammals that serve as dispersal agents.

The Ginkgophyta, once a diverse lineage, today has only a single living representative: *Ginkgo biloba*. This species forms tall, branched trees, with fleshy seeds and fan-shaped leaves that turn brilliant yellow

in autumn ([Fig. 31.17](#)). Once common in temperate forests, ginkgos declined in abundance, diversity, and geographic distribution over the past 100 million years, and it is unclear whether any truly natural populations exist in the wild. However, ginkgos have long been cultivated in China, especially near temples.

FIG. 31.17 *Ginkgo biloba*. (a) The fan-shaped leaves of *Ginkgo* turn yellow in autumn. (b) The fleshy seeds enclose a large female gametophyte, as in cycads.

Today, ginkgos are found all over the world. Their ability to tolerate the pollution and other stresses of urban environments have made them a tree of choice for street plantings.

## Conifers are woody plants that thrive in dry and cold climates.

The approximately 630 species of conifers are, for the most part, trees. The tallest (more than 100 m) and oldest (more than 5000 years) trees on Earth are both conifers ([Fig. 31.18](#)). In addition, most conifers are evergreen, meaning that they retain their often needle-like leaves throughout the year and, in some species, for decades. Well-known

conifers include pines, junipers, and redwoods.

Source: Charles J. Smith.

FIG. 31.18 Conifers. Giant sequoia (*Sequoiadendron giganteum*) can reach 85 m in height and have stems that are 8 m in diameter.

Most conifers have strong apical dominance, so they develop a single straight stem from which extend much smaller horizontal branches. Conifers have traditionally served as masts for sailing ships, and today they are used for telephone poles. Conifer xylem consists almost entirely of tracheids, single-cell conduits that both support the tree and transport water. The abundance of similar-sized xylem conduits is why conifer wood is strong for its weight and well suited as a building material. Conifers supply much of the world's timber, as well as the raw material for producing paper.

Conifer reproduction tends to be slow. After pollination, it can take more than a year before the seeds are ready to be dispersed. Conifers are wind pollinated, and most species also rely on wind for seed

dispersal. However, some conifers, such as junipers and yews, produce seeds surrounded by fleshy and often brightly colored tissues that attract birds and other animals.

Conifers dominate the vast boreal forests of Canada, Alaska, Siberia, and northern Europe. Conifers also tend to become more abundant as elevation increases, and they are common in dry areas, such as the western parts of North America and much of Australia. Only a small number of conifer species are found in tropical latitudes, most commonly at higher elevations. Before the rise of the angiosperms, conifers were more evenly distributed across the globe, including in the lowland tropics. One of the great questions in the evolutionary history of plants is why conifers were largely displaced from tropical latitudes by the angiosperms but continued to thrive in cold and dry environments.

An important difference between angiosperms and conifers is that angiosperms transport water in the xylem vessels, whereas conifers transport water in tracheids. In wet and warm environments, the xylem vessels of angiosperms can be both wide and long, increasing the efficiency of water transport through their stems. One hypothesis is that the evolution of xylem vessels gave angiosperms a competitive advantage in moist tropical environments. With more water flowing through their stems, angiosperms could have higher rates of photosynthesis and grow larger leaves. Once conifer populations began to dwindle, they could have disappeared completely, because wind pollination requires dense populations to be effective. In colder or drier regions, however the dangers of cavitation due to drought or freeze

followed by thaw ([Chapter 27](#)) constrain the size of angiosperm vessels. This may explain the greater coexistence of conifers and angiosperms in cold or dry climates.

## Gnetophytes are gymnosperms that have independently evolved xylem vessels and double fertilization.

Gnetophytes are a small group of gymnosperms (about 90 species) made up of three genera that look completely different from one another ([Fig. 31.19](#)). *Welwitschia mirabilis* is found only in the deserts of southwestern Africa. It produces just two straplike leaves that elongate continuously from their base. *Gnetum* grow in tropical rain forests, where they form woody vines and small trees with large broad leaves. *Ephedra*, which is native to arid regions, produces shrubby plants with photosynthetic stems and tiny leaves.

Sources: a. M. Philip Kahl/Science Source; b. Ahmad Fuad Morad [Flickr page] 072112; c. Bob Gibbons/Science Source.

FIG. 31.19 Gnetophytes. The three genera in this group include some of the most distinctive seed plants: (a) *Welwitschia mirabilis*; (b) *Gnetum* species; and (c) *Ephedra* species.

The fossil record shows that gnetophytes originated perhaps as early as 200 million years ago. They reached their greatest diversity at approximately the same time as the angiosperms began to diversify. Gnetophytes have long attracted the attention of plant biologists because they exhibit a number of traits that are typical of angiosperms, notably the formation of xylem vessels and double fertilization. Despite these shared features, DNA analysis indicates that gnetophytes are not closely related to the angiosperms but are, instead, more closely related to conifers. Thus, both xylem vessels and double fertilization evolved independently in this group.

#### Self-Assessment Questions

11. How has the evolution of angiosperms affected the distribution of cycads and of conifers?
12. How does the xylem produced by conifers differ from that of angiosperms? How could this difference have influenced the present-day distribution of conifers?
13. Double fertilization evolved independently in gnetophytes and in flowering plants. What are two other features usually associated with angiosperms that evolved independently in gymnosperms?

## 31.5 ANGIOSPERMS

The evolution of angiosperms transformed life on land. The total number of plant species increased significantly as angiosperms diversified. Some non-angiosperm plant groups thrived as they expanded into new niches created by angiosperms, whereas others declined as many of their species went extinct. Terrestrial ecosystems became more productive as rates of photosynthesis increased in plants with the more efficient angiosperm xylem. As a result, more food became available for insects, birds, and mammals. All of these animal groups diversified along with the flowering plants.

Angiosperms are distinguished from other seed plants by a number of innovations that make pollination and provision of offspring more efficient. These innovations include the emblematic flower, but also closed carpels, double fertilization leading to the formation of endosperm, and fruits. Angiosperm vascular tissues are also distinct: water transport to photosynthetic leaves is more efficient in plants with multicellular xylem vessels. We briefly review some of these innovations in the next section and then consider how these new features may have contributed to the spectacular diversity of the flowering plants.

**Several innovations increased the efficiency of the angiosperm life cycle and xylem transport.**

Recall from [Chapter 28](#) that flowers are a plant's way of enlisting animals to help them reproduce. The majority of angiosperms rely on

animals to carry pollen from one plant to another, instead of depending on the wind for dispersal. Brightly colored petals and volatile scents advertise the presence of flowers, while rewards such as nectar encourage pollinators to return repeatedly to individuals of the same species. The movement of animals from one flower to another provides an efficient mode of pollen transfer. As a result, animal-pollinated plants are able to reduce their production of pollen compared to a wind-pollinated plant.

A second way in which angiosperms are more efficient at completing their life cycle than other seed plants is the process of double fertilization, in which one fertilization leads to the embryo and the other to the endosperm. In angiosperms, endosperm is the tissue that supports the growth of the embryo. Double fertilization allows angiosperms to delay forming nutritive tissue for the embryo until after fertilization occurs ([Chapter 28](#)). In contrast, in gymnosperms, resources for the embryo are committed before fertilization. Double fertilization prevents resources from being wasted when ovules are provisioned but never fertilized.

Fruits are another feature that contributes to the efficiency of angiosperm reproduction. Fruits result from the maturation of the ovary containing the seeds. By packaging seeds within a larger structure, angiosperms increase the ways in which seeds can be dispersed. In particular, because fruits provide rewards for animal dispersal agents, they make it more likely that seeds will be dispersed widely. This may be especially true for small seeds, which otherwise would be unlikely to attract an animal disperser.

In addition to reproducing efficiently, angiosperms are able to grow efficiently into a wide variety of forms, ranging from short-lived herbaceous plants to trees with large spreading crowns. One reason may be the structure of the angiosperm vascular system: instead of having a single cell type for mechanical support and water transport like gymnosperms, angiosperms produce thick-walled, elongate fibers that support the stem and xylem vessels that transport water. One outcome of this arrangement is that because xylem vessels are not a stem's sole source of support, they can be wide and long. Angiosperms with these wide xylem vessels are able to transport water through their stems at higher rates than plants with tracheids. Another outcome of producing efficient xylem is that angiosperms can grow quickly and with great flexibility of form. The diversity of shapes and sizes made possible by xylem vessels reduces competition for light and space, potentially allowing more species to coexist. Finally, because they can grow quickly, angiosperms may be able to make use of habitats and resources that are only fleetingly available, such as ephemeral pools or open areas that appear following a fire.

## Angiosperm diversity may result in part from coevolutionary interactions with animals and other organisms.

Evidence in the fossil record shows that for the first 30 to 40 million years of their evolution, angiosperms were not particularly diverse. Nor were they the dominant plants of their ecosystems. In fact, fossil pollen indicates that, between about 140 and 100 million years ago, gnetophytes diversified just as much as angiosperms. Later in the

Cretaceous Period, beginning about 100 million years ago, angiosperm diversity began to increase at a much higher rate. It is at this time that we first encounter fossils of the two groups that would come to dominate both angiosperm diversity and the ecology of many terrestrial environments: the monocots and the eudicots ([Fig. 31.20](#)).

FIG. 31.20 Angiosperm phylogeny. Most angiosperm species belong to the

Before looking at the diversity of these two groups, let's consider how characteristics of the angiosperms may have promoted their diversification. While many factors likely contributed to their success, here we focus on the ways in which angiosperms interact with other types of organisms.

The interaction of flowers and animal pollinators is thought to contribute to angiosperm diversity. Plants whose flowers attract different pollinators tend to more readily diverge to form new species than do wind-pollinated species. In addition, the carpel (the closed vessel in which seeds develop) is able to block the growth of pollen from different species and from closely related individuals, including pollen from the same plant. These genetic recognition systems may contribute to the reproductive isolation required for speciation ([Chapter 21](#)).

Diversity results from both high rates of species formation *and* low rates of species loss. The fossil record suggests that the persistence of species may play a particularly important role in angiosperm diversity. Wind-pollinated plants can reproduce only when their populations have a relatively high density. Since no wind-carried pollen is likely to fall on isolated individuals, species with low population density are more likely to go extinct. In contrast, animal pollinators actively searching for rare species are much more likely to find them, so animal-pollinated angiosperm populations can persist at low population densities.

Another reason rare species may be more persistent is that they are less likely to encounter soil pathogens and seed predators. These threats to survival tend to gather near adults of the same species. Because the seeds of rare species are more likely to land away from an individual of the same species, these seeds suffer less from density-dependent mortality than do those of more common species. Of course, this strategy works only if rare isolated individuals can remain in contact with a large enough population of potential mates. Once again, flowers and animal pollinators play a key role in species persistence.

If animal pollination has so many advantages, why did approximately 20% of angiosperm species subsequently evolve a dependence on wind for pollination? Wind-pollinated species grow primarily in seasonal environments. There, fewer animal pollinators are available than in tropical forests, and soil pathogens and seed predators are less abundant.

That angiosperm diversity is the result of multiple factors is reinforced by the observation that some of these “angiosperm” features are also present in other groups of plants. For example, cycads rely on animal pollination, and gnetophytes produce xylem vessels, yet neither group is particularly diverse. The initially slow but increasingly rapid buildup of angiosperm diversity may be explained by two factors: (1) the compounding effect of coevolutionary interactions with pollinators and dispersers and (2) adaptive radiations triggered by chemical arms races with pathogens and herbivores ([Chapter 30](#)). This is what is meant by the adage “Diversity begets diversity,” a phenomenon further explored in [Chapter 45](#).

## Monocots are diverse in shape and size despite not forming a vascular cambium.

Monocots (more formally, monocotyledons) make up nearly one-fourth of all angiosperms. Monocots come in all shapes and sizes and are found in virtually every terrestrial habitat on Earth ([Fig. 31.21](#)). Some monocots grow in arid regions; an example is agave, which is used to make tequila. Others, such as orchids, grow primarily as epiphytes in tropical forests. A few monocots form vines—for example, the rattan palms, whose stems are used to produce rattan furniture. Monocots are the most important group of plants in our diets. Grasses such as corn, rice, wheat, and sugarcane are staples in the diets of most people around the world. Other monocots that make their way to our dinner table include banana, ginger, asparagus, pineapple, and vanilla.

FIG. 31.21 Monocot diversity and phylogeny. This diverse group of angiosperms includes (a) *Agave shawii*, a desert succulent; (b) *Leucojum vernum*, a spring wildflower; (c) bamboo, a forest grass; and (d) *Costus* species, which grow in the rain forest understory. (e) Monocot phylogeny indicates that orchids (approximately 22,000 species) and grasses (approximately 11,500) make up much of monocot diversity.

Monocots take their name from the fact that they have one embryonic seed leaf, or cotyledon, whereas all other angiosperms have two. However, monocots are distinct in form in many other ways. For example, monocot flowers typically produce organs in multiples of three (for example, having three, six, or nine stamens), whereas eudicot flowers typically produce organs in multiples of four or five. Another difference is that in monocot leaves, the major veins are typically parallel and the base of the leaf surrounds the stem, forming a continuous sheath. However, the major difference is that monocots do not form a vascular cambium. In the stems of most monocots, the vascular bundles are scattered throughout the cross section, instead of being arranged in a ring like those of most other seed plants. The scattered arrangement of vascular bundles is thought to preclude the formation of a continuous layer of vascular cambium. As a result, monocots do not exhibit secondary growth.

Because monocots lack a vascular cambium, the vascular capacity of their stems and roots cannot increase even as the plants increase in size. Some monocots overcome this limitation by producing horizontal stems that continuously initiate new roots each time a new leaf is added. Others limit the production of new leaves that would need to be

supported by an expanded vascular system: they form upright stems that are unbranched and, therefore, have a relatively fixed total leaf area. A few monocots, such as palm trees, have evolved alternative ways of producing larger-diameter stems and, in some cases, a small amount of additional xylem and phloem. Most monocots, though, lack the ability either to grow in diameter or to increase their vascular transport capacity.

Which factors might have led to such a radical revision in how monocots build their bodies? One hypothesis is that monocots evolved from ancestors that produced creeping, horizontal stems as they grew along the shores of lakes and other wetlands. Many monocots today grow in such habitats. In addition, many features of the monocot body plan are well adapted to environments with loose substrates, flowing water, and fluctuating water levels. For example, their leaf base provides a firm attachment that prevents leaves from being pulled off by flowing water. Furthermore, many monocots produce strap-shaped leaves that elongate from a persistent zone of cell division and expansion located at the base of the leaf blade. By continually elongating from the base, monocot leaves can extend above fluctuating water levels.

Although monocots may have originated in wet habitats, today they grow in a wide range of environments, including ones that are seasonally dry. One of the most diverse groups within the monocots is the grasses. Many grasses produce stems that grow horizontally and branch, allowing them to cover large areas. Grasses have linear leaves that elongate from the base, allowing them to survive grazing as well

as fire and drought. Many grasses are able to tolerate dry environments by producing roots that extend deep into the soil. In addition,  $C_4$  photosynthesis has evolved within the grasses multiple times. As described in [Chapter 27](#),  $C_4$  plants can avoid photorespiration, thereby photosynthesizing with greater efficiency. Grasses are among the most successful groups of plants, becoming widespread within the past 20 million years as climates changed ([Fig. 31.22](#)). Today, nearly 30% of terrestrial environments are grasslands.

HOW DO WE KNOW?

## FIG. 31.22

### When did grasslands expand over the land surface?

#### BACKGROUND

Today, prairies, steppes, and other grasslands spread over broad areas in the interiors of continents. Grasses, however, do not fossilize readily. How can we understand how grasslands developed through time?

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

Data from Edwards, E. J., C. O. Osborne, C. A. E. Stromberg, S. A. Smith, and the  $C_4$

Grasses Consortium. 2010. "The Origins of C<sub>4</sub> Grasslands: Integrating Evolutionary and Ecosystem Science." *Science* 328:587–591.

## HYPOTHESIS

Grasslands expanded as climate changed over the past 50 million years.

## OBSERVATIONS AND EXPERIMENTS

Many plants, including grasses, form small structures of silica (SiO<sub>2</sub>) called phytoliths in their cells. Phytoliths provide a window into the past because they persist in the soil (i.e., they do not decay) and different groups of plants can be identified based on the structure of their phytoliths. Thus, phytolith assemblages in the soil can be used to distinguish between grasses growing in open grasslands (where grasses are present but there are few or no trees) and grasses growing in a forest understory. In addition, mammals that feed on grasses evolved high-crowned teeth, which are also preserved well, giving us an indirect record of grassland history. Finally, C<sub>4</sub> grasses, which are adapted to hot, sunny environments with limited rainfall, have a distinctive carbon isotopic composition imparted by the initial fixation of CO<sub>2</sub> by PEP carboxylase ([Chapter 27](#)). Scientists can track C<sub>4</sub> grasslands through time by examining measurements of <sup>13</sup>C and <sup>12</sup>C in mammal teeth, soil carbonate minerals, and, more recently, tiny amounts of organic matter incorporated into phytoliths.

## RESULTS

Studies of mammal tooth structure (top graph), phytoliths (middle graph), and carbon isotopic composition of horse teeth enamel from the North American midcontinent (bottom graph) show that grasslands expanded 20 to 15 million years ago, and C<sub>4</sub> grasslands expanded later, about 8 to 6 million years ago.

## CONCLUSION

In North America, grasslands expanded as atmospheric  $CO_2$  levels declined and climates became drier. Other continents show evidence of a similar linkage of grassland expansion to climate change.

## FOLLOW-UP WORK

At present, atmospheric  $CO_2$  levels are increasing rapidly, which may affect the competitive abilities of  $C_3$  and  $C_4$  grasses. Scientists are working to understand how global change will influence grasslands and other vegetation.

# Eudicots are the most diverse group of angiosperms.

Eudicots first appear in the fossil record about 125 million years ago. By 90 to 80 million years ago, most of the major groups we see today were present. Today, an estimated 160,000 species of eudicots are found on Earth, accounting for nearly three-fourths of all angiosperm

species ([Fig. 31.23](#)). Eudicots are well represented in the fossil record, in part because their pollen is easily distinguished. Each eudicot pollen grain has three openings from which the pollen tube can grow. Pollen from all other seed plants has only a single opening.

FIG. 31.23 Eudicot diversity and phylogeny. Eudicots include (a) red oak trees (*Quercus rubra*); (b) tropical passionflower vines (*Passiflora caerulea*); (c) *Banksia* shrubs, native to Australia; and (d) beavertail cactus (*Opuntia basilaris*).

(e) The tree shows a phylogeny of eudicots, with well-known species indicated. Groups with a small number of species are not shown.

Eudicots take their name from the fact that they produce two cotyledons, whereas monocots produce one. Because all other angiosperms except monocots also have two cotyledons, this largest of all angiosperm groups is referred to as the *eu-* or “true” dicots.

Many eudicots produce highly conductive xylem. Their high rates of water transport, and therefore their high rates of photosynthesis, may explain why eudicot trees are so abundant in many forests. In addition, many eudicot trees lack strong apical dominance and produce crowns with many spreading branches. The diversity of crown architecture exhibited by eudicot trees reduces competition for light and space, potentially allowing more species to coexist. Today, tropical rain forest trees are an important component of the diversity of eudicots. Familiar eudicot trees in temperate regions include oaks, willows, and eucalyptus.

At the other end of the size spectrum are the herbaceous eudicots. These small plants make up a substantial fraction of eudicot diversity. Herbaceous plants do not form woody stems. Instead, the aboveground shoot dies back each year rather than withstand a period of drought or cold. The herbaceous growth form appears to have evolved many times within eudicots as tropical groups represented by woody plants expanded into temperate regions. Important to the success of herbaceous plants is the ability to produce efficient xylem: they can rebuild their stems year after year with minimal investment. Examples

of herbaceous eudicots include violets, buttercups, and sunflowers.

At one extreme of herbaceous eudicots are annuals, which complete their life cycle in less than a year. Annuals persist during the unfavorable period as seeds. This plant form is unique to angiosperms, and the majority of annuals are eudicots.

Eudicots are diverse in other ways as well. Most parasitic plants and virtually all carnivorous plants are eudicots, as are water-storing cacti that grow in deserts. Some, such as roses and blueberry, are woody shrubs. Others grow as epiphytes in the canopy of rain forests. Still others, such as grapes and honeysuckle, are vines.

Finally, eudicots make a significant contribution to the diversity of the dinner table. Apples, carrots, pumpkins, and potatoes are all eudicots, as are coffee, cacao (the source of chocolate), and tea. Many plants with oil-rich seeds, such as olives, walnuts, soybean, and canola, are eudicots, as are members of the legume, or bean, family. Some members of this family can form symbiotic interactions with nitrogen-fixing bacteria ([Chapter 27](#)), and as a result produce seeds that are rich in nitrogen, such as lentils and soybean.

## CASE 6 AGRICULTURE: FEEDING A GROWING POPULATION

# What can be done to protect the genetic diversity of crop species?

Of the more than 400,000 species of plants on Earth today, we eat surprisingly few. Of those we do eat, nearly all are angiosperms. Most of the plants we eat come from species that are grown in cultivation, and many of these cultivated species have, as a consequence of artificial selection, lost the ability to survive and reproduce on their own. Of the approximately 200 such domesticated species, 12 account for more than 80% of human caloric intake. Just three—wheat, rice, and corn—make up more than two-thirds of that intake.

Crop breeders select for varieties that grow well under cultivation and are easy to harvest, but a consequence of selective breeding is decreased genetic diversity of crop species. Because pathogens and pests continue to evolve, any loss in genetic diversity of crop species creates substantial risks. For example, before 1970, the fungal pathogen *Bipolaris maydis* had destroyed less than 1% of the U.S. corn crop annually. In 1970, however, it destroyed more than 15% of the corn crop in a single year. The severity of the epidemic was due to the genetic uniformity of the corn varieties planted at that time. In natural plant populations, genetic variation for pathogen resistance makes it highly unlikely that a newly evolved pathogen strain will be able to infect every plant.

Nicolai Vavilov, a Russian botanist and geneticist, was one of the first to recognize the importance of safeguarding the genetic diversity of both crop species and their wild relatives. In the early twentieth century, he mounted a series of expeditions to collect seeds from around the globe. Vavilov's observations of cultivated plants and their relatives led him to hypothesize that plants had been domesticated in

specific locations. From these locations, plant domestication spread through human migration and commerce ([Fig. 31.24](#)). Vavilov called these regions “centers of origin.” He believed that they coincided with the centers of diversity for both crop species and their wild relatives. In World War II, during the siege of Leningrad, in which more than 700,000 people perished, scientists at the Vavilov Institute sought to protect what was then the world’s largest collection of seeds. At least one of the self-appointed caretakers died of starvation, despite being surrounded by vast quantities of edible seeds. The dedication of these scientists illustrates the priceless nature of the genetic diversity on which our food supply rests.

Today, seed banks help preserve the genetic diversity of crop species and their wild relatives. However, seed banks can store only a fraction of the genetic diversity present in nature. To help make up the

difference, some have suggested establishing protected areas that coincide with Vavilov's centers of origin. As we discuss in [Chapter 48](#), new threats lie just over the horizon. Meeting these threats will require that every genetic resource be brought to bear.

The reproduction, growth, and physiology of angiosperms are summarized in [Fig. 31.25](#).

FIG. 31.25 VISUAL SYNTHESIS: Angiosperms: Structure and Function  
Integrating concepts from [Chapters 27–31](#)

### Self-Assessment Questions

- How does the movement of pollen from an animal-pollinated angiosperm compare with that from a wind-pollinated conifer?
- What are two features (and their possible advantages) that have

contributed to the diversity and success of angiosperms?

16. What are some of the distinctive features of monocots?
  17. Explain how features found in angiosperms may have allowed the evolution of herbaceous plants, including annual plants.
  18. Which three species make up more than two-thirds of human food consumption?
-

## CORE CONCEPTS SUMMARY

### 31.1 MAJOR THEMES IN THE EVOLUTION OF PLANT

**DIVERSITY:** The evolutionary history of plants has been shaped by the challenges of fertilization, dispersal, and photosynthesis on land.

Four major transformations in land plants have occurred, each of which defines a monophyletic group: alternation of generations is a characteristic of all land plants; formation of xylem and phloem is a trait common to all vascular plants; seeds and pollen are features of seed plants; and flowers (among other traits) define the flowering plants. [page 685](#)

Evolutionary trends in land plants are increasing dominance of the sporophyte stage and decreasing dependence on surface moisture. [page 687](#)

Nearly 400,000 species of plants are believed to exist today. Of these, 90% are angiosperms; the remaining 10% are distributed among the six other major groups of plants. [page 688](#)

Angiosperms first appear in the fossil record about 140 million years ago, more than 300 million years after plants first evolved on land. [page 688](#)

The rapid and dramatic increase in angiosperms starting 140 million years ago has resulted in an overall increase in plant diversity, but a decline in other plant groups such as gymnosperms and ferns. [page 688](#)

Moist tropical rain forests dominated by angiosperms provided new

types of habitat into which other plants could evolve. [page 688](#)

**31.2 BRYOPHYTES:** Bryophytes have a dominant gametophyte generation; they are small in stature and rely on surface moisture for hydration.

The bryophytes are three groups of plants (mosses, liverworts, and hornworts) that share many features. The relationships among these three groups remain uncertain, but all diverged before the evolution of vascular plants. [page 689](#)

Bryophytes are small plants with a dominant gametophyte stage in the form of either a flattened thallus or a leafy stalk. [page 689](#)

Bryophytes do not form roots, but rather absorb water through their surfaces. Because they cannot restrict water loss, the hydration of bryophytes fluctuates with that of the environment. [page 689](#)

The sporophyte generation of bryophytes remains physically and physiologically dependent on the gametophyte. The sporophyte elevates the sites of spore production and, by drying out, enhances the likelihood of spores being dispersed by wind. [page 690](#)

Convergent evolution between bryophytes and vascular plants has occurred several times, resulting in insect dispersal of spores in some mosses and the evolution of internal transport cells in some mosses and liverworts. [page 691](#)

Sphagnum moss, the dominant plant of peat bogs, soaks up water and acidifies the environment, slowing decomposition. As a consequence, large amounts of organic carbon build up year after

year in these bogs. [page 691](#)

**31.3 SPORE-DISPERSING VASCULAR PLANTS:** Spore-dispersing vascular plants have small free-living gametophytes and much larger free-living sporophytes with xylem and phloem; they are most commonly found growing as epiphytes or in forest understories.

Only two groups of spore-dispersing vascular plants have living relatives today: lycophytes, and ferns and horsetails. [page 692](#)

Three hundred million years ago, lycophytes included large trees that dominated swamp forests. Today, lycophytes are small plants that either grow in the forest understory as epiphytes or occur in shallow ponds. [page 694](#)

Ferns and horsetails are morphologically diverse. Ferns produce large leaves that uncoil as they grow; horsetails have tiny leaves; and whisk ferns have no leaves at all. [page 696](#)

Although ferns have a long history, most present-day species are the result of a radiation that occurred after the rise of the angiosperms. [page 697](#)

**31.4 GYMNOSPERMS:** Gymnosperms rely on pollen for fertilization and seeds for dispersal; they have woody stems and today are most common in seasonally cool or dry regions.

Seed plants, which include both gymnosperms and angiosperms, have dominated terrestrial environments for more than 200 million years. Gymnosperms were once much more diverse and widespread; today, there are fewer than 1000 species of these

plants. [page 697](#)

Gymnosperms (including the many extinct groups) are paraphyletic. There are four groups of living gymnosperms: cycads, ginkgos, conifers, and gnetophytes. [page 697](#)

Cycads produce large leaves on thick, unbranched stems. Although they once were widely distributed, they now occur in small, fragmented populations, primarily in the tropics and subtropics. Many cycads are insect pollinated, and all form symbiotic associations with nitrogen-fixing bacteria. [page 698](#)

*Ginkgo* is the single living species of a group that was distributed globally before the evolution of the angiosperms. *Ginkgo* is wind pollinated and produces tall, branched trees. [page 699](#)

Conifers include the tallest and longest-lived trees on Earth. Wind-pollinated and largely evergreen, they are found primarily in cool to cold environments. [page 700](#)

Before the angiosperms appeared, conifers were widespread. Their rarity in the tropics and persistence in temperate regions may be due to their dependence on wind pollination and their xylem, which is formed entirely of tracheids. [page 700](#)

The gnetophytes are a small group, containing only three genera and few species, that has independently evolved xylem vessels and double fertilization. [page 700](#)

**31.5 ANGIOSPERMS:** Angiosperms are distinguished by flowers, fruits, double fertilization, and xylem vessels; they are the most diverse

group of plants found today.

Angiosperms reproduce quickly and with more efficient use of resources as a result of pollination and double fertilization. [page 701](#)

Angiosperm diversity may result as much from low rates of extinction as from high rates of speciation. [page 702](#)

Flowering plants with animal pollinators can reproduce even if they are far apart, allowing rare species to persist and reproduce. [page 702](#)

The angiosperm phylogeny indicates a major split between two diverse groups, monocots and eudicots. [page 702](#)

Monocots have a single cotyledon, or embryonic seed leaf, and do not form a vascular cambium. [page 703](#)

Eudicots have two cotyledons. Many eudicots produce highly conductive xylem, and exhibit a wide range of growth forms. [page 705](#)

Herbaceous plants evolved multiple times within eudicots and make an important contribution to eudicot diversity. [page 706](#)

Modern agriculture is based on just a few plant species with low genetic diversity, making crops vulnerable to pests and pathogens. [page 706](#)

## CHAPTER 32 Fungi

Chris Ted/Getty Images

### CORE CONCEPTS

**32.1 GROWTH AND NUTRITION:** Fungi are heterotrophic eukaryotes that feed by absorption.

**32.2 REPRODUCTION:** Fungi reproduce both sexually and asexually, and disperse by spores.

**32.3 DIVERSITY:** Other than animals, fungi are the most diverse group of eukaryotic organisms.

---

In tropical rain forests, vascular plants make up most of the biomass. Animals eat the plants, but they feed selectively. That is, animals consume leaves, fruits, and seeds, but largely avoid a much more abundant tissue—wood. In fact, most leaves also escape grazing and eventually fall, dead, onto the forest floor. Animals, too, may be eaten by predators, but some die of other causes and contribute their remains to the soil. Given this constant rain of biological materials, we might expect wood, leaves, and animal carcasses to accumulate in great piles, but a walk through the rain forest reveals that the forest floor is remarkably clean. What happened to all of the dead plant and animal tissues?

The reason we are not overwhelmed with dead plants and animals is that their bodies decompose. On land, the organisms principally responsible for the decomposition of plant and animal tissues are **fungi**, one of the most abundant and diverse groups of eukaryotic organisms. Many of us have seen mushrooms and toadstools in a meadow or woodland, but most fungal biomass lies within the soil, out of sight. Fungi are able to locate and break down the complex molecules and bulky tissues in plant and animal bodies. For this reason, fungi play an important role in the carbon cycle. Moreover, because they form intimate relationships with living plants and animals, fungi may either enhance or hinder the growth and

reproduction of many other organisms. For example, fungi associated with plant roots dramatically increase plant growth by enhancing the uptake of mineral nutrients from the soil ([Chapter 27](#)). Other fungi are major agricultural pests ([Chapter 30](#)). Some helpful fungi enable us to turn wheat into bread, barley into beer, and milk into cheese. Other fungi cause athlete's foot, yeast infections, and, especially in patients with compromised immune systems, overwhelming infections that can lead to death.

## 32.1 GROWTH AND NUTRITION

Fungi are heterotrophs: they depend on preformed organic molecules for both carbon and energy. Unlike animals, fungi do not have organs that enable them to ingest food and break it down in a digestive cavity ([Chapter 38](#)). Instead, fungi absorb organic molecules directly through their cell walls. This mode of feeding presents two major problems.

First, although simple molecules like amino acids and sugars pass readily through the cell wall, more complicated molecules do not. To deal with this problem, fungi secrete a multitude of enzymes that break down complex organic molecules like starch or cellulose into simpler compounds that can be absorbed. Fungi, then, digest their food first and take it into the body afterward.

A second challenge is to find food in the environment. Other heterotrophic organisms such as bacteria, protists, and animals commonly move through their own habitats, actively searching for food. Fungi have no means of locomotion, so these organisms use the process of growth itself to find nourishment.

### Hyphae permit fungi to explore their environment for food resources.

Most fungi consist of highly branched, multicellular filaments called [hyphae](#) ([Fig. 32.1](#)). The hyphae are slender, typically 10 to 50 times thinner than a human hair. The numerous long, thin hyphae provide fungi with a large surface area for absorbing nutrients. The network of

branching hyphae that forms the body of a fungus is called a [mycelium](#) (plural, [mycelia](#)).

Source: Susumu Nishinaga/Science Source.

FIG. 32.1 Fungal hyphae. These thin filaments have an enormous surface area that increases absorption of nutrients. Shown here are hyphae of *Trichophyton*, a fungus that infects the skin of humans, as seen under a scanning electron microscope.

Hyphae maintain their slender form by growing only at their tips. Elongating hyphae penetrate ever farther into their environment, encountering new food resources as they grow. Enzymes needed to break down complex food sources are secreted at the growing tip where new cell wall is being formed. In this way, hyphal growth is important for both finding and digesting food resources. Where resources are low, growth is slow or may stop entirely.

When fungi encounter a rich food resource, their hyphae grow rapidly and branch repeatedly. Mycelia can grow to be quite large—the largest known individual of the fungus *Armillaria ostoyae* covers more

than 2000 acres in the Blue Mountains of Oregon and weighs many hundreds of tons. We may be impressed by blue whales and redwoods, but in fact some fungi are the largest living organisms on Earth.

A strong but flexible cell wall is key to hyphal growth. In fungi, cell walls are made of [chitin](#), the same compound found in the exoskeletons of insects. Chitin is a modified polysaccharide that contains nitrogen. Because of their chemical makeup, fungal cell walls are thinner than plant cell walls. The fungal cell walls prevent hyphae from swelling and rupturing as water flows into the cytoplasm by osmosis, when cells are exposed to dilute solutions such as those in freshwater environments and in the soil. The inflow of water by osmosis provides the force that enables fungi to explore their surroundings: the inflow of water generates positive turgor pressure ([Chapters 5](#) and [27](#)), pushing the hyphal tip ever deeper into the local environment.

## Fungi transport materials within their hyphae.

Fungi can transport food and signaling molecules across long distances in mycelia. As a result, they are able to grow between resource patches and to produce reproductive structures such as mushrooms that rise up above the ground. Molecules taken up actively from the environment drive water into the cell by osmosis, thereby increasing turgor pressure. At the same time, growth and respiration consume these molecules, resulting in a decrease in turgor pressure. These increases and decreases in turgor pressure along the hyphae drive bulk flow in a manner similar to phloem transport in plants ([Chapter 27](#)). Materials

obtained in a nutrient-rich location are carried by bulk flow within fungi and used to fuel hyphal elongation across nutrient-poor locations. Transport by bulk flow also allows fungi to build relatively large reproductive structures aboveground. All the raw materials used to build a mushroom, for example, must be transported from hyphae in contact with a source of nutrients, such as the soil or a rotting log.

A continuous stream of cytoplasm, not divided by barriers, is essential for the movement of materials by bulk flow within mycelia. In some groups, the hyphae have many nuclei but no cell walls to separate them. In other groups, nuclear divisions are accompanied by the formation of [septa](#) (singular, [septum](#)), walls that partially divide the cytoplasm into separate cells ([Fig. 32.2](#)). Each septum contains one or more pores that allow water and solutes to move freely between cells. Septa play an important role when hyphae are damaged. Injury activates sealing mechanisms that plug pores in the septa, preventing the loss of pressurized cytoplasm.

FIG. 32.2 Septa separating individual cells in fungi. Septa, partitions between cells, have pores that allow transport of solutes along the hypha.

## Not all fungi produce hyphae.

**Yeasts** are single-celled fungi found in moist, nutrient-rich environments. In this kind of setting, the search for food does not require hyphae. All yeasts are descended from ancestors that developed hyphae, but hyphal development has been lost independently several times. Thus, the lack of hyphae is an example of convergent evolution, in which the same trait develops independently in different lineages in response to similar selective pressures ([Chapter 22](#)).

Most yeasts divide by budding. In this process, a small outgrowth increases in size and eventually breaks off to form a new cell ([Fig.](#)

**32.3**). The growth of the bud is similar to growth by elongation at hyphal tips. In fact, some yeasts can form hypha-like structures under certain conditions. For example, in *Candida albicans*, a yeast that infects humans, hyphae are produced during the transition of the fungus from a harmless variant to a pathogenic form.

Source: Andrew Syred/Science Source.

FIG. 32.3 The yeast *Saccharomyces cerevisiae*. Yeasts are unicellular fungi that often divide by budding smaller cells off larger ones.

Yeasts are commonly found on the surfaces of plants, and to a lesser extent on the surfaces and in the guts of animals. Humans have long used the yeast *Saccharomyces cerevisiae* to ferment plant carbohydrates as part of the process of producing leavened bread and alcoholic beverages. *Saccharomyces cerevisiae* is also an important model organism used in laboratory studies of genetics.

## Fungi are principal decomposers of

## plant tissues.

Most fungi use dead organic matter as their source of energy and raw materials. On land, the organic matter in dead tissues on and within soils far exceeds the amount in the living biomass. In essence, the ground beneath our feet provides tremendous resources for heterotrophic growth. Bacteria and some protists can use this resource, but for the most part it is the fungi that convert dead organic matter back to carbon dioxide and water. Their activity helps to keep the biological carbon cycle in balance ([Chapter 46](#)) and returns nutrients to the soil, where they are available to support new plant growth.

A brief consideration shows why fungi have the advantage on a forest floor or in soil. Like fungi, bacteria secrete enzymes that break down organic molecules in their immediate environment, but in the soil bacteria have only a limited capacity to move from place to place. Their flagella can propel them a few micrometers through a thin film of water, but when local resources become depleted, bacteria must wait for new food to appear. In contrast, the growing hyphae of fungi can search actively through the soil for new food resources. Furthermore, because their hyphae can penetrate into the interior of a food source, fungi are particularly well suited for breaking down the bodies of multicellular organisms, such as tree stems.

Although fungi can obtain nutrition from dead animal, protozoan, or even bacterial cells, the most abundant biomolecule on and within soils is cellulose, the principal component of plant cell walls ([Chapter 29](#)). Cellulose is a polymer of the sugar glucose, so it is a particularly rich source of carbon and energy. But cellulose is also difficult to degrade

because individual cellulose polymers bind tightly to one another. Fungi secrete enzymes that break the cellulose into individual glucose molecules, which are then absorbed and metabolized. Woody tissues, however, pose an additional challenge. In wood, cellulose is closely associated with lignin, which makes the cellulose even harder to get at. Lignin is difficult for enzymes to break apart, in part because it lacks a regular chemical structure. Wood-rotting fungi produce enzymes that degrade lignin, allowing them to access the cellulose polymers within the wood. A few bacteria are known to degrade lignin, but in nature, fungi account for most of the decomposition of wood ([Fig. 32.4](#)).

To break down lignified plant cell walls, fungi require oxygen. In water-logged environments, where oxygen concentrations are typically low, decay proceeds slowly, if at all. For this reason, woody biomass, once submerged in water, tends to accumulate, leading to the buildup of partially decayed plant material as peat. Over geologically long time

intervals, peat becomes coal. Thus, this energy staple of the industrial world owes its existence to the inhibition of fungal decay.

## Fungi are important plant and animal pathogens.

Fungi not only feed on dead plants and animals, but also are well adapted to infect living tissues ([Fig. 32.5](#)). Plants, for example, are vulnerable to a diverse array of fungal pathogens—rusts, smuts, and molds—that cause huge losses in agricultural production, as we discuss in [section 32.3](#).

Sources: a. Centers for Disease Control and Prevention/ ScienceSource; b. Biophoto Associates/Science Source.

FIG. 32.5 Fungal infection of living tissue. (a) This stained section of heart tissue (pink) is infected with the fungus *Candida albicans* (the purple threadlike structures). (b) A scanning electron micrograph shows hyphae of *Ceratocystis ulmi*, a vascular wilt fungus, growing in xylem vessels of an elm tree.

Invasion is the key to success for plant pathogens ([Chapter 30](#)). Successful pathogens must be able to get past a plant's physical or chemical defenses. This explains why fungal pathogens exhibit host

specificity, meaning that they are able to infect only one or a small number of host species. In many cases, fungi infect plants through wounds, which provide a route through a plant's outer defenses. Some fungi enter through stomata. Others penetrate epidermal cells directly, degrading the wall with enzymes and then using turgor pressure to push their hyphae into the plant's interior. The extent of infection usually depends on the ability of hyphae to expand into new tissues. Vascular wilt fungi ([Chapter 30](#)) send their hyphae through xylem vessels, exploiting this route to spread throughout the entire plant. Old photographs of towns in the eastern United States show streets shaded by American elm trees, but today nearly all those trees are dead, victims of a vascular wilt fungus introduced into the United States early in the twentieth century.

Aboveground, plant infections are usually transmitted by fungal spores, carried either by the wind or on the bodies of insects. For example, many fungi that attack fruits are transmitted by insects also seeking those fruits; yeasts that feed on nectar within flowers may hitch rides on pollinators. Some fungi secrete sugar-rich droplets that attract insects. The insects then transport their fungal spores to other sites.

Belowground, infection is typically transmitted by hyphae that penetrate the roots of plants. Hyphae can feed on organic matter in the soil until they encounter the root of a suitable host plant. The persistence of fungal hyphae in soils means that populations of pathogenic fungi can build up in the soil near a host plant. As a consequence, seedlings germinating close to an adult tree of the same

species are at risk of infection, whereas seedlings of distantly related species may be spared. By favoring the establishment of seedlings of less common species, fungal pathogens are thought to play an important role in maintaining high levels of species diversity in tropical rain forests ([Chapter 30](#)).

Insects and other invertebrates are also susceptible to fungal pathogens. Certain fungi exploit living animals in a unique way: by trapping them. Some fungal predators form sticky traps with their hyphae, whereas others actually lasso their prey ([Fig. 32.6](#)). The hyphae of these fungi form rings that can inflate within seconds, trapping anything within the ring. Nematodes, tiny worms common in soils, may inadvertently pass through the rings, setting off hyphal inflation. The nematodes are then trapped, providing food for the fungus.

FIG. 32.6 A fungal lasso. Hyphae of *Drechlerella doedycoides* form inflated

rings that capture nematode worms moving through the soil.

Fungal infection is relatively rare in vertebrates. Severe infections are more frequent among fish and amphibians than in mammals, perhaps because fungi grow poorly at mammalian body temperatures. An apparent exception is the fungal infection that has caused dramatic declines in North American bat populations. These fungi tend to infect the bats during their winter hibernation, when the bats have lowered body temperatures that conserve energy. In humans, most fungal infections are annoying rather than life threatening; athlete's foot and yeast infections are prime examples. However, in individuals with immune systems compromised by human immunodeficiency virus (HIV) or illness, fungal infection can be fatal.

## Many fungi form symbiotic associations with plants and animals.

While some interactions between species benefit the fungus at the expense of its host, others benefit both partners. In [Chapter 27](#), we saw that mycorrhizal fungi supply plant roots with nutrients such as phosphorus and nitrogen from the soil and, in return, receive carbohydrates from their host ([Fig. 32.7](#)). Two main types of mycorrhizae exist. The hyphae of [ectomycorrhizal](#) fungi surround, but do not penetrate, root cells. In contrast, the hyphae of [endomycorrhizal](#) fungi penetrate into root cells, where they produce highly branched structures that provide a large surface area for nutrient exchange. As we discuss in [section 32.3](#), the endomycorrhizal fungi constitute a monophyletic group dating back more than 400 million

years. In contrast, ectomycorrhizae are present in multiple groups and appear to have evolved more than once.

*Source: Dr. Jeremy Burgess/Science Source*

FIG. 32.7 Mutualistic relationship between fungi and plants. Mycorrhizal fungi (white) surround roots (brown) and produce extensively branched hyphae that extend into the soil.

Other fungi, called [endophytes](#), live within leaves. Although endophytes are much less studied than mycorrhizae, they may be just as widespread. Endophytic hyphae grow within cell walls and in the spaces between cells. Long thought to be harmless, endophytes are now recognized as beneficial to the host plant. They may improve plant growth during stressful conditions, such as drought, or produce chemicals that deter invasion by pathogens and consumption by herbivorous insects.

Mutually beneficial associations between fungi and animals are much less common, but a few examples are known. None is more

striking than the relationship in which insects grow fungi for food. The fungi benefit because the insects provide shelter, food, and protection from predators and pathogens. Insect–fungal agriculture has evolved at least three times: in leaf-cutter ants that live in tropical forests, in a group of African termites, and in some wood-boring beetles. These beetles maintain fungal gardens within tunnels that they excavate in damaged or dead trees.

## Lichens are symbioses between a fungus and a green alga or a cyanobacterium.

**Lichens** are familiar sights in many environments, often forming colorful growths on rocks and tree trunks ([Fig. 32.8](#)). Lichens look, function, and even reproduce as if they are single organisms, but they are actually stable associations between a fungus and a photosynthetic microorganism. The microorganism is usually a green alga but sometimes a cyanobacterium. Nearly 15% of all known fungal species grow as lichens.

Sources: (left to right) Wallace Garrison/Getty Images; Stephen Sharnoff; Stephen Sharnoff.

**FIG. 32.8 Lichens.** A lichen is a mutualistic association between a fungus and a photosynthetic microorganism.

---

The dual nature of lichens was first proposed by a Swiss botanist, Simon Schwendener, in 1867, but his hypothesis found little favor at the time. The possibility of a composite “organism” challenged the idea that all life could be divided into discrete categories such as animals and plants. Biologists also questioned how an association of distinct species could function as an integrated whole. Given what we now understand about the widespread nature of mutualisms, the opposition to Schwendener’s proposal may seem surprising. Yet lichens’ dual nature was widely accepted only in 1939, after Eugen Thomas showed that lichens could be separated into their individual parts and then reassembled.

The bulk of a lichen consists of fungal hyphae. The photosynthetic algae or cyanobacteria form a thin layer just under the surface ([Fig. 32.9](#)). The hyphae anchor the lichen to a rock or tree. They also aid in the uptake and retention of water and nutrients, and produce chemicals that protect the organism against excess light and herbivorous animals. In turn, the photosynthetic partners provide a source of reduced carbon, such as carbohydrates. Cyanobacteria living in lichens can fix nitrogen ([Chapter 24](#)) using  $N_2$  from the atmosphere. The two partners exchange nutrients through fungal hyphae that tightly encircle or even penetrate the walls of the photosynthetic cells. As a result of the association between the two partners, lichens can thrive where neither partner could exist on its own.

It remains an open question whether either partner can exist independently in nature. In cases where the fungal partner can be grown in the laboratory in culture, it produces a relatively undifferentiated hyphal mass. Thus, it appears that chemical signals from the photosynthetic partner influence the form and shape of the fungus.

Surprisingly, these associations are not species specific. There are approximately 13,500 known lichens, but only about 100 participating photosynthetic species. Thus, different lichens may include the same algae or cyanobacteria. Conversely, a given fungal partner may associate with more than one photosynthetic species without affecting the lichen's outward form. Because the lichen's shape and structure depend on the fungal species rather than the photosynthetic partner, the lichen and fungus are assigned the same scientific name.

Lichens spread asexually by fragmentation or through the formation

of dispersal units consisting of a single photosynthetic cell surrounded by hyphae. Sexual reproduction, at least by the fungi, is common, whereas the photosynthetic cells reproduce asexually by mitotic cell division. Whether sexual or asexual reproduction is more important in allowing lichens to establish in new habitats is not known.

Lichens are remarkable for their ability to grow on the surfaces of rocks and tree trunks. They are among the first colonizers of lava flows and the barren land left after glacial retreat. In these habitats, lichens obtain nutrients from rainfall or by secreting organic acids that help release some nutrients from rocky substrates. Not surprisingly, lichens in these harsh environments grow slowly. Other lichens grow on soil. For example, reindeer “moss” grows in the Arctic tundra, where it is eaten by caribou. Reindeer moss is thought to compete successfully for space by secreting chemicals that hinder the growth of plants.

Given their small size and exposure to the environment, lichens must be able to tolerate drying out from time to time. All lichens have a high tolerance for desiccation, and can tolerate wide fluctuations in temperature and light. In contrast, lichens are quite sensitive to air pollution, particularly sulfur dioxide (SO<sub>2</sub>). For this reason, lichen growth is sometimes used as an indicator of industrial pollution.

#### Self-Assessment Questions

1. What are two ways in which fungi differ from other heterotrophic organisms in how they obtain and digest their food?
2. What are two roles of hyphae?

3. How do fungi contribute to the carbon cycle?
4. Which types of organisms make up a lichen? How does each partner benefit from the association?

## 32.2 REPRODUCTION

Fungi face two challenges in completing their life cycles. First, to maintain genetic diversity within populations, they must find other individuals to mate with. Second, they must be able to disperse from one place to another. The majority of fungi reproduce both sexually and asexually. As we discuss in this section, one feature of the sexual life cycle of fungi distinguishes it from all other eukaryotes, and some asexual fungi have a unique way to generate genetic diversity. Fungal adaptations for dispersal broadly resemble those of plants. Fungi rely on wind, water, or animals to carry spores through the environment. Recall from [Chapter 28](#) that spores are specialized cells well adapted for dispersal and long-term survival.

We most often come into contact with fungi through their reproductive structures. Fungal spores commonly cause respiratory illness, and mushrooms attract our attention because they are delicious or poisonous. Many other aspects of fungal reproduction are less easily observed. In this section, we emphasize the most general principles and patterns.

### Fungi proliferate and disperse using spores.

The tissues, living or dead, that fungi feed on often have a patchy distribution. For this reason, fungi must be able to travel from one food source to another. The extensive networks of hyphae within soils or host organisms can spread locally but cannot disperse over great distances, so fungi produce spores that can be carried by the wind ([Fig.](#)

[32.10a](#)), in water, or attached to (or within) animals. In fungi that live in aquatic environments, spores have flagella that allow them to swim. The great majority of fungi, however, live on land, and their spores lack flagella. To overcome these obstacles to their proliferation, fungal spores are encased in a thick wall that protects them as they are dispersed over habitats unsuitable for growth.

FIG. 32.10 Fungal spores dispersed by wind.

The probability that any given spore will come to rest in a favorable habitat is low, so fungi produce large numbers of spores. Fungal spores remain viable, able to grow if provided with an appropriate environment, for periods ranging from only a few hours in some species to many years in others. Thus, spores allow fungi to use resources that are patchy in time as well as in space. In fact, a shortage of resources is one of the cues that triggers spore formation.

Spores can form through either sexual or asexual reproduction. As part of sexual reproduction, spores form by meiotic cell division. In contrast, asexual spores form by mitotic cell division and, therefore, are genetically identical to their parent. In many species, asexual spores are produced within sporangia that form at the ends of erect hyphae, allowing the spores to be released into the air at the appropriate time. Take a close look at a moldy piece of bread: the surface is covered with hyphae carrying sporangia containing asexual spores ([Fig. 32.10b](#)).

Fungal species vary in the extent to which they rely on asexual versus sexual spore production. In some groups, including the most common mushrooms, sexual reproduction is the dominant means of spore production. In a small number of fungi, including the endomycorrhizal species, spores produced by meiotic cell division have never been observed. Although sexual reproduction appears to be absent in some fungal species, asexual fungi have other mechanisms for producing genetic diversity, as discussed later in this section.

## Multicellular fruiting bodies facilitate the dispersal of sexually produced spores.

Fungi employ an astonishing array of mechanisms to enhance spore dispersal. You are probably most familiar with the multicellular [fruiting bodies](#) produced by some fungi. Fruiting bodies are structures that release sexually produced spores into the air for dispersal. (Fungal fruiting bodies should not be confused with the fruits of flowering plants, which are unrelated and very different structures.) Mushrooms,

stinkhorns, puffballs, bracket fungi, and truffles are all fungal fruiting bodies.

Fruiting bodies are highly ordered and compact structures compared with the mycelia from which they grow, yet they are constructed entirely of hyphae ([Fig. 32.11](#)). In fact, in many cases their mechanisms of spore dispersal demand a high degree of structural precision. How tip-growing hyphae can produce such complex and regular structures remains largely a mystery.

The fruiting bodies of many fungi rise above the ground or grow outward from the trunks of dead trees, so the sexually produced spores are released high above the ground. Nevertheless, elevation by itself is not enough to ensure dispersal. To give their spores a boost on their travels, many fungi forcibly eject their spores. The tiny spores achieve velocities of more than 1 m/s, enough to penetrate the layer of unstirred air that surrounds the fruiting body ([Fig. 32.12](#)). Other fungi rely on

external agents such as raindrops or animals to move their spores around. In [section 32.3](#), we will encounter examples of the diverse dispersal mechanisms found in the fungi.

#### HOW DO WE KNOW?

### FIG. 32.12

## What determines the shape of fungal spores that are ejected into the air?

#### BACKGROUND

Many fungi eject spores forcibly into the air. For spores to be picked up by the wind, however, they must escape a layer of still air, called the boundary layer, that lies close to solid surfaces. Escape from the boundary layer is easier if spores have a size and shape that minimize drag, the resistance of air to the movement of an object.

#### HYPOTHESIS

In fungi that eject their spores into the atmosphere, natural selection favors spore shapes that minimize drag.

#### EXPERIMENT

Working from computer models for minimizing drag on airplane wings, Marcus Roper and colleagues calculated which spore shapes would minimize drag. These models took into account spore size as well as the physical characteristics of the air through which spores travel. The scientists then measured spore shape for more than 100 species of spore-ejecting fungi.

#### RESULTS

Nearly three-fourths of the examined spores had shapes that came within 1% of the shape calculated to minimize drag (shown in the figure as blue outlines). Related species that do not eject spores forcibly were less than

half as likely to have drag-minimizing shapes.

# Sexual reproduction in fungi often includes a stage in which haploid cells fuse, but nuclei do not.

Like other sexually reproducing eukaryotes, fungi have life cycles that include haploid ( $1n$ ) and diploid ( $2n$ ) stages. The nuclei in fungal hyphae are haploid, so the fungal life cycle is similar to the life cycles of eukaryotic organisms that exist normally in the haploid stage (see [Fig. 25.3a](#)). Haploid-dominant organisms can multiply by either sexual

or asexual reproduction. Asexual reproduction takes place through the production of haploid spores by mitosis, whereas sexual reproduction takes place as two haploid cells (often male and female gametes) fuse to form a diploid zygote. The zygote undergoes meiosis as its first division, giving rise to sexually produced haploid spores. Sexual reproduction in most fungi differs from all other haploid-dominant organisms in one important respect: in these fungi, the fusion of haploid cells is not immediately followed by the fusion of their nuclei.

In most fungi, the sexual phase of the life cycle takes place through the fusion of hyphal tips rather than the fusion of specialized reproductive cells, or gametes. During mating, two hyphae grow together and release enzymes that digest their cell walls at the point of contact. The contents of the two hyphal cells then merge, forming a single cell with two haploid nuclei.

In most sexually reproducing organisms, when two gametes merge, their nuclei fuse almost instantly to form a diploid zygote. In fungi, however, the cytoplasmic union of two cells ([plasmogamy](#)) is not always followed immediately by the fusion of their nuclei ([karyogamy](#)). Instead, the haploid nuclei retain their independent identities for a while. The period between cell fusion and nuclei fusion is known as the [heterokaryotic](#) (“different nuclei”) stage ([Fig. 32.13](#)). During that stage, a cell contains nuclei from two parental hyphae, but the nuclei remain distinct and even continue to divide. The heterokaryotic stage ends when pairs of nuclei fuse to form diploid zygotes.

FIG. 32.13 Generalized fungal life cycle. In many fungi, plasmogamy and karyogamy are separated by a heterokaryotic stage.

In some groups, the heterokaryotic stage consists of a single cell with many haploid nuclei. In other groups, new septa form as the genetically distinct nuclei replicate so that each cell contains two haploid nuclei, one from each parent. Heterokaryotic cells with two genetically distinct haploid nuclei are referred to as **dikaryotic**, or  **$n + n$** , cells. In dikaryotic fungi (fungi with dikaryotic cells), there may be either a small number of dikaryotic cells or extensively developed hyphae made up of dikaryotic cells. Some edible mushrooms found on market shelves consist entirely of dikaryotic hyphae.

Dikaryotic fungi account for more than 98% of all known fungal species. Their dominance suggests that the separation of plasmogamy and karyogamy in time and space may confer an evolutionary advantage. We can see one such advantage by thinking about the environments where fungi live. Mating takes place principally within the soil or inside the trunks of rotting trees, as those are the sites where hyphae are most likely to come into contact. Dispersal, however, is most effective when spores can be released into the air. The separation of plasmogamy and karyogamy allows mating and spore production to occur where each is most effective.

Nevertheless, in some dikaryotic fungi, the separation of plasmogamy and karyogamy is neither distant in space nor long in time. These fungi produce highly branched dikaryotic hyphae with many cells in which karyogamy will eventually take place. In these fungi, the dikaryotic stage may serve primarily as a means of increasing the number of sexually produced spores that are formed.

At present, we really don't know why fungi proliferate  $n + n$  cells rather than forming a multicellular diploid phase. There may be no single answer to the question of why the dikaryotic fungi have this unique cell type.

## Genetically distinct mating types promote outcrossing.

Under most conditions found in nature, genetically diverse populations persist better than those lacking diversity. Indeed, sexual reproduction is widely viewed as a means of promoting genetic diversity for long-

term ecological success in variable environments ([Chapters 11](#) and [40](#)). But with the exception of fungi that live in aquatic habitats, fungi do not produce male and female gametes. What prevents an individual from mating with itself?

Fungi have different [mating types](#) that are genetically determined and prevent self-fertilization. The mating type of an individual is determined by a mating-type gene. Fertilization can take place only between individuals that have different alleles at the mating-type gene. In some species, there are only two mating-type alleles. In this case, mating patterns are identical to those for species with male and female sexes. If the two mating-type alleles are spread evenly throughout the population, an individual should be able to mate with 50% of the general population.

Other fungi have more than two mating-type alleles. These fungi have a greater likelihood of encountering a compatible mating type. That likelihood is even higher for fungi in which mating type is determined by two different mating-type genes, each of which has multiple alleles. Fungi in the group that includes the common mushrooms can have as many as 20,000 different mating-type alleles. In this case, the odds of finding a compatible mate are close to 100%.

Genetic compatibility is a prerequisite for mating. How do fungi go about finding a suitable mate? The answer is that they secrete chemical signals that attract fungi with mating types different from their own. The chemical structure of these signals differs among groups.

# Parasexual fungi generate genetic diversity by asexual means.

Approximately 20% of fungi appear to lack sexual reproduction altogether. Among these are such well-known groups as *Penicillium* (the source of the antibiotic penicillin), *Aspergillus* (the major industrial source of vitamin C), and all the endomycorrhizal fungi. To proliferate and disperse, these fungi form spores by mitosis.

How are asexual species able to persist without a mechanism for generating genetic diversity? The short answer is, they don't. These fungal species are hypothesized to have another mechanism of generating genetic diversity: the crossing over of DNA during mitosis ([Fig. 32.14](#)). Such species are described as [parasexual](#).

genetic diversity in asexual fungi.

In parasexual fungi, the haploid nuclei within a heterokaryotic cell undergo karyogamy to form a diploid nucleus—so far, a familiar pattern. But then, during mitosis, a rare crossing over may occur between the two sets of chromosomes. Like sexual reproduction, crossing over produces novel gene combinations. The cells lose excess chromosomes over time, such that the haploid state is restored. The key difference between parasexuality and sexual reproduction is that parasexual species do not undergo meiosis.

Entirely asexual species of fungi posed a problem for early taxonomists. These species lack many of the morphological characters such as fruiting bodies or sporangium-bearing stalks that had been used to define different groups. With the advent of DNA sequence data, it has become clear that many asexual species are closely related to sexual forms, indicating that their evolutionary history as asexual species is not long. A major exception are the Glomeromycota, for which fossils as old as 450 million years have been reported.

#### Self-Assessment Questions

5. How do fungi disperse?
6. What is the difference between a diploid cell and a dikaryotic cell?

## 32.3 DIVERSITY

When Aristotle classified the living world into animals and plants, he grouped fungi with plants because of their lack of motility. As discussed in [Chapter 25](#), molecular sequence comparisons now make it clear that fungi are actually related more closely to animals. In fact, it would not be amiss to refer to mushrooms and molds as our “cousins.”

Fungi share a number of features with animals: their motile cells, when present, have a single flagellum attached to their posterior ends; fungi and many animals synthesize chitin; and fungi store energy as glycogen, as do animals. Nevertheless, the last common ancestor of fungi and animals was a single-celled microorganism that lived in aquatic environments approximately 1 billion years ago.

Multicellularity evolved independently in fungi and animals ([Chapter 26](#)), so the fungi have many features that are unique in the biological world.

### Fungi are highly diverse.

By any measure, fungi are diverse, although just how diverse is not known. Approximately 75,000 species have been formally described, but estimates of true fungal diversity run as high as 5 million species. Among eukaryotes, the only organisms more diverse than fungi are the animals. The availability of DNA sequence data has greatly advanced our understanding of phylogenetic relationships within the fungi. The phylogeny depicted in [Fig. 32.15](#) clearly shows how the characters present in familiar mushrooms accumulated through the course of evolution: first cell walls of chitin, then hyphae, then regularly placed

septa, and finally the complex multicellular reproductive bodies we call mushrooms.

The evolutionary history of fungi can be viewed as the transition from flagellated ancestral forms that lived in aquatic environments to soil-dwelling forms in which hyphae divided by septa develop complex structures visible to the naked eye. Moreover, in the ancestral forms, karyogamy is hypothesized to have followed quickly on the heels of

plasmogamy without the formation of a heterokaryotic stage. Thus, another evolutionary trend is the progressive separation in time between plasmogamy and karyogamy in fungal life cycles. Many of the distinguishing features of fungi evolved as adaptations to the challenges faced by land-dwelling nonmotile heterotrophs that absorb nutrients directly from their substrate.

We also see that the numbers of species are not spread evenly across the phylogeny. The two dikaryotic groups include more than 98% of known species, while the remaining 2% is divided among all other groups.

## Chytrids are aquatic fungi that lack hyphae.

Fungi are opisthokonts, members of the eukaryotic superkingdom that includes animals ([Chapter 25](#)). Among fungi, the Chytridiomycota (commonly referred to as [chytrids](#)) were the first groups to diverge. Molecular clock analysis estimates that chytrids began to diversify 800 to 700 million years ago. Today, there are about 1000 species of chytrids found in aquatic or moist environments ([Fig. 32.16](#)).

Source: John Hardy, University of Wisconsin—Stevens Point Department of Biology.

FIG. 32.16 Chytrids. Chytrids are aquatic fungi that attach to decomposing organic matter by rhizoids.

Many chytrids are single cells with walls of chitin. They may also form short multinucleate structures, but they lack the well-defined hyphae characteristic of other fungi. Chytrids, therefore, do not form a true mycelium, although in some species elongated cellular outgrowths called rhizoids penetrate into organic substrates. Rhizoids anchor the organism in place and absorb food molecules.

Chytrids generally disperse by flagellated spores. Sexual reproduction appears to be rare, but there is substantial life-cycle diversity within this group. Chytrids lack a heterokaryotic stage but form flagellated gametes that swim through their aqueous environment.

Most chytrids are decomposers, and a few of them are pathogenic. Notably, infection by the chytrid *Batrachochytrium dendrobatidis* may

be a cause of a widespread decline in amphibian populations ([Chapter 48](#)).

## Zygomycetes produce hyphae undivided by septa.

Moving through the phylogenetic tree, we next encounter several groups traditionally united as the Zygomycota, or [zygomycetes](#) (see [Fig. 32.15](#)). These groups share a number of traits.

Collectively, zygomycetes account for less than 1% of the known fungal species. Some are decomposers, specializing on dead leaves, animal feces, and food. There are probably zygomycetes in your kitchen. Others live on and in plants, animals, and even other fungi. Zygomycetes have many typical fungal traits. For example, they produce mycelia and aerial spores, traits that may have evolved as adaptations for finding food and dispersing on land. Their spores lack flagella, possibly also an adaptation for life on land. Unlike more complex fungi, zygomycetes do not form regular septa along their hyphae, nor do they produce multicellular fruiting bodies.

Earlier, we introduced the black bread mold *Rhizopus*, which is a zygomycete (see [Fig. 32.10b](#)). *Rhizopus* and its relatives are specialists that grow on substrates containing abundant, easy-to-digest carbon compounds, such as bread, ripe fruits, and the dung of herbivorous animals. These fungi consume their substrates rapidly. Once their meal is finished, they release large numbers of aerial spores to locate another food source.

Sexual reproduction occurs when two compatible hyphal tips fuse to form a thick-walled structure containing many nuclei of each mating type. Karyogamy and meiosis follow, then the haploid cell germinates to form an elevated stalk. Each stalk develops a sporangium that contains spores produced asexually by mitotic cell division. If you look closely at a bread mold, you can see the white filamentous hyphae and small black sporangia on slender stalks. Each sporangium can produce as many as 100,000 spores that are dispersed by the wind, explaining how these organisms seem to get everywhere.

Some zygomycete fungi have evolved truly spectacular means of dispersal. *Pilobolus* is a zygomycete that consumes the dung of herbivorous animals. Its life cycle is similar to that of *Rhizopus* except that, instead of releasing individual spores, it forcibly ejects the entire sporangium ([Fig. 32.17](#)). Turgor pressure generated in the supporting stalk propels the sporangia as far as 2 m. Light-sensitive pigments in the stalk's hyphae control the orientation of this water cannon, sending the sporangia hurling toward light. Release in that direction ensures that the spores have the best chance of escaping the dung pile and landing on vegetation that is attractive to grazing herbivores. Feeding herbivores then disperse the spores further, while supplying them with fresh dung for food. The remarkable dispersal of *Pilobolus* sporangia benefits other species as well: parasitic nematode worms hitch a ride on the sporangia to find a new host.

Source: Carolina Biological/Medical Images.

FIG. 32.17 Spore dispersal in a zygomycete. In *Pilobolus*, light-sensing pigments orient the turgor-propelled ejection of the sporangia.

## Glomeromycetes form endomycorrhizae.

The Glomeromycota, or **glomeromycetes**, are a monophyletic group of apparently low diversity (there are only some 200 described species) but tremendous ecological importance. All known glomeromycetes occur in association with plant roots. The most famous species are those that form endomycorrhizae. Molecular clock estimates suggest that glomeromycetes diverged from other fungi 600 to 500 million years ago, before the evolution of vascular plants. Establishment of glomerophyte–root symbiosis changed the course of evolution for both participants. Today, most vascular plant species harbor endomycorrhizae, which dramatically increase the plants' nutrient

uptake from the soil.

Glomeromycetes are difficult to study because they cannot be grown independently of their plant partners, so many unanswered questions remain. For example, no evidence of sexual reproduction has ever been found in this group. Yet genetic studies of glomeromycete populations show some genetic diversity, which is thought to result from parasexual processes. Glomeromycetes produce extremely large (0.1 to 0.5 mm in diameter) multinucleate spores asexually. These large spores can persist in soils until they come into contact with an uninfected root.

## The Dikarya produce regular septa during mitosis.

The final major node, or branching point, in the fungal phylogeny marks the origin of the **Dikarya**, the group that includes approximately 98% of all described fungal species. A key feature of the dikaryotic fungi is that every mitotic division is accompanied by the formation of a new septum. Once septa separated hyphae into many cells, these fungi could control the number of nuclei within each cell and, in turn, proliferate dikaryotic cells. The Dikarya include all the edible mushrooms; the yeast species used in the production of beer, bread, and cheese; the major wood-rotting fungi; and pathogens affecting both crops and humans.

The Dikarya contain two monophyletic subgroups (see [Fig. 32.15](#)), each named for the shape of the cell in which the key reproductive processes of nuclear fusion (karyogamy) and meiosis take place. The

Ascomycota, or [ascomycetes](#), are sometimes called sac fungi because nuclear fusion and meiosis take place in an elongated saclike cell called an ascus (*askos* is Greek for “leather bag”). The Basidiomycota, or [basidiomycetes](#), are popularly known as club fungi because the nuclear fusion and meiosis take place in a club-shaped cell called a basidium. (“Basidium” is derived from the Greek *basis*, which means “base” or “pedestal”; the reference is to the position of sexually produced spores at the tips of this club-shaped body.)

Although ascomycetes and basidiomycetes have the same basic life cycle, they diverged from each other as much as 600 to 500 million years ago and evolved complex multicellular structures independently of each other. The morel found in the supermarket produce section is an ascomycete, whereas the shiitake mushroom next to it is a basidiomycete ([Fig. 32.18](#)). In addition to asci and basidia, the two groups differ in several other features. For example, the septal pores that connect adjacent cells within hyphae are distinct in the two groups. So are the ways in which cells can plug the pores to minimize damage to a mycelium. When ascomycetes reproduce, mating cells form and their nuclei fuse in relatively close succession. Thus, the heterokaryotic stage is brief. In contrast, when basidiomycetes reproduce, the nuclei of two fused cells may remain separate for a long time. The dikaryotic hyphae, containing both types of nuclei, can continue to absorb nutrients from the substrate for a while before the nuclei fuse.

FIG. 32.18 Two groups of dikaryotic fungi. (a) The morel (*Morchella esculenta*) is an ascomycete, whereas (b) the shiitake mushroom (*Lentinula edodes*) is a basidiomycete.

## Ascomycetes are the most diverse group of fungi.

Ascomycetes make up 64% of all known fungal species. They include important wood-rotting fungi, many ectomycorrhizal species, and significant pathogens of both animals and plants. Ascomycetes form the fungal partner in most lichens; approximately 40% of all ascomycete species occur in lichens.

Ascomycetes loom large in human history. They contribute the baker's and brewer's yeasts used to make bread and beer, respectively; the antibiotic penicillin; and model systems employed in laboratory investigations of eukaryotic cell biology and genetics. Ascomycetes are used to produce soy sauce, sake, rice vinegar, and miso, and to transform milk into Brie, Camembert, and Roquefort cheeses. They

cause athlete's foot and other skin infections, as well as many more serious fungal diseases.

Ascomycetes include species that form multicellular fruiting bodies. A remarkable feature of these fruiting bodies is that they contain both dikaryotic and haploid cells. The proliferation of dikaryotic cells leads to the production of many asci, while the growth of haploid cells contributes to the bulk of the fruiting body.

Two ascomycete lineages consist largely of unicellular yeasts, but their close relatives all produce hyphae. Thus, the unicellular nature of yeasts is thought to be a derived feature evolved through loss of hyphae.

**Fig. 32.19** illustrates the life cycle of a common ascomycete, the brown cup fungus. In ascomycetes, meiosis is followed by a single round of mitosis, producing eight haploid spores in each ascus. After they mature, the spores are ejected from the top of the asci, expelled by turgor pressure. In many ascomycetes, fruiting bodies elevate the asci on one or more cup-shaped surfaces. Spores released from these surfaces are easily caught and carried away by wind.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Photo source: Ed Reschke/Getty Images.

FIG. 32.19 The sexual cycle of a common ascomycete, the brown cup fungus (*Peziza* species).

In the fruiting bodies of some ascomycetes, the asci are completely enclosed by a layer of tissue. The spores in these asci must be dispersed by other organisms rather than by the wind. The truffles prized in cooking provide an example. The edible truffle is the fruiting body of an ascomycete that grows as an ectomycorrhizal fungus on tree roots. Not only do truffles encase their spores in protective tissues, but they also develop underground. How, then, can their spores be dispersed? Developing truffles release androstenol, a hormone also

produced by boars before mating. The hormone attracts female pigs, and the pigs unearth and consume the fruiting body. The spores pass through the pig's digestive tract without damage and are released into the environment in feces.

Another ascomycete is thought to have played a role in the events that unfolded in Salem, Massachusetts, in 1692. That year, several girls came down with an unknown illness manifested by delirium, hallucinations, convulsions, and a crawling sensation on the skin. The girls were thought to be bewitched, and their accusations led to the infamous Salem witch trials. Today many scholars prefer a simpler diagnosis for the girls' illness: poisoning by the ascomycete fungus ergot. Ergot is a common pathogen of rye and related grasses, and ingestion of contaminated plants can lead to the symptoms reported in Salem. Like many defensive compounds produced by plants, alkaloid molecules produced by ergot and their derivatives are used in medicine in low doses, such as in the treatment of migraines.

Ascomycetes are even known for producing so-called zombie ants, a topic explored in [Fig. 32.20](#).

#### HOW DO WE KNOW?

### FIG. 32.20

## Can a fungus influence the behavior of an ant?

#### BACKGROUND

A curious death ritual unfolds in the rain forest of Thailand. Spores of the ascomycete fungus *Ophiocordyceps* infect *Camponotus leonardi* ants, growing hyphae inside their bodies. The fungus eventually kills the ant,

and fruiting bodies emerge from the dead ant's head to disperse spores that begin the life cycle anew.

*Camponotus leonardi* ants nest and forage for food high in the forest canopy. The fungus is unable to reproduce in the canopy because ants actively remove fungi from their nests and because the hot dry conditions of the canopy prevent the fungus from developing properly. Infected ants, however, undergo convulsions that cause them to fall to the forest floor. There, the infected ants wander erratically and are unable to climb more than a few meters above the ground before convulsions make them fall again. In their final act, the ants bite into the undersides of leaves and die. Growing within the dead ant, which is now suspended from a leaf, the fungus produces its spores in the humid forest understory and releases them into the air well above the ground.

Is the ants' behavior, including both the convulsions and leaf biting, induced by the fungus?

Source: Alex Wild Photography.

An infected ant attached to a leaf; the ant bit into the leaf with a “death grip” as its final act. A fungal fruiting body is growing from the ant's head.

#### HYPOTHESIS

A parasitic fungus manipulates ant behavior to complete its own reproductive cycle.

## OBSERVATIONS

Biologist David Hughes observed infected and uninfected ants for many hours, recording their behavior.

## RESULTS

Infected ants have repeated convulsions (indicated by vertical bars in the graph), but uninfected ants show no such behavior (not shown).

Transitions from erratic wandering to a “death grip” moment in which the ant bites into a leaf (indicated by red triangles in the graph and shown in the photograph) occur at about the same time of day. In addition, dissections showed that the ants’ death grip results from jaw-muscle wasting caused by the fungus.

## CONCLUSION

The fungi change the behavior of infected ants, inducing a stereotypical behavior that facilitates completion of the fungus’s life cycle. The molecular basis of this manipulation is not yet known.

## FOLLOW-UP WORK

The zombie-like behavior induced by the fungus is an example of what has been called the extended phenotype: the idea that a phenotype should include the effects that an organism has on its environment—in this case,

its effects on host behavior.

SOURCE Hughes, D. P., et al. 2011. “Behavioral Mechanisms and Morphological Symptoms of Zombie Ants Dying from Fungal Infections.” *BMC Ecology* 11:13–22.

## Basidiomycetes include smuts, rusts, and mushrooms.

The basidiomycetes make up 34% of all described fungal species. There are three major groups ([Fig. 32.21](#)). Two of these groups, the smuts and rusts, consist primarily of plant pathogens. The third includes many of the most commonly observed mushrooms.

Sources: a. Inga Spence/Science Source; b. Bitty Roy, University of Oregon; c. David Clapp/Getty Images.

FIG. 32.21 Basidiomycetes. (a) Corn smut (*Ustilago maydis*); (b) pseudoflowers that form when plants are infected by the rust *Puccinia monoica*; (c) a toadstool fungus, the highly toxic *Amanita*.

Smut fungi, which infect the reproductive tissues of grasses and related plants, take their name from the black sooty spores that they produce. *Ustilago maydis*, the corn smut, turns developing corn kernels into soft gray masses that are a culinary delicacy in Mexico. Because smuts infect seeds, their spread is magnified by the harvest, storage, and eventual sowing of crop seeds. Before the introduction of chemical

seed treatments in the 1930s, infection by *Tilletia* (the stinking smut) commonly caused the loss of as much as 50% of the wheat harvest. Smuts remain a problem in parts of the world where untreated seeds are still planted.

Rusts can also have profound impacts on plant function and development. For example, the rust *Puccinia monoica* alters leaf development in its host plant *Arabis*. The affected leaves develop into a pseudoflower that attracts insects by visual and olfactory cues as well as nectar rewards. These pseudopollinators then transport the spores. In this way they enhance outcrossing as well as dispersal of the fungi, but provide no service to the plant. In the next section we examine Ug99, a highly virulent wheat rust first reported in Uganda in 1999.

The third basidiomycete group is characterized by the formation of multicellular fruiting bodies. This group includes the iconic toadstools with their central stalk and umbrella-like cap, as well as the diverse shapes seen in stinkhorns, puffballs, and bracket fungi ([Fig. 32.22](#)).

Sources: a. Bill Gozansky/AGE Fotostock; b. Wally Eberhart/Getty Images; c. Bob Gibbons/Science Source.

FIG. 32.22 Diverse fruiting bodies of basidiomycetes. (a) Stinkhorn (*Dictyophora indusiata*); (b) puffball (*Calvatia gigantea*); (c) bracket fungi (*Ganoderma*

*australe*).

**Fig. 32.23** shows the life cycle of a typical basidiomycete mushroom. It is similar to the life cycle of ascomycetes (see [Fig. 32.19](#)), with a few differences. The fruiting body is made up entirely of dikaryotic hyphae, instead of a combination of dikaryotic and haploid hyphae as in ascomycetes. In addition, nuclear fusion (karyogamy) takes place in a specialized cell called a basidium rather than in an ascus. Finally, the haploid products of meiosis (the spores) do not undergo mitosis, so four spores are produced from each basidium rather than eight.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 32.23 The sexual cycle of a basidiomycete that forms multicellular fruiting bodies.

---

Most species in this third group form ectomycorrhizal associations or decompose wood and other substrates. The fruiting bodies that we see elevated above a rotting log or the soil are connected to extensive mycelia that provide resources for fruiting-body development.

Basidiomycetes that form conspicuous fruiting bodies have diverse mechanisms for dispersing their spores. For example, puffballs function like bellows: the impact of raindrops forces the loose, dry spores out of a small hole at the tip of the ball (see [Fig. 32.10a](#)). Bird's nest fungi function like splash cups: raindrops displace groups of spores (the "eggs" in the nest) onto nearby vegetation. Herbivores then consume the spores along with the vegetation and deposit the spores in a new dung pile. Stinkhorns produce spores in a stinky, sticky mass that attracts insects; the spores stick to the insects' legs and bodies, and are carried off in this way to new locales.

Perhaps the most remarkable mechanism for spore dispersal occurs in the many basidiomycetes that depend on surface tension to catapult their spores through the air. The placement of their four spores on the ends of short stalks is the key to this mechanism. Both the spores and the supporting basidial cell actively secrete solutes that cause water to condense on their surfaces. At first, the droplets are independent, but as they grow they eventually come into contact with one another. At this point, the high surface tension of water causes them to merge into a single, smooth droplet. This change in shape shifts the center of mass of the water with enough force that it catapults the spore into the air.

Basidiomycetes that rely on surface tension produce their basidia on

tightly packed vertical surfaces, such as the “gills” of common mushrooms ([Fig. 32.24](#)). The spores are flung from the basidia into the air between the vertical surfaces, where they sink due to gravity until they are outside of the fruiting body and can be carried off by the wind. For this mechanism to work, both the orientation of the basidia-lined surfaces and the catapult mechanism must be exquisitely coordinated. If the surfaces are not perfectly vertical, then the spores will not be able to fall from the mushroom. Similarly, if the surfaces are too close together or the force that ejects the spores is too great, the spores will crash into the opposing surface. This arrangement allows huge numbers of basidia to be produced within a single fruiting body, while providing a way for the spores to reach the surrounding air.

## CASE 6 AGRICULTURE: FEEDING A GROWING

## POPULATION

# How do fungi threaten global wheat production?

Throughout much of human history, crops have been vulnerable to infection by *Puccinia graminis*, the black stem rust of wheat. *Puccinia graminis* first infects wheat leaves and stems through their stomata, and then extends within the plant's living tissues to fuel its own growth. Rust-colored pustules erupt along the stem. These pustules release a vast number of spores, leaving the host plant to wither and die.

Crop losses from *P. graminis* can be devastating. In the past, recognizing how badly food supplies could be disrupted using this fungus, both the United States and the Soviet Union tried to develop black stem rust as a biological weapon. The U.S. version was cluster bombs (since destroyed) containing turkey feathers smeared with rust spores. The aim was to disrupt crop yields in enemy countries.

Many rusts have a life history in which they alternate between different host species. For example, to complete its life cycle, *P. graminis* must infect first wheat and then barberry bushes (*Berberis* species). During a particularly severe outbreak of wheat rust during World War I, crop losses equaled one-third of total U.S. wheat consumption. In response, a major program of barberry eradication was started to bring stem rusts under control. This program reduced the threat, but did not totally eliminate it.

The Green Revolution seemed to give growers a decisive advantage over stem rust. During World War II, the Rockefeller Foundation sent Norman Borlaug, whose original training was in plant pathology, to Mexico to help combat crop losses due to stem rust. Borlaug was eventually able to breed resistant wheat varieties. Much of the resistance shown by his varieties could be attributed to variation in a small number of genes. Stem rusts were apparently vanquished by Borlaug's discoveries—that is, until the appearance of Ug99, a wheat stem rust first identified in Uganda in 1999 (hence the name). At that time, Ug99 was capable of defeating all known resistance genes. Although scientists have recently identified new genes that confer resistance to Ug99, it will take time to incorporate these into cultivated varieties. Given that wheat accounts for 20% of daily global calorie consumption by [humans](#) and that 90% of cultivated wheat has little or no resistance to Ug99, the appearance of this resistant fungus is cause for major concern.

At present, Ug99 shows every sign of spreading ([Fig. 32.25](#)). This fact is not surprising given that a single hectare of infected wheat produces upward of 1 billion spores. Ug99 currently devastates wheat production in Kenya and has been found in Yemen (2006), Iran (2007), and South Africa (2009). As you read this, Ug99 is poised to reach the major wheat-growing regions of Turkey and South Asia. Even more rapid spread is possible if spores accidentally lodge on cargo or airline passengers.

Sources: After Food and Agriculture Organization of the United Nations. 2010. "The Spread of Wheat Stem Rust Ug99 Lineage." JPEG image, <http://www.fao.org/agriculture/crops/rust/stem/rust-report/stem-ug99racettksk/en/>; (photos) Yue Jin, USDA-ARS, Cereal Disease Laboratory.

FIG. 32.25 The spread of Ug99. Ug99 is a highly resistant stem rust of wheat and a major threat to global food production.

Just before his death in 2009, Norman Borlaug urged the world to take this threat seriously. Today, plant breeders are actively searching ancestral wheat varieties for genetic sources of resistance to Ug99, while other scientists try to understand how plants defend themselves against rusts and what makes Ug99 so virulent. The resurgence of *P. graminis* as a serious threat to world food production underscores the importance of safeguarding the genetic diversity of agricultural species

so that the inevitable evolutionary battles with pathogenic species may be waged successfully.

#### Self-Assessment Questions

7. What are two key innovations in the evolutionary history of fungi that allowed them to move from water to land?
8. Based on the phylogenetic tree shown in [Fig. 32.15](#), did complex multicellular fruiting bodies evolve once or twice (independently) in fungi?
9. Draw the life cycle of an ascomycete, and indicate the heterokaryotic stage.
10. Draw the life cycle of a basidiomycete, and indicate the heterokaryotic stage.
11. How did the evolution of vascular plants provide opportunities for fungal diversification?

## CORE CONCEPTS SUMMARY

**32.1 GROWTH AND NUTRITION:** Fungi are heterotrophic eukaryotes that feed by absorption.

Most fungi produce slender, multicellular filaments called hyphae that form a network called a mycelium. Fungi rely on the growth of hyphae to find food and absorb nutrients. [page 713](#)

Fungi can transport food and signaling molecules within their hyphae using bulk flow, allowing them to grow between nutrient patches and to produce reproductive structures aboveground. [page 714](#)

Some fungi, such as yeasts, do not produce hyphae. [page 715](#)

Fungi are critical elements of the carbon cycle, feeding on dead organic matter and converting it back into carbon dioxide and water. [page 715](#)

Many fungi feed on living animals and plants, causing diseases. [page 716](#)

Fungi have repeatedly evolved mutually beneficial relationships with plants and animals. [page 717](#)

Lichens are stable associations between a fungus and a photosynthetic microorganism that look, function, and even reproduce as single organisms. [page 718](#)

**32.2 REPRODUCTION:** Fungi reproduce both sexually and asexually, and disperse by spores.

Fungi produce haploid spores that are dispersed by wind, water, or animals. Spores can be produced asexually (by mitosis) or sexually (by cell fusion and meiosis). [page 719](#)

During sexual reproduction, many fungi produce spores within multicellular fruiting bodies that enhance spore dispersal. [page 720](#)

The fungal life cycle is similar to the haploid-dominant life cycles found in many eukaryotic organisms, except that plasmogamy (cell fusion) and karyogamy (nuclear fusion) are often separated. [page 722](#)

During the period between cell fusion and nuclear fusion, called the heterokaryotic stage, genetically distinct haploid nuclei are found in the same cell. [page 722](#)

Genetically determined mating types prevent self-fertilization in many fungi. [page 723](#)

Parasexual fungi lack sexual reproduction. They are hypothesized to generate genetic diversity by fusion of haploid nuclei, followed by crossing over during mitosis and chromosome loss. [page 723](#)

**32.3 DIVERSITY:** Other than animals, fungi are the most diverse group of eukaryotic organisms.

Approximately 75,000 fungal species have been formally described, but the total diversity may be as high as 5 million species. [page 724](#)

Chytrids are fungi that reside in aquatic or moist habitats and lack well-defined hyphae. Only about 1000 species have been identified.

[page 724](#)

Zygomycetes produce hyphae without septa and account for less than 1% of known fungal species. [page 725](#)

The glomeromycetes are a group of fungi of low diversity but tremendous ecological importance because of their association with plant roots. [page 726](#)

Most fungi belong to the Dikarya (ascomycetes and basidiomycetes), which form septa along their hyphae. During the heterokaryotic stage, these fungi produce cells that contain two haploid nuclei, one from each parent. [page 726](#)

Ascomycetes include wood-rotting fungi, many ectomycorrhizal species, plant and animal pathogens, the fungal partner in most lichens, and baker's and brewer's yeasts. [page 726](#)

Basidiomycetes include the familiar toadstools and puffballs, as well as plant pathogens [page 728](#)

## CASE 7

### Biology-Inspired Design

*Using Nature to Solve Problems*

What does Velcro have in common with the Eiffel Tower? At first, it might seem very little. Velcro is a common fastener, found in everything from sneakers to coats to tents. The Eiffel Tower is a landmark in Paris and symbol of France. It turns out, however, that both were inspired by nature.

*Biology-inspired design holds great promise for tackling all kinds of problems.*

Velcro was invented in the 1940s by George de Mestral, a Swiss engineer. He realized that the burs of plants, which seem

to stick everywhere, might provide a model for an effective way to hold things together. Taking a closer look, he noticed that their “stickiness” is due to the presence of small hooks that grab on to the loops of fabric, like pants, or to the fur of passing animals.

Why not use this same structure to build something that holds firmly, but releases easily? Taking his cue from nature, de Mestral constructed a fastener made up of two parts: one with small hooks and the other with small loops. He called this new material Velcro. Ever

since its invention, Velcro has had many practical applications; it is used to fasten clothing, hang pictures, and close packages, to name just a few.

*Sources: a. visual7/Getty Images; b. curtoicurto/Getty Images.*

**Plant burs and Velcro.** (a) A bur is a seed or fruit with small hooks that grab on to passing animals. (b) Velcro has two strips: one with loops, and the other with hooks similar to the burs of plants.

The engineers who built the Eiffel Tower in Paris also looked to nature to solve the problem of how to construct what was the tallest

building in the world at the time. Built in 1889 for the World's Fair, the tower stands 324 m tall (approximately 1063 feet or 80 stories). The engineers who constructed the tower examined other structures notable for their strength, namely bones, and asked how these relatively light structures can support tremendous weight. Bones, like the human femur (thighbone), have an internal meshwork at the ends that is aligned in the direction of the major stresses, and strong support along the shafts.

Sources: a. B Christopher/Alamy; b. Denitsa Ivanova/EyeEm/Getty Images.

Bones and the Eiffel Tower. (a) Bones consist of a spongy meshwork of material

with support along lines of stress. (b) The Eiffel Tower uses principles similar to those found in bones so that the structure is both strong and lightweight.

The Eiffel Tower, too, is made up of crisscrossing beams that help to distribute the weight and includes strong lines of support running from the base to the tip. As a result, it is lightweight and uses very little material for its size. Many cranes, bridges, and skyscrapers use similar architectural principles, borrowed from nature.

The use of nature to tackle problems is known as biology-inspired design. It draws from many fields, including biology, engineering, physics, and materials science, providing an interdisciplinary way to solve all kinds of practical problems.

Take the problem of suction. Remoras (fishes in the family Echeneidae) are famous for their ability to hitch a ride on sharks, whales, rays, small boats, and occasionally scuba divers. A remora has a modified fin along its back that acts like a suction cup. It uses this structure to stick to other fishes and get a free ride, catch scraps of food, and aerate its gills as the host fish swims along.

Dr. Jason Nadler and his colleagues at the Georgia Tech Research Institute are studying the anatomy and physiology of the remora's "suction cup" in an effort to understand how it functions so effectively. The cup creates a tight seal, but it can also be released quickly and easily. When they understand how it functions, the researchers will try to mimic it so as to design, for example, underwater adhesives or medical bandages that hold firmly but can be removed easily.

Source: Papilio/Alamy.

A remora. Remoras use a modified dorsal fin to stick to surfaces, such as this shark.

Biology-inspired design sometimes uses biology to solve problems, as we have seen. Another aim of the field is to mimic nature to provide replacement parts, particularly in the field of medicine. Whether the replacement part is a mechanical valve to replace a damaged or diseased heart valve, a dialysis machine that functions like a kidney, a limb prosthesis for an arm or leg lost to trauma or disease, or a cochlear implant to provide a sense of hearing for individuals with hearing loss, many parts of the human body can now be built and replaced.

There is an old saying: If you can model something, you understand it. Another goal of biology-inspired design, then, is to test our understanding of a structure or process. Take the gravity-defying climbing ability of geckos (lizards in the group Gekkota). They are famous for running up smooth walls and even scurrying across ceilings. How do they do it?

Geckos have toe pads made up of many small hairs. It is thought that these hairs adhere to surfaces by van der Waals interactions ([Chapter 2](#)). Although these interactions are weak individually, the large number of hairs (an estimated 6.5 million in total!) results in a strong force overall.

We can test this idea by building it. In 2014, researchers at Stanford University's Biomimetic Dexterous Manipulation Laboratory engineered synthetic toe pad hairs made of silicone that allow humans to scale a glass wall. By examining gecko toe pads' adhesive properties, the researchers were able to copy it to provide suction that would support humans.

Sources: a. nico99/Shutterstock; b. Eric Eason/  
Biomimetics and Dexterous Manipulation Lab,  
Stanford University.

Geckos and “gecko gloves.” (a) Geckos can climb up walls. (b) Adhesive gloves modeled after gecko toe pads allow this man to scale a glass wall.

Sometimes, researchers don’t just mimic part of an organism, like the toe pads of geckos. Instead, they build the entire animal. To date,

researchers have developed bipedal human-like robots, as well as robotic dogs, hummingbirds, fishes, jellyfish, flies, grasshoppers, and even cockroaches. These devices are made in part to understand how the animals move, but also to take advantage of specific features of these animals. Cockroaches can move quickly and fit into tight spaces, so a robotic cockroach could be used to search for survivors after a building collapse, for example.

Recently, Dr. Joanna Aizenberg and her colleagues at Harvard University went beyond mimicking just one organism. Specifically, they combined parts of a desert beetle, cactus, and pitcher plant to make a material that collects water from the air. This material provides a way to collect water in deserts, where water is scarce. It also might prove useful in industries where it's important to keep the air dry and avoid condensation.

Biology-inspired design holds great promise for tackling all kinds of problems. In the end, what we build and what we find in nature may look quite similar to each other, but they arrived there along two different paths. We typically build things with a clear goal in mind, like the tallest tower or adhesive gloves. What we find in nature, by contrast, evolved over time without a goal. Evolution works by “tinkering,” as the French biologist François Jacob famously said, using what it has and sometimes even modifying existing structures for new functions. After 4 billion years of life on Earth, it has stumbled across some beautiful and clever solutions that are worth mimicking.

---

## DELVING DEEPER INTO CASE 7

**For each of the Cases, we provide a set of questions to pique your curiosity. The questions cannot be answered directly from the Case itself, but instead introduce issues that will be addressed in chapters to come. We revisit this Case in [Chapters 33–42](#) on the pages indicated below.**

1. How can we mimic the form and function of animals to build robots? See [page 607](#).
  2. How do cochlear implants work? See [page 774](#).
  3. How can we design smart materials to heal damaged bones and improve artificial joints? See [page 805](#).
  4. How can we engineer replacement heart valves? See [page 849](#).
  5. How does dialysis work? See [page 894](#).
  6. How can we use a protein that circulates in the blood to treat sepsis? See [page 930](#).

## CHAPTER 33 Animal Form, Function, and Evolutionary History

4FR/Getty Images

---

### CORE CONCEPTS

**33.1 ANIMAL BODY PLANS:** Animals have a limited number of

distinct body plans.

**33.2 TISSUES AND ORGANS:** Most animals have four different types of tissue, which combine to form organs.

**33.3 HOMEOSTASIS:** Homeostasis actively maintains a stable internal environment.

**33.4 EVOLUTIONARY HISTORY:** Animals evolved more than 600 million years ago in the oceans, and by 500 million years ago the major body plans were in place.

---

Animals move, feed, and behave in many different ways. Indeed, animals have evolved a remarkable variety of structures to carry out these and other functions. As an example, consider the ways in which animals move ([Chapter 35](#)). Sponges have no muscle cells at all; rooted to the ground, they don't move from place to place. Jellyfish have muscle fibers that contract to squeeze a fluid-filled cavity, powering movement by jet propulsion. Mammals have limbs for locomotion, which are powered by the coordinated actions of muscles attached to an internal skeleton. Insects move in much the same way, but their skeleton is external. Other organ systems show comparable variation among animals. The wide range of anatomical and physiological variations has permitted animals to diversify to a remarkable degree.

Biologists have described approximately 1.8 million species of eukaryotic organisms from the world's forests, deserts, grasslands, and oceans. Of these, some 1.3 million species are animals. There is reason to believe that animal diversification began in the oceans, but today most animal species are found on land. Indeed, the majority of all

animal species are insects. In this chapter, we look at animals as a group, focusing on their basic form, function, and evolutionary history.

## 33.1 ANIMAL BODY PLANS

As discussed in [Chapter 22](#), it is relatively easy to understand how the body plans of humans, chimpanzees, and gorillas show them to be more closely related to one another than any of them is to other animal species. Furthermore, it isn't hard to see that humans, chimpanzees, and gorillas are more closely related to monkeys than they are to lemurs, and that humans, chimpanzees, gorillas, and monkeys are more closely related to lemurs than they are to horses. Anatomy and morphology reveal key evolutionary relationships among vertebrate animals, but how do we come to understand the place of vertebrates in a broader tree that includes all animals? More generally, how can we construct an animal phylogeny that includes organisms with body plans as different as those of sponges, jellyfish, earthworms, mussels, sea stars, and humans?

### What is an animal?

Let's begin by asking what an animal is. Which features differentiate animals from all other organisms? And, more specifically, which features differentiate animals from their nearest relatives?

As introduced in [Chapter 25](#), the organisms most closely related to animals are choanoflagellates, a group of single-celled eukaryotes. This relationship was first proposed in the nineteenth century by scientists who noticed similarities in cell shape between choanoflagellates and the feeding cells of sponges; it was confirmed in the twenty-first century through comparisons of molecular sequences. Choanoflagellates are unicellular, whereas animals are multicellular.

But multicellularity is not a unique feature of animals: plants and fungi are also multicellular. Thus, we need to find another feature to distinguish animals from other organisms.

Animals are heterotrophs, gaining energy and carbon from preformed organic molecules ([Chapter 6](#)). This character differentiates animals from plants, but not from fungi, which are also heterotrophs. Animal cells lack cell walls, allowing them to move during development and in the adult animal ([Chapter 26](#)). This character differentiates animals from both plants and fungi. Animals have a pattern of early embryological development that begins with a hollow ball of cells called a blastula and includes the movement of embryonic cells, usually to form a gastrula ([Chapters 19, 26, and 40](#)), a process unique to animals.

Animals, therefore, can be described as multicellular heterotrophic eukaryotes with a distinctive mode of early development. Other features also distinguish animals from other organisms, but as we learn more about choanoflagellates, some of these lines have blurred. For example, collagen, long considered to be unique to animals, is now known to occur in choanoflagellates.

## Animals can be classified based on type of symmetry.

Early in the history of biology, taxonomists such as Carl Linnaeus recognized that for all their diversity, animals have a limited number of distinctive body plans. Animals with the same type of body plan can be placed into a group called a phylum. The problem for biologists has

long been how to understand the evolutionary relationships among animal phyla. Indeed, this is still an active field of research.

In [Chapter 21](#), we saw that the fundamental mechanism by which biological diversity increases is speciation, the divergence of two populations from a common ancestor. Played out repeatedly through time, speciation gives rise to a treelike pattern of evolutionary relatedness: more closely related groups diverge from branch points close to the tips of the tree, whereas more distantly related groups diverge from branch points nearer its base. Distinctive features of organisms, called characters, evolve throughout evolutionary history. We can estimate when a character arose from its shared presence in the descendants of the population in which the character first evolved. Often the characters analyzed are anatomical traits.

[Fig. 33.1](#) shows a phylogenetic tree of animals. Most animals can be divided into three groups based on the symmetry of their bodies.

[Porifera](#) (sponges) are irregular in form, with no clearly developed plane of symmetry. [Cnidaria](#) (the group that includes jellyfish, corals, and sea anemones) display radial symmetry. Their bodies have an axis that runs from mouth to base, with many planes of symmetry cutting through this axis ([Fig. 33.2a](#)). Because of this structure, jellyfish can move up and down in the water column by flexing the muscles around their bell-like bodies, and many sea anemones and corals can wave their ring of food-gathering tentacles in all directions at once.

Fig. 33.2 Symmetry in animal form. (a) Radial versus (b) bilateral symmetry distinguishes cnidarians and bilaterian animals.

**Bilateria** (most other animals, including humans, insects, and snails) show bilateral symmetry. Their bodies have a distinct front and back, top and bottom, and right and left, with a single plane of symmetry running between right and left at the midline ([Fig. 33.2b](#)). Animals with bilateral symmetry are able to move in a horizontal direction to capture prey, find shelter, and escape from enemies. These animals develop specialized sensory organs at the front end for guidance ([Chapter 34](#)), and specialized appendages along both sides for locomotion, grasping, and defense.

The phylogenetic tree in [Fig. 33.1](#) also indicates that animals are closely related to choanoflagellates, but differ from them in having persistent multicellularity and in forming a blastula during early development. Poriferans have only a few different cell types, and these cells are organized into only simple tissues, not the well-defined tissues and complex organs found in other animals ([Section 33.2](#)). Cnidarians have well-defined tissues, but lack complex organs. Bilaterians have both well-defined tissues and complex organs. These organs are specialized for movement, digestion, gas exchange, and other functions.

Note that the phylogenetic tree shown in [Fig. 33.1](#) does not tell us that sponges are older than other animals. Instead, it says that sponges and other animals diverged from a common ancestor, but it doesn't tell us what that common ancestor looked like. Similarly, cnidarians and

animals with bilateral symmetry diverged from their last common ancestor at a single point in time and so are equally old, but structurally distinct.

## Many animals have a brain and specialized sensory organs at the front of the body.

A notable feature of many bilaterian animals is that nervous system tissue, including specialized sense organs such as eyes, becomes concentrated at one end of the body. For example, the eyespots of flatworms are located at one end of its body, as are the brain and sense organs of earthworms, insects, and vertebrates ([Fig. 33.3](#)). The concentration of nervous system components at one end of the body, defined as the “front,” is referred to as [cephalization](#). Cephalization is a key feature of the body plan of most animals, including vertebrates.

Photo sources: (left to right) Science History Images/Alamy Stock Photo; bazillfoto/iStock/Getty Images; marcoulina/Getty Images; taviphoto/Getty Images.

**Fig. 33.3 Cephalization.** (a) Flatworms, (b) earthworms, (c) insects, and (d) vertebrates all have a distinct head region with specialized sense organs.

Cephalization is considered an adaptation for locomotion because it allows animals to take in sensory information from the environment ahead of them as they move forward. In addition, the proximity of the sensory organs to the brain makes it possible to process this information quickly, thereby enabling a suitable behavioral response. As the quality and amount of sensory information taken in by animals increased, their brain size and complexity also increased. Cephalization is also considered to be an adaptation for predation, since animals with cephalization can better detect and capture prey, and for predator avoidance, providing a means of escaping capture.

Although cephalization is a feature of many animals, it has been particularly well studied in vertebrates. In vertebrates, the brain, many sense organs, and the mouth are all located in the head. Vertebrates have also evolved several novel features located in the head, including a jaw, teeth, and tongue. These structures are all thought to be adaptations for predation, or more generally the acquisition and processing of food.

As a result of evolutionary selection for enhanced sensory perception and the ability to respond to important cues in the environment, the brain, sensory organs, and nervous system of many animals are complex in their organization. Notably, they are linked to more sophisticated abilities that allow for a broad range of behaviors. Such abilities are critical to the success of both predators and prey, and they underlie the complex interactions that occur among members of a species when they mate, reproduce, disperse, and care for their young.

## Some animals also show segmentation.

In addition to cephalization, another broad pattern that is evident among the body plans of bilaterian animals is segmentation.

**Segmentation** is the organization of the body into units, or segments, that are repeated from front to back (along the anterior–posterior axis), but modified depending on where they are located in the body.

Insects, for example, have a head, thorax, and abdomen ([Fig. 33.4](#)). Each of these regions can be further subdivided into segments. For example, each of three pairs of legs grows from one of the three segments that make up the thorax. In [Chapter 19](#), we considered some of the genetic mechanisms that generate this segmented pattern in the fruit fly *Drosophila*. Humans and other vertebrates also develop in a segmented fashion, as is evident in the repeated pattern of vertebrae and nerves that make up the backbone and spinal cord.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
Photo source: Herman Eisenbeiss/Getty Images.

Fig. 33.4 Segmentation. Insects, such as the fruit fly *Drosophila melanogaster*, have a head, thorax, and abdomen, each of which is made up of segments.

Three animal phyla are known for showing a segmented body plan: arthropods (including insects, spiders, and crustaceans), annelids (segmented worms), and chordates (including vertebrates). Segmentation allows for the differentiation of segments into distinct body parts and may have evolved as an adaptation for higher motility.

## Animals can be classified based on the number of their germ layers.

New insights about animals became possible with the advent of microscopes that enabled the direct study of early animal embryos. One important observation was that some animals that look very different as adults share patterns of early embryological development. For example, adult sea stars and catfish look very different from each

other, but their embryos show a number of key similarities, including the way that the early cell divisions occur and the number of embryonic tissue layers they develop.

In cnidarians (radially symmetrical animals), the embryo has two germ layers, the endoderm and the ectoderm, from which the adult tissues develop. Because of this characteristic, these animals are called **diploblastic** (Fig. 33.5). In bilaterians (bilaterally symmetrical animals), the embryo has three germ layers, with the mesoderm between the endoderm and ectoderm. These animals are called **triploblastic** (Fig. 33.5). The evolution of the mesoderm in triploblasts allowed for the development of new types of tissues and organs, such as muscles and circulatory systems. These new types of tissues and organs, in turn, facilitated the evolution of new modes of locomotion, feeding, and behavior.

Fig. 33.5 Variation in embryonic development. Early development of germ tissues in the embryo separates the diploblastic cnidarians from the triploblastic bilaterians.

Comparative embryology also enabled biologists to divide bilaterian animals into the two groups shown in [Fig. 33.6](#): the **protostomes** (from the Greek for “first mouth”) and the **deuterostomes** (from the Greek for “second mouth”). In protostomes, the earliest-forming opening to the internal cavity of the developing embryo, called the blastopore, becomes the mouth. Protostomes include such groups as nematodes (roundworms), arthropods (including insects, spiders, and crustaceans), mollusks (gastropods like snails and slugs; bivalves like clams and mussels; and cephalopods like squids and octopus), annelids (segmented worms), and flatworms ([Fig. 33.7](#)). In deuterostomes, the blastopore becomes the anus, and the mouth forms second. Deuterostomes include chordates, such as vertebrates, and echinoderms, such as sea stars, sea urchins, and sand dollars ([Fig. 33.7](#)).

Fig. 33.7 Phylogeny of animals, showing major phyla of bilaterians.

While the names of the protostomes and deuterostomes focus our attention on which structure the blastopore becomes, these groups exhibit a host of other differences. For example, they differ in the nature of the early divisions of the embryo, the origin of the mesoderm, and the position of the nerve cord running the length of the body. Only in the age of molecular sequence comparisons have the relationships among phyla within each of these two groups become clear.

## Molecular sequence comparisons have confirmed some relationships and raised new questions.

Early biologists laid the groundwork for understanding animal phylogeny by relying on their observations of comparative anatomy and embryonic development. Yet as was true for phylogenetic relationships in Bacteria, Archaea, and Eukarya as a whole, a modern understanding of evolutionary relationships among animals had to wait for the revolution in molecular sequencing. Over the past two decades, comparisons among DNA, RNA, and amino acid sequences have greatly improved our understanding of animal phylogeny. Molecular comparisons support many of the conclusions reached by the early biologists, including the early divergence of sponges and the separation of radially and bilaterally symmetrical animals. Moreover, molecular sequence comparisons confirm that choanoflagellates are the closest protistan relatives of animals.

Other hypotheses have been rejected. For example, some biologists pointed to the presence or absence of a cavity, or [coelom](#), surrounding

the gut, as a character that could be used to organize bilaterians into three groups: those without a body cavity (acoelomates) and those with a body cavity (coelomates and pseudocoelomates, which differ in the embryonic origin of the cells lining the cavity). These body plans are shown in [Fig. 33.8](#). The coelom cushions the internal organs against hard blows to the body and enables the body to turn without twisting these organs. Once molecular studies were conducted, however, researchers discovered that they did not support this traditional phylogenetic division of bilaterians into acoelomate, coelomate, and pseudocoelomate groups. Similarly, molecular sequence comparisons have not supported the once widespread view that segmented bodies indicate a close relationship between earthworms and lobsters.

Fig. 33.8 Major types of anatomical organization of bilaterian animals. Bilaterians vary in the presence, absence, or structure of a body cavity.

## CASE 7 BIOLOGY-INSPIRED DESIGN: USING NATURE TO SOLVE PROBLEMS

### Can we mimic the form and function of animals to build robots?

Scientists who design robots often try to mimic the form and function of animals. Fishes are one of the most popular types of robotic animals. We can learn a great deal about innovations by studying fishes, whose remarkable adaptations have been shaped by natural selection over more than 500 million years.

The first robotic fish was created in the 1980s by a team of scientists and engineers at Massachusetts Institute of Technology. It was called RoboTuna because it mimicked the form and function of a tuna, allowing it to swim effectively through water. Since then, many more fish-like robots have been made, so that today there are more than 400 different types of robotic fishes. Some, like RoboTuna, have one joint; others have many joints; and still others are made of dynamic materials that can bend fluidly.

Why build a robotic fish? The first and most basic reason is to understand how fish move. Fish are spectacular swimmers. If we can build a robotic fish that swims like a living one, it suggests that we understand how a fish is able to move forward, turn, and navigate its surroundings. Robotic fishes can also be used in studies of fish behavior. A robotic fish that looks and even smells like a real fish, and that has sensors to detect and record its surroundings, provides a way

to quietly “spy” on fish in a way that is not possible by direct observation or by the use of cameras. There are all kinds of practical applications of robotic fish as well, from mapping coastlines, coral reefs, and the sea floor, to monitoring underwater cables and pipelines, to exploring marine life.

Scientists and engineers have copied the form and function of many animals, including cockroaches, geckos, jellyfish, hummingbirds, and bats, to name just a few. One of the most recent and exciting robots is based on an octopus. Octopuses show incredible dexterity and strength, all without an internal skeleton.

The robot octopus, called an octobot and designed by researchers at Harvard University, has several remarkable characteristics ([Fig. 33.9](#)). It is entirely soft, with no rigid components like metal or even batteries. It is powered by a simple chemical reaction: liquid hydrogen peroxide is converted to a gas in the presence of a catalyst (in this case, platinum), providing pressure that powers movement. Finally, the robot is produced with a 3D printer.

*Source: Lori K. Sanders, Ryan Truby, Michael Wehner, Jennifer Lewis & Robert Wood, Harvard University.*

Fig. 33.9 Octobot. Octobot is a soft robot inspired by the octopus.

The octobot brings together engineers, material scientists, and chemists to create a robot that is inspired by biology. This truly interdisciplinary effort is the first step toward more flexible and innovative robots for research and diverse applications.

#### Self-Assessment Questions

1. Draw a simplified animal tree of life, indicating the relationships among sponges, cnidarians, protostomes, and deuterostomes.
2. Which features distinguish sponges, cnidarians, protostomes, and deuterostomes? Place these features on the phylogeny that you drew for Self-Assessment Question 1.
3. How is cephalization an adaption for forward locomotion?
4. Which animals are more closely related to sponges: cnidarians or bilaterians?

## 33.2 TISSUES AND ORGANS

As we have seen, animals show a diversity of form. Nevertheless, the cells of most animals are organized into just four types of tissues: epithelial, connective, muscle, and nervous. **Tissues** are collections of cells that carry out a specific function ([Chapter 10](#)). They are combined in various ways to make **organs**, such as the heart, lung, or kidney. Most organs consist of several different types of tissues. For example, the skin is made up of two layers: the outer layer is the epidermis, which is epithelial tissue, and the inner layer is the dermis, which is connective tissue ([Fig. 33.10](#)). In this section, we discuss the four tissue types that combine to make organs in animals.

## Most animals have four types of tissues.

Except in sponges, animal cells are organized into different kinds of well-defined tissue. **Epithelial tissue** provides a lining for all of the spaces inside and outside the body. The outer layer of the skin is epithelial tissue, as is the inner lining of the gut, bladder, and blood

vessels. The cells that make up epithelial tissue are closely packed together and connected by cellular junctions ([Chapter 10](#)), forming a continuous sheet of cells. This sheet provides a boundary and controls the movement of substances into and out of the body.

Epithelial tissue is classified based on certain characteristics. The first characteristic is layering: a single layer of cells is considered simple, and more than one layer is labeled as stratified. The second characteristic is the shape of the cells: flat cells are squamous, round or square cells are cuboidal, and tall cells are columnar. For example, a single layer of flat cells is called simple squamous epithelium; this type of epithelial tissue lines the inside of blood vessels and the interior surface of the lung. Some epithelial tissues have special features, such as a layer of the protein keratin in the case of the skin, or cilia in the case of the upper airways.

Epithelial tissue not only forms a boundary, but also may absorb substances from and secrete substances into the space it surrounds. In the gut, for example, the epithelial lining absorbs nutrients. Notably, epithelial tissue has no blood vessels, so it gets its blood supply from the underlying tissue, which is connective tissue.

**[Connective tissue](#)** underlies epithelial tissues and is found elsewhere as well. In contrast to epithelial tissue, which is composed of closely packed cells, connective tissue has an extensive extracellular matrix and few cells. The extracellular matrix is an insoluble meshwork composed of proteins and polysaccharides. Its components are synthesized, secreted, and modified by the cells that reside within

the connective tissue. Many different forms of extracellular matrix exist, which differ in the amount, type, and organization of the proteins and polysaccharides that compose them. The extracellular matrix not only contributes structural support, but also provides informational cues that determine the activity of the cells that are in contact with it ([Chapter 10](#)).

Connective tissue is characterized by the properties of the specific extracellular matrix. For example, two layers of connective tissue lie beneath the epidermis of the skin: first a specialized type of connective tissue called the basal lamina, and then the dermis, a type of connective tissue made up of cells that secrete the components of the extracellular matrix ([Fig. 33.10](#)). The dermis is strong and flexible because its extracellular matrix is composed of tough protein fibers. This layer contains blood vessels that nourish both the dermis and the overlying epidermis. The dermis also provides a cushion for the body.

The dermis of the skin is one of several types of connective tissue found in the body. Other connective tissues, such as bones, cartilage, tendons, and ligaments, help support the body and provide a system of levers for movement ([Chapter 35](#)). Finally, specialized connective tissues also include adipose tissue (fat) and blood.

**Muscle tissue** is made up of cells (called fibers) that are able to shorten or contract ([Chapter 35](#)). These specialized cells contain actin thin filaments and myosin thick filaments. Myosin is a motor protein that uses the energy of ATP to change conformation. This conformational change moves the thin filament relative to the thick

filament. As a result, individual muscle cells shorten and the entire muscle tissue contracts. True muscle tissue is present in bilaterians but not cnidarians.

Vertebrate animals have three types of muscle tissues. Skeletal muscle attaches to bone and makes voluntary movements possible ([Fig. 33.11](#)). Cardiac muscle is found in the heart and contracts to make the heart beat. Smooth muscle can be found in such places as the gut, where it causes waves of contraction that push food along the digestive tract, and blood vessels, which constrict and relax to control blood flow.

**Nervous tissue** is the fourth type of animal tissue ([Chapter 34](#)). It can be found, for example, in the nerve nets of cnidarians and in the brain, spinal cord, and peripheral nerves of vertebrates. Nervous tissue takes in sensory information from the environment, processes information, and sends signals to target organs to elicit a response. For example, signals sent to muscles direct movement, and signals sent to organs help the body maintain a relatively constant internal state, called homeostasis ([Section 33.3](#)).

Nervous tissue is made up primarily of neurons (nerve cells) that send electrical impulses from one end of the cell to the other ([Fig. 33.12](#)). They communicate with each other at specialized junctions called synapses, where chemical signals are released by one nerve cell and received by another. The ability of nerve cells to communicate quickly and specifically and to form networks underlies rapid decision making and complex behaviors.

*Source: Eye of Science/Science Source.*

Fig. 33.12 Nerve cells. Nerve cells, or neurons, send electrical impulses along

their length.

## Tissues are organized into organs that carry out specific functions.

In bilaterians, multiple tissues can combine to make an organ. For example, the intestine is an organ that includes all four types of tissues: epithelial, connective, muscle, and nervous. In turn, organs may combine to form an [organ system](#). For example, the intestine is one organ of the digestive system, which also includes the stomach, liver, pancreas, and other organs ([Chapter 38](#)).

Sponges have only simple epithelia that line the surface of the body. In contrast, jellyfish, corals, and sea anemones (cnidarians) have some tissues, but not true organs (see [Fig. 33.1](#)). These organisms have a set of nerves called a nerve net, but their nerves are not organized into a brain or central nervous system. Moreover, cnidarians have muscle cells, but not well-developed muscle tissues. They exchange gases by diffusion rather than by using lungs or gills, and they digest food in a central cavity with a single opening for both eating and excretion.

Mollusks, arthropods, mammals, and other bilaterians have true organs made up of one or more types of tissue (see [Fig. 33.1](#)). These include such organs as the heart for pumping blood ([Chapter 37](#)), gills or lungs for gas exchange ([Chapter 37](#)), stomach and intestine for nutrient absorption as substances pass through a digestive tract with two openings ([Chapter 38](#)), and kidneys or (in invertebrate bilaterians) nephridia for water balance and waste excretion ([Chapter 39](#)). Many of

these organs play important roles in maintaining an internal environment compatible with life, a topic we turn to next.

#### Self-Assessment Questions

5. What are the properties and functions of the four types of animal tissues?

## 33.3 HOMEOSTASIS

Animals commonly experience a range of environments during their lifetimes, yet many of them are able to maintain various physiological states such as body temperature and blood pH within a relatively narrow range. The active maintenance of stable internal conditions is called [homeostasis](#). Homeostasis is a critical feature of cells and of life itself. In this section, we examine how animals are able to maintain homeostasis.

### Homeostasis is the active maintenance of stable conditions inside of cells and organisms.

In [Chapter 5](#), we looked at how cells maintain homeostasis. The environment outside of cells may change, but the environment inside of cells remains relatively constant. This consistency is critical for many functions that support life. Chemical reactions and protein folding, for example, are carried out efficiently only within a narrow range of conditions, such as pH range or salt concentration.

For cells, the selectively permeable plasma membrane actively maintains intracellular conditions compatible with life. The lipid bilayer with its embedded protein channels and pumps lets some molecules through freely but restricts the passage of others, allowing the cell to regulate what goes in and what goes out ([Chapter 5](#)). For example, the plasma membrane keeps ion concentrations within narrow ranges. The firing of action potentials by neurons is an example of a cell function that requires particular ion concentrations on either

side of the membrane. Recent evidence suggests that nerve cell firing rates are maintained at a steady level in the brain of rats, regardless of sensory stimulus or deprivation, or whether the animals are awake or asleep. Temperature and pH are other parameters that do not vary much, because enzymes often work effectively only in narrow temperature and pH ranges. For example, cells found in the highly acidic waters associated with mine drainage nevertheless maintain an internal pH that is roughly neutral. To do so, they actively pump protons across the cell membrane.

Homeostasis is also maintained for the body as a whole. Many physiological parameters are maintained in a narrow range of conditions throughout the body, including temperature, heart rate, blood pressure, blood sugar, blood pH, and other ion concentrations. Similarly, the water content of the body as a whole is kept stable through the careful regulation of ions and other solutes, as discussed in [Chapter 39](#).

The concept of homeostasis was first described as regulation of the body's "interior milieu" in the late 1800s by the French physiologist Claude Bernard, who is often credited with bringing scientific methods to the field of medicine. The term "homeostasis" was coined by the American physiologist Walter Cannon, whose book *The Wisdom of the Body* (first published in 1932) popularized the concept.

Maintaining steady and stable conditions takes work in the face of changing environmental conditions. That is, a cell or organism actively performs various processes that maintain homeostasis. For example,

long periods of drought challenge an animal's ability to remain hydrated and maintain a stable water and ion balance. Animals facing drought must respond rapidly by changing the permeability of their skin and respiratory organs so that they can retain as much water as possible.

## Homeostasis is often achieved by negative feedback.

How does the body maintain homeostasis? Homeostatic regulation often depends on **negative feedback** ([Fig. 33.13](#)). In negative feedback, a stimulus acts on a sensor that communicates with an effector, which produces a response that opposes the initial stimulus. For example, negative feedback is used to maintain a constant temperature in a house. Cool temperature (the stimulus) is detected by a thermostat (the sensor). The thermostat sends a signal to the furnace or other heating system (the effector), prompting it to generate heat (the response). The response (heat) opposes the initial stimulus (cool temperature) until the temperature setting of the thermostat is reached. No additional heat is produced until the temperature drops below the temperature setting. In this way, a stable temperature is maintained ([Fig. 33.13a](#)).

Fig. 33.13 Temperature regulation by negative feedback in (a) a house and (b) a mammal. In negative feedback, a response (such as heat) opposes the stimulus (cold), leading to a stable state (a steady temperature).

In a similar way, humans and other mammals maintain a steady body temperature even as the temperature outside fluctuates. Nerve cells in the hypothalamus (located in the base of the brain) act as the body's thermostat or sensor ([Fig. 33.13b](#)). When a decrease in the temperature in the environment causes a drop in body temperature (the stimulus), the hypothalamus (the sensor) activates the nervous system to induce shivering and the production of metabolic heat (the effectors), as discussed in [Chapter 36](#). At the same time, the hypothalamus activates nerves that cause peripheral blood vessels to constrict (additional effectors). The reduction in blood flow near the body's surface reduces heat loss to the surrounding air. Conversely, an increase in temperature signals sweat glands to secrete moisture and peripheral blood vessels to dilate to aid heat loss from the skin.

Homeostatic regulation, therefore, relies on negative feedback to maintain a [set point](#), or steady-state value. In the example, the set point

is an animal's preferred body temperature. The ability to maintain a constant body temperature is known as thermoregulation, and preferred body temperature is just one of many physiological set points that the body actively maintains, as we discuss in subsequent chapters.

#### Self-Assessment Questions

6. What is homeostasis? Provide one example of a condition that is maintained by homeostasis.

## 33.4 EVOLUTIONARY HISTORY

Because many animals form hard, mineralized skeletons, sedimentary rocks deposited throughout their evolutionary history over the past 541 million years contain a rich fossil record of shells and bones. Animals also leave sedimentary calling cards in the form of their tracks, trails, and burrows, which are also widespread in sedimentary rocks.

Nevertheless, not all animal phyla are well represented in the fossil record. For example, fossil earthworms are rare and fossil flatworms are essentially unknown because they lack mineralized body parts ([Chapter 22](#)). In contrast, the fossilized shells and bones of bivalve mollusks (such as clams and mussels), brachiopods (marine shelled animals), echinoderms (such as sea stars and sea urchins), and mammals preserve an excellent record of evolutionary history within these groups.

Fossils also provide a record of now extinct species that often resemble, yet are distinct from, modern groups. They can show combinations of traits not seen in living animals—think, for example, of dinosaurs. In addition, they underscore the evolutionary importance of extinctions: a small number of events removed a majority of existing species, paving the way for renewed diversification among survivors. If we step back and look at the big picture, what do fossils tell us about the evolutionary history of the animal kingdom?

**Fossils and phylogeny show that animal forms were initially simple but**

## rapidly evolved complexity.

In [Chapter 22](#), we discussed how to interpret and build phylogenetic trees based on morphological, developmental, and molecular traits of organisms. Phylogeny suggests that animals are relative latecomers in evolutionary history, and the fossil record supports this hypothesis. Life originated more than 3.5 billion years ago, but microorganisms were the only members of ecosystems for most of our planet's history. As noted in [Chapter 26](#), macroscopic fossils of organisms thought to be animals first appear in rocks deposited only 575 million years ago. Called Ediacaran fossils after the Ediacara Hills of South Australia where they were discovered, these fossils have simple shapes that are not easily classified among living animal groups ([Fig. 33.14](#)).

Source: O. Louis Mazzatenta/Getty Images.

Fig. 33.14 Dickinsonia, an Ediacaran fossil. *Dickinsonia* and similar fossils are structurally simple, showing that the earliest animals had not yet evolved the complex morphologies and organ systems seen today in bilaterians.

Based on phylogenetic trees, we should look for sponges, cnidarians (jellyfish, corals, and sea anemones), and other diploblastic animals among the oldest animal fossils. Sponges, at least, are rare among

Ediacaran fossils, probably because early sponges did not make mineralized parts. Instead, the majority of the organisms preserved as Ediacaran fossils show simple, fluid-filled tubes, without identifiable mouths or other organs. Many may have formed colonies, gaining complexity through colonial growth and differentiation, as some living cnidarians do. These early animals had epithelia and are thought to have obtained food by taking in dissolved organic matter or phagocytosing small particles. They would have exchanged gases by diffusion. Most Ediacaran fossils probably branched from an early node or nodes on the animal tree.

Why did the first observable animal radiation occur so late in the history of life? Scientists continue to debate this question, but part of the answer appears to lie in Earth's environmental history. Geochemical data suggest that only during the Ediacaran Period did the atmosphere and oceans come to contain sufficient amounts of oxygen to support the metabolism of large, active animals.

## The animal body plans we see today emerged during the Cambrian Period.

Ediacaran fossils differ markedly from the shapes of living animals. In contrast, in the next interval of geologic history, the Cambrian Period (541–485 million years ago), we begin to see the fossilized remains of animals with familiar body plans ([Fig. 33.15](#)). Cambrian fossils commonly include skeletons made of the minerals silica, calcium carbonate, and calcium phosphate, and they record the presence of arthropods (the group that today includes insects, spiders, crabs, and their close relatives), echinoderms, mollusks, brachiopods, and other

bilaterian animals in the oceans. The rocks also preserve complex tracks and burrows made by early organisms. And in a few places, notably at Chengjiang in China and the Burgess Shale in Canada, unusual environmental conditions have preserved a treasure trove of animals that did not form mineralized skeletons ([Chapter 22](#)).

**Fig. 33.15 Fossils of the Cambrian Period.** Cambrian rocks preserve early representatives of present-day phyla, including (a) early arthropods called trilobites, (b) annelid worms, (c) early deuterostomes, and (d) primitive vertebrates.

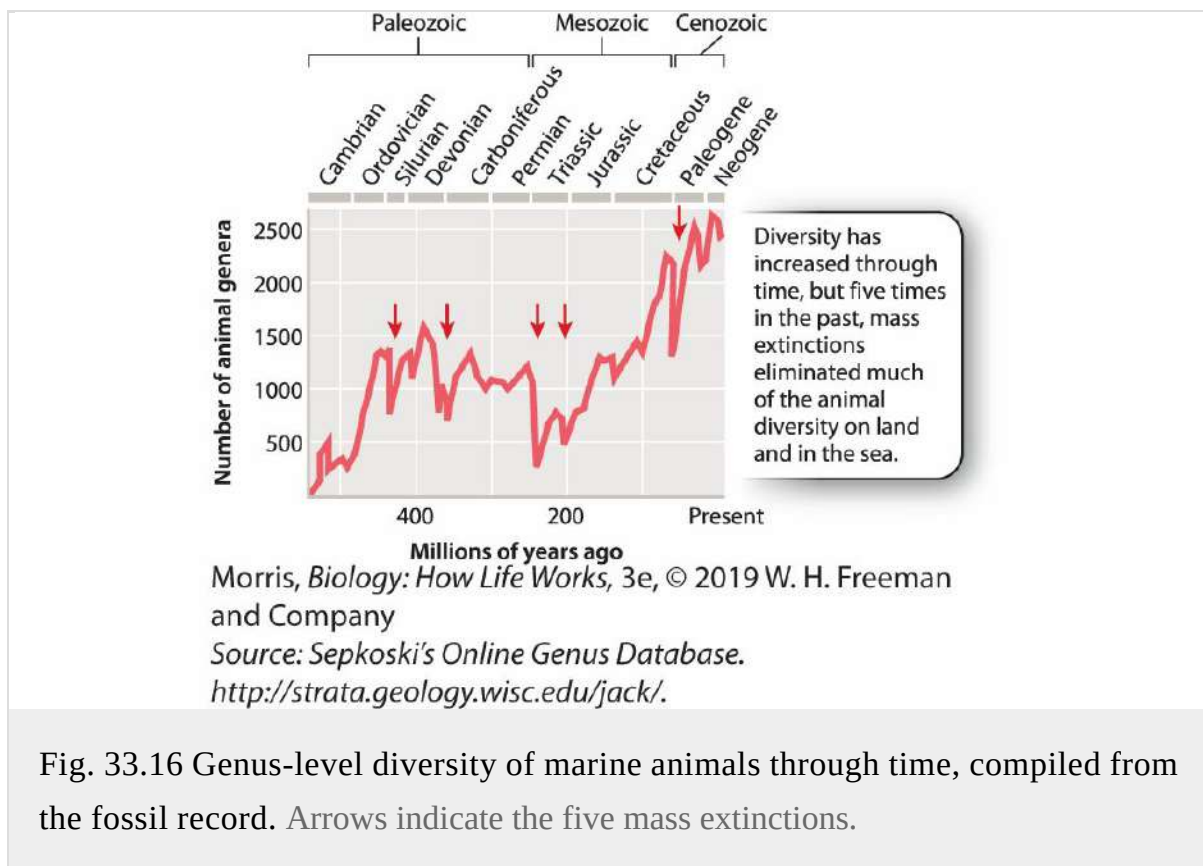

These exceptional windows into early animal evolution show that, during the first 40 million years of the Cambrian Period, the body plans characteristic of most bilaterian phyla took shape. This period of rapid diversification in the fossil record is sometimes called the [Cambrian explosion](#). Sponges and cnidarians radiated as well, producing through time the diverse habitats of reefs and imparting an ecological structure to life in the sea broadly similar to what we see today.

Scientists sometimes argue about whether the name “Cambrian explosion” is apt. The fossil record makes it clear that bilaterian body plans did not suddenly appear fully formed, so the event was not truly “explosive.” Rather, fossils demonstrate a large accumulation of new characters in a relatively short period of time during which the key attributes of modern animal phyla emerged. For example, living arthropods have segmented bodies with a protective cuticle, jointed legs, other appendages specialized for feeding or sensing the environment, and compound eyes with many lenses. Cambrian fossils include the remains of organisms with some, but not all, of the major features present today in arthropods. In short, the first 40 million years of the Cambrian Period ushered in a world utterly distinct from anything known in the preceding 3 billion years.

## Five mass extinctions have changed the trajectory of animal evolution during the past 500 million years.

The wealth of paleontological data we have show a dynamic history of animal radiations and extinctions through time ([Chapter 22](#)). [Fig. 33.16](#)

is a graph of fossil occurrences through time, compiled from the paleontological literature by American paleontologist Jack Sepkoski. A notable feature of this graph is that great reductions in the number of animal genera appear to have occurred five times (indicated by the arrows), suggesting events that we call **mass extinctions**. A mass extinction is a large, widespread, and relatively rapid loss of life on Earth.

In [Fig. 33.16](#), we also see that despite the burst of body plan evolution recorded by Cambrian fossils, there were still relatively few genera at the end of the Cambrian Period. The following Ordovician Period (485–444 million years ago) was a time of renewed animal diversification. In particular, heavily skeletonized animals evolved in the world's oceans. The number of genera recorded by fossils

increased fivefold during this period, suggesting that species diversity might have increased by an order of magnitude (most genera contain multiple species). The Ordovician radiation established a marine ecosystem that persisted for more than 200 million years.

One interesting note: if you had walked along an Ordovician beach, the shells washing about your feet would have been far different from the ones you see today. The dominant shells were those of brachiopods, not clams ([Fig. 33.17](#)). The broken corals in the Ordovician surf were the skeletons of now-extinct cnidarians only distantly related to modern reef-forming corals. And arthropod exoskeletons, molted during growth, were those of now-extinct trilobites, not lobsters or crabs. Why was the Ordovician world so distinct from our own?

*Source: Richard Paselk, HSU Natural Museum.*

Fig. 33.17 Brachiopod fossils. Brachiopods were common in marine communities during the Ordovician Period.

Another look at [Fig. 33.16](#) provides the answer. At the end of the Permian Period, 252 million years ago, a mass extinction eliminated

most genera in the oceans. Early coral-like cnidarians become extinct, as did the trilobites. Brachiopods survived as a group, but most species disappeared. As noted in [Chapter 22](#), the likely trigger for this devastation was a massive eruption of volcanos that unleashed global warming, ocean acidification, and oxygen loss from subsurface oceans.

As ecosystems recovered from this mass extinction, they came to be dominated by new groups descended from survivors of the extinction. Notably, bivalves and gastropods (two groups of mollusks) diversified. New groups of arthropods also radiated, including the ancestors of the crabs and shrimps we see today. In addition, the surviving cnidarians evolved a new ability to make skeletons of calcium carbonate, resulting in the corals that build modern reefs. In short, mass extinction reset the course of evolution, as it did four other times during the past 500 million years (see [Fig. 33.16](#)).

## Animals began to colonize the land 420 million years ago.

The movement from water to land presented numerous challenges for animals, just as it did for plants ([Chapter 27](#)). In particular, animals had to develop ways to move about without the buoyancy provided by water ([Chapter 35](#)), extract oxygen from air rather than water ([Chapter 37](#)), and reproduce on land ([Chapter 40](#)).

Animals began to colonize land only after plants had already established themselves there. Land plants evolved during the Ordovician Period, about 460 million years ago. The first animals to colonize the land were arthropods, which moved onto land during the

Silurian Period, about 420 million years ago. These arthropods included insects and chelicerates (the group that today includes spiders, mites, and scorpions).

The radiation of the major groups of insects began about 360 million years ago with a marked diversification of dragonflies and the ancestors of cockroaches and grasshoppers. Some of the dragonfly-like insects that darted among the plants of this period had bodies the size of a lobster and 75-cm wing spans! You might well wonder what prevents insects from attaining this size today. Scientists debate this question, but part of the answer probably implicates flying vertebrates—first now-extinct groups such as pterosaurs, and later, birds and bats—which competed with and preyed upon large insects.

Flies, beetles, bees, wasps, butterflies, and moths radiated later. Their rise in diversity parallels that of the flowering plants and reflects the coevolution of these pollinators and flowering plants.

Fossils of tetrapods (four-legged land vertebrates, such as amphibians) first appear in sedimentary rocks deposited near the end of the Devonian Period, about the same time as the early insect radiations of 360 million years ago. As discussed in [Chapter 22](#) (see [Fig. 22.22](#)), the fossil record documents in some detail the shifts in skull, trunk, and limb morphology that allowed vertebrate animals to colonize land. These include the evolution of muscled, articulated legs from fins, together with a set of strong, articulated digits where the limbs meet the ground; lungs and a rib cage to support the muscles that control breathing; and an erect, elevated head with eyes oriented for forward

vision.

Amniotes (the large group that includes reptiles, birds, and mammals) evolved later, about 310 million years ago. A key innovation that separates amniotes from amphibians is the evolution of a water-tight, or amniotic, egg ([Chapter 40](#)). This feature allowed land vertebrates to reproduce on land without returning to the water. The appearance in the fossil record of amphibians and then amniotes follows the predictions of phylogenies based on comparative biology.

During this time, new species of land animals continued to diversify, including small bipedal species that gave rise to some of the most remarkable creatures ever to walk on land: the dinosaurs. From their beginnings approximately 240 million years ago, dinosaurs radiated to produce many hundreds of species, dominating terrestrial ecosystems until the end of the Cretaceous Period, 66 million years ago. At that time, another mass extinction, caused by a catastrophic asteroid impact, eliminated nearly all dinosaur species ([Chapter 1](#)). We say “nearly all” because the fossil record documents the evolutionary divergence of birds from a specific subgroup of dinosaurs approximately 150 million years ago ([Chapter 22](#)).

Mammals have been the dominant vertebrates on land since the extinction of dinosaurs. This group actually originated much earlier, at least 210 million years ago. During the age of dinosaurs, most mammals were small nocturnal or tree-dwelling animals that stayed out of the way of large dinosaurs, although fossils from China show clearly that the largest mammals of this interval ate small dinosaurs and their

eggs. Mammals are dominant components of terrestrial ecosystems today in part because they survived the end-Cretaceous mass extinction.

## Some animals show a trend toward increased body size over time.

In our brief overview of animal evolution, we have seen giant dragonflies and large dinosaurs. A newly described dinosaur, *Patagotitan mayorum*, is thought to be the largest animal ever to have walked on land. The blue whale (*Balaenoptera musculus*) is the largest animal to have ever existed on Earth. These are just a few examples, but it turns out that many groups of animals show increases in body sizes over time ([Fig. 33.18](#)). These groups include the brachiopods, chordates (including vertebrates), and echinoderms (such as sea stars, sea urchins, and sand dollars).

### HOW DO WE KNOW?

#### FIG. 33.18

### Do animals tend to get bigger over time?

#### BACKGROUND

Cope's rule, named after the American paleontologist Edward Cope, suggests that there is a trend through time toward increasing size among animals. However, it is unclear whether such a general trend actually exists. Large body size can be associated with increased fitness—for example, by making it easier to capture prey or compete with other organisms. Notable examples of very large animals that lived long ago are the dinosaurs. There are also exceptions to this trend in some groups of

animals.

### HYPOTHESIS

Animals tend to increase in size over evolutionary time.

### EXPERIMENT

Jonathan Payne and his colleagues at Stanford University decided to test the hypothesis that animals tend to get bigger over time, focusing on marine animals over the last 541 million years. They measured the three major body axes of images of animal specimens to determine the mean volume (as a measure of body size) for more than 17,000 genera of animals, including arthropods, brachiopods, echinoderms, mollusks, and chordates.

### RESULTS

The researchers found that the mean volume for all genera increased over time (the dark line in the graph). In addition, they found that the range in sizes increased dramatically (the difference between the two light lines in the graph). Most of this expansion resulted from an increase in the maximum size of animals (the upper light line in the graph).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

### CONCLUSION

The data support the hypothesis that there is an evolutionary trend toward

larger body size in many groups of animals.

#### FOLLOW-UP WORK

The researchers next asked whether the increase in size is the result of natural selection or genetic drift ([Chapter 20](#)). They compiled observed trends in the mean, maximum, and minimum sizes of a number of animal groups and compared them to the predictions of models based on selection and drift. They found that their observations are consistent with models based on selection, and not consistent with models based on drift. These findings suggest that increased body size has selective advantages.

SOURCE Heim, N. A., et al. 2015. "Cope's Rule in the Evolution of Marine Mammals." *Science* 347:867–870.

Large body size presents distinct challenges. Within those large bodies, animals need to transport oxygen, nutrients, and signaling molecules over long distances. Diffusion, the random motion of molecules, is effective only over short distances. In [Chapter 27](#), we discussed how bulk flow can transport molecules over the long distances present in larger organisms. In some animals, for example, blood is circulated throughout the body by the pumping action of the heart, and oxygen is transported into the lungs by contraction of the muscular diaphragm ([Chapter 37](#)).

More generally, the form of animals is in part determined by their size. Therefore, as animals got bigger, their form changed as well. To understand why this is so, consider what happens if the size of an ant increases 10-fold without a change in its form. The strength of the legs would increase as the *square* of the scale factor, or  $10^2$  (100 times), because strength is proportional to the cross-sectional area of the legs.

However, the weight of the ant would increase as the *cube* of the scale factor, or  $10^3$  (1000 times), because weight is proportional to volume. Therefore, as an ant gets bigger, its weight would quickly outstrip the strength of its legs, and it would not be able to support itself. So, an ant looks like an ant in part because of its size.

The issue with a large ant is that it increases in size but keeps its overall shape. This kind of change is called [isometry](#) (“same measure”). By contrast, increases in size are possible if they are accompanied by changes in shape. This kind of change is called [allometry](#) (“different measure”). For example, in the 1600s, Galileo Galilei noticed that the bones of larger animals are not simply scaled-up versions of the bones of smaller animals. Instead, in many cases, the bones of larger animals are disproportionately wider than those of smaller animals so as to support the increased weight.

As an animal (or any three-dimensional object) gets bigger, both surface area and volume increase, but surface area increases more slowly than does volume ([Chapter 26](#)). Therefore, shape changes often accompany size differences to balance the two. For example, nutrients are absorbed through the lining of the gut, which is one large surface area, but they support the entire body, which represents a volume. Larger organisms, therefore, have adaptations of the lining of the gut to increase the surface area, enabling them to “keep up” with the increased volume. These adaptations include folds of the lining of gut (called villi) and projections of the surface of the intestinal cells (called microvilli) that greatly increase the surface area available to absorb nutrients ([Chapter 38](#)).

The British biologist J. B. S. Haldane wrote, “For every type of animal there is a most convenient size, and a large change in size inevitably carries with it a change of form.” In the subsequent chapters, we will see many examples of adaptations that can be explained at least in part by considering the size of the animal.

#### Self-Assessment Questions

7. What is the evolutionary significance of the Cambrian explosion?
8. What are two examples of how mass extinctions changed the ecological structure of life on Earth?
9. Which has more surface area relative to volume: a grape or a grapefruit?

## CORE CONCEPTS SUMMARY

**33.1 ANIMAL BODY PLANS:** Animals have a limited number of distinct body plans.

Animals are multicellular heterotrophic eukaryotes that form a blastula and, commonly, a gastrula during development. [page 740](#)

Early biologists grouped animals on the basis of shared features of adult bodies, such as symmetry. [page 740](#)

Poriferans (sponges) have no well-defined plane of symmetry; cnidarians (jellyfish, corals, and sea anemones) are radially symmetric; and bilaterians (insects and vertebrates, for example) are bilaterally symmetric. [page 740](#)

Cephalization is the concentration of the nervous system and special sensory organs at the front of the body. [page 741](#)

Segmentation is the organization of the body into repeated units along the anterior–posterior (head–tail) axis. [page 742](#)

Cnidarians have two germ layers (ectoderm and endoderm), whereas bilaterians have three germ layers (ectoderm, mesoderm, and endoderm). [page 742](#)

**33.2 TISSUES AND ORGANS:** Most animals have four different types of tissues, which combine to form organs.

Most animals organize their cells into tissues. [page 746](#)

The four types of tissues found in animals are epithelial, connective, muscle, and nervous. [page 746](#)

Epithelial tissue lines spaces, such as cavities or the outside of the body. [page 746](#)

Connective tissue is characterized by an extensive extracellular matrix and few cells. It provides nutrients and a cushion for the overlying epithelial tissue, among other functions. [page 746](#)

Muscle tissue is able to shorten, or contract. [page 746](#)

Nervous tissue is specialized for transmitting electrical impulses, thereby allowing animals to take in information from the environment, process it, and elicit a response. [page 747](#)

Most animals with tissues, with the exception of cnidarians, have organs, which are collections of tissues that perform a specific function. [page 747](#)

Organs often work with other organs form an organ system. [page 747](#)

**33.3 HOMEOSTASIS:** Homeostasis actively maintains a stable internal environment.

Homeostasis is an active process that is often maintained for individual cells as well as for an organism as a whole. [page 748](#)

Many parameters, such as blood pH, ion concentrations, and body temperature, are actively maintained in a narrow range by homeostasis. [page 748](#)

Homeostasis is often achieved by negative feedback, in which the response inhibits the stimulus to maintain a set point. [page 748](#)

**33.4 EVOLUTIONARY HISTORY:** Animals evolved more than 600 million years ago in the oceans, and by 500 million years ago the major body plans were in place.

Ediacaran fossils from 575 million years ago provide evidence of early animals. [page 749](#)

Most of the animal body plans we see today first evolved during the Cambrian explosion, a time of rapid diversification that began 541 million years ago. [page 750](#)

Animal diversity has been shaped by five mass extinctions, which were followed by adaptive radiations, over the past 500 million years. [page 751](#)

Arthropods were the first animals to colonize the land, sometime around 420 million years ago. [page 752](#)

Four-legged vertebrates (tetrapods) first appear in the fossil record approximately 360 million years ago. [page 752](#)

Mammals originated at least 210 million years ago, but became dominant only after the extinction of the non-avian dinosaurs 66 million years ago. [page 752](#)

Some animal groups show a tendency toward larger sizes over time, resulting in changes in form. [page 753](#)

## CHAPTER 34 Animal Nervous Systems

Callista Images/AGE Fotostock

### CORE CONCEPTS

**34.1 NERVOUS SYSTEM FUNCTION AND EVOLUTION:** Nervous systems allow animals to sense and respond to the environment, coordinate movement, and regulate internal functions of the body.

**34.2 NEURON STRUCTURE:** The functional unit of the nervous system is the neuron, which has dendrites that receive information and axons that transmit information.

**34.3 SIGNAL TRANSMISSION:** The electrical properties of neurons allow them to communicate rapidly with one another.

**34.4 NERVOUS SYSTEM ORGANIZATION:** Nervous systems are organized into peripheral and central components, and include voluntary and involuntary functions.

**34.5 SENSORY SYSTEMS:** Animal sensory receptors detect chemical, physical, and electromagnetic stimuli by changes in membrane potential.

**34.6 BRAIN ORGANIZATION AND FUNCTION:** The brain integrates information from diverse sources and is organized into distinct regions with specialized functions.

---

Gazelles grazing on an African plain are constantly alert to the threat of predators. Members of the herd scan the landscape for visual cues that might reveal the stealthy approach of a cheetah. Olfactory (smell) and auditory (sound) cues from the environment can also warn of the cheetah's approach. Herd members communicate the presence of the cheetah to one another by the directed attention of a dominant male or the pawing of a hoof. At what point is the threat real? When do the animals decide to stop grazing and turn to run? Which direction should the escape take to keep the herd together?

The cheetah scans the horizon, its keen vision spotting a grazing gazelle. The cheetah's ability to recognize wind direction enables it to move downwind of the gazelle to minimize auditory and olfactory cues

that might otherwise be carried by the air toward suspecting prey. At what point does the cheetah decide to sprint in pursuit of its quick-running prey?

The perceptions and reactions of these animals depend on the activity of their nervous systems. The nervous system takes in information from the environment through sensory organs, processes that information by networks of nerve cells, and guides motor responses. In this chapter, we explore the organization of the nervous system, including the brain and the nerve cells that compose it.

# 34.1 NERVOUS SYSTEM

## FUNCTION AND EVOLUTION

Most multicellular animals possess a [nervous system](#), a network of many interconnected nerve cells. Nervous systems first evolved in animals like jellyfish and flatworms. These early nervous systems could sense basic features of the environment, such as light, temperature, and chemical odors. Guided by these cues, nervous systems could trigger movements useful for obtaining food, finding a mate, or choosing a suitable habitat.

As animals evolved more complex bodies with increasingly specialized organ systems, their nervous systems also became more elaborate. These nervous systems could regulate internal body functions in response to sensory cues received from the environment. They also made possible more sophisticated behaviors that relied on improved decision making, learning, and memory.

### Animal nervous systems have three types of nerve cells.

Nerve cells, or [neurons](#), are the functional units of nervous systems. All animal nervous systems are made up of three types of neurons with different functions: [sensory neurons](#), [interneurons](#), and [motor neurons](#). Sensory neurons receive and transmit information about an animal's environment or its internal physiological state. These neurons respond to physical features of the environment such as temperature, light, and touch, or to chemical signals such as molecules conveying odor and taste. Interneurons process information received by sensory

neurons and transmit it to different body regions to produce a suitable response. Often, interneurons communicate with motor neurons. A motor neuron may, for example, stimulate a muscle to contract to produce movement. Other motor neurons may adjust an animal's internal physiology, constricting blood vessels to affect blood flow or causing wavelike contractions of the gut to aid digestion. In this way, nervous system function plays a fundamental role in maintaining homeostasis, the ability of animals, organs, and cells to actively regulate and maintain a stable internal state ([Chapters 5](#) and [33](#)).

Most nerve cells have fiberlike extensions, some of which receive information and others of which transit information. The result is a network of interconnected nerve cells that form a circuit. These circuits allow information to be received, processed, and delivered. In most animals, interneurons form circuits that may consist of a diverse array of nerve cells having different shapes, sizes, and chemical properties.

The ability to process information first evolved with the formation of [ganglia](#) (singular, [ganglion](#)). Ganglia are groups of nerve cell bodies that process sensory information received from a nearby region, then send signals to motor neurons that control some physiological function of the animal. They can be thought of as relay stations in nerve cell circuits. For example, ganglia assist in processing information from the eyes and controlling the digestive state of an animal's gut ([Chapter 38](#)).

Over time, a centralized concentration of neurons called a [brain](#) evolved. As a central nervous system organ, an animal brain is able to

process complex sensory stimuli received from the environment or anywhere in the body. Neurons in the brain form complex circuits, allowing the brain to regulate a broad array of behaviors, as well as to learn and retain memories of past experiences.

## Nervous systems range from simple to complex.

Single-celled organisms have cell-surface receptors that enable them to sense and respond to their environment. In contrast, most multicellular animals have a nervous system. In general, the organization and complexity of an animal's nervous system reflect its lifestyle. Some animals, such as sea anemones and clams, are sessile (immobile) and have relatively simple sense organs and nervous systems. By contrast, active animals such as arthropods (which include insects, spiders, and crustaceans), squid, and vertebrates have more sophisticated sense organs linked to a brain and more complex nervous systems. The nervous systems of these animals help to maintain homeostasis and coordinate complex behaviors that require decision making, forming memories, and learning.

Sponges are the only animals that lack a nervous system ([Fig. 34.1](#)). These marine animals lack any form of body symmetry. Many small pores along the side and a larger opening at the top draw nutrient-laden water into a central cavity of the sponge. The cells lining the cavity first capture food particles and dissolved organic matter by endocytosis, then metabolize these nutrients in the cell interior. The functions of different body regions are coordinated by groups of cells specialized for functions such as contracting or taking in water. These

cells respond to local chemical and physical cues. For example, a pore-like cell that allows water to enter the sponge closes when touched.

FIG. 34.1 A simplified phylogenetic tree of multicellular animals. All multicellular organisms except sponges have a nervous system.

Among multicellular organisms, the simplest nervous systems are found in cnidarians, which are radially symmetric animals such as jellyfish and sea anemones ([Fig. 34.1](#)). At one end of a cnidarian's body is a mouth, surrounded by tentacles, that opens into a central body cavity, where food is digested. The nervous system of these animals is made up of neurons that are arranged like a net, but the system lacks ganglia and a central brain ([Fig. 34.2a](#)). The nerve net of a sea anemone is organized around an internal gut cavity. Sensory neurons sensitive to touch signal when one of the anemone's tentacles has captured food, and then motor neurons react to coordinate the tentacle's movement toward the mouth for feeding. Sensory neurons

responding to a noxious stimulus signal the sea anemone to retract or detach from its substrate.

FIG. 34.2 Animal nervous systems. (a) Sea anemones have a nerve net; (b) flatworms have paired ganglia; (c) earthworms, (d) insects, (e) squid, and (f) frogs have a brain.

More complex nerve connections develop in the head end of flatworms, annelid worms, insects, and cephalopod mollusks, such as squid and octopuses. These animals are all bilaterians, meaning they have symmetrical right and left sides and distinct front and back ends (see [Fig. 34.1](#)). Flatworms were one of the earliest groups of bilaterians to evolve that were well adapted for forward locomotion. These elongated, flattened organisms glide along a streambed, trapping small animals under their bodies and sucking them in through a muscular opening in their underside. Sensory neurons are most numerous in the animal's front end, so the flatworm can perceive the environment ahead of it as it moves forward. The flatworm's nervous system can compare inputs from different sensory neurons and then send signals to the appropriate muscles to move toward a target. Paired ganglia (one on each side of the animal) in the head end of flatworms handle this processing task ([Fig. 34.2b](#)).

In animals with an organized nervous system, information is transmitted to different regions along the length of the animal's body by distinct [nerve cords](#) and [nerves](#). These bundles contain long, fiberlike extensions from multiple nerve cells. Nerves connect the ganglia of a flatworm to the muscles along its body used for locomotion.

In earthworms, paired ganglia, each made up of many interneurons, are located in each of the body's segments ([Fig. 34.2c](#)). These segmental ganglia help regulate key processes in local regions and organs of the animal's body. For example, paired ganglia near the head regulate the activity of motor neurons that control movements of the earthworm's mouth for feeding.

Centralized collections of neurons forming a brain are present in earthworms and other annelid worms, insects, and mollusks ([Figs. 34.2d](#) and [34.2e](#)). Sense organs also developed in the head region, ranging from the eyespots in flatworms that respond to light to the more sophisticated image-forming eyes in octopuses and squid. The evolution of a brain in these invertebrate animals enabled them to learn and perform complex behaviors.

The evolution of a brain ([Fig. 34.2f](#)) also enabled vertebrates to evolve complex behaviors, learning, and memory. At the same time, animal brains became increasingly complex in terms of the number of nerve cells they contain (fruit fly, about 0.25 million; cockroach, about 1 million; mouse, about 75 million; humans, about 100 billion), the number of connections between neurons, and the variety of shapes and

sizes of nerve cells.

#### Self-Assessment Questions

1. What are the three basic types of neurons?
2. What are the functions of these three types of neurons?

## 34.2 NEURON STRUCTURE

Although animal nervous systems differ in organization and complexity, their nerve cells are fundamentally alike: they all have the same basic features and they use the same mechanisms to communicate with neighboring cells. These mechanisms have been retained over the course of evolution to code and reliably transmit information. The ability to receive sensory information from the environment, and to transmit and process this information within a nervous system, is shared across a wide diversity of animal life and has greatly contributed to the success of animals.

### Neurons share a common organization.

Neurons all share some basic features. For example, they have a cell body from which emerge two kinds of fiberlike extensions, **dendrites** and **axons** (**Fig. 34.3**). These extensions are the input and output ends of the nerve cell, respectively. Both types of cellular extensions can be highly branched, enabling neurons to communicate over large distances with many other cells.

FIG. 34.3 Neuron organization. Nerve cells typically have dendrites that receive signals as well as axons that transmit signals.

A neuron's dendrites receive signals from other nerve cells or, in the case of sensory nerves, from specialized sensory endings. These signals travel along the dendrites to the neuron's cell body. At the junction of the cell body and its axon (an area known as the **axon hillock**), the signals from multiple dendrites are combined. If the sum of the signals is high enough, the neuron fires an **action potential**, or nerve impulse, that travels down the axon. An action potential is a brief electrical signal transmitted from the cell body along one or more axon branches.

Axons generally transmit signals away from the nerve's cell body. The end of each axon forms a swelling called the axon terminal. An axon terminal communicates with its neighboring cell through a junction called a **synapse**. A space, the **synaptic cleft**, separates the end of the axon of the presynaptic cell and the neighboring postsynaptic cell. This synaptic cleft is commonly only 10 to 20 nm

wide.

Molecules called [neurotransmitters](#) convey the signal from the presynaptic cell across the synaptic cleft to the postsynaptic cell. The arrival of a nerve signal at the axon terminal triggers the release of neurotransmitter molecules from vesicles located in the terminal. The vesicles fuse with the axon's membrane, releasing neurotransmitter molecules into the synaptic cleft. These molecules then diffuse across the synapse and bind to receptors on the plasma membrane of the target cell. The binding of neurotransmitters to these receptors causes a change in the electrical charge across the membrane of the receiving postsynaptic cell, which in turn propagates the signal in the second cell. In this way, most neurons communicate by forming hundreds to thousands of synapses with other cells. The massive number of interconnections enables the formation of complex nerve cell circuits and the transmission of information from one circuit to others.

Some neurons do not synapse with other neurons, but instead with other types of cell that produce some physiological response in the animal. Examples are muscle cells, which contract in response to nerve signals, and secretory cells in glands, which release hormones in response to nerve signals.

## Neurons differ in size and shape.

In spite of their common organization, neurons show a remarkable diversity in terms of their size and shape. Some neurons, such as many interneurons, are very short, whereas others, like the motor neurons that extend from your spinal cord to muscles that control your toes, are

several feet long. The number of extensions coming off the cell body can also vary ([Fig. 34.4](#)). Some sensory neurons involved in smell, sight, and taste have just two extensions coming off the cell body ([Fig. 34.4a](#)), whereas other neurons have many more ([Fig. 34.4b](#) and [34.4c](#)).

The degree of branching of a neuron's extensions varies from one neuron to the next. A neuron with more dendritic branches receives inputs from more sources than one with fewer branches. Some neurons receive information only from nearby regions through a few dendrites that branch close to the cell body. Other neurons receive information from many branching dendrites. Axons typically have fewer branches than dendrites.

Signals from all the dendrites converge on the neuron cell body. These signals determine the frequency and timing of signals carried by the neuron's axon. In turn, the frequency of the signals carried by the

neuron's axon determine their strength. The process of bringing together information gathered from different sources is referred to as information integration. The degree of branching and the number of synapses that a neuron makes with neighboring nerve cells, therefore, reflect how information is processed and integrated by the cell.

## Neurons are supported by other types of cells.

Neurons in many body regions, and in particular within the brain, are supported by other types of cells that do not themselves transmit electrical signals. These include [glial cells](#). Indeed, the human brain has more glial cells than neurons.

Glial cells have many functions. They surround neurons and provide them with nutrition and physical support. Some glial cells, called astrocytes, support endothelial cells that make up blood vessels in the brain. These endothelial cells are linked by tight junctions ([Chapter 10](#)) to form a selective barrier, called the blood–brain barrier, that limits the types of compounds that can diffuse from the blood into the brain. This barrier prevents pathogens and toxic compounds in the blood from entering the brain. Because nerve cells have limited capacity to regenerate after damage, protection of the brain and spinal cord is critically important. Nevertheless, lipid-soluble compounds such as alcohol and certain anesthetics readily diffuse across the blood–brain barrier, so they can affect an animal's mental state. They can also damage and even destroy neurons.

During development, glial cells help orient neurons as they develop

their connections. They also provide electrical insulation to vertebrate neurons that allows nerve signals to be transmitted rapidly, as we discuss next.

#### Self-Assessment Questions

3. Diagram and label the basic features of a neuron, indicating where information is received and where it is sent.
4. How are signals transmitted from one end of a nerve cell to the other, and from one neuron to another?

## 34.3 SIGNAL TRANSMISSION

As described in the previous section, neurons send signals to other neurons by releasing neurotransmitters that diffuse across the synaptic cleft and bind to receptors. In [Chapter 9](#), we introduced the binding of a chemical signal to receptors as a general mechanism of cell communication. In neurons, once the receptor has bound the neurotransmitter and become activated, neurons send electrical signals from one end of the cell to the other. These electrical signals travel at high speeds, up to 200 m/sec (450 mph). In this section, we discuss the electrical properties of neurons and consider how signals are propagated along neurons. We also describe how signals are transmitted between neurons.

**The resting membrane potential is negative and results in part from the movement of potassium and sodium ions.**

The inside surface of a neuron carries an electrical charge that is due to the presence of charged ions; the same is true of the outside surface. However, the electrical charge on the inside and the electrical charge on the outside are not the same because unequal numbers of charged ions are located inside and outside the cell. When no signal is present, there are more negative ions inside the cell, so the inside is negatively charged relative to the outside. Because the charge differs between the inside and the outside of the cell, the membrane is said to be [polarized](#).

The charge difference between the inside and outside of a neuron due to differences in the numbers of charged ions is known as the cell's **membrane potential**, and is measured in volts. Other cells also have membrane potentials, but only nerve cells and muscle cells respond to changes in their membrane potential. Therefore, these cells are considered electrically excitable. The key to producing an electrical signal in a nerve cell is the movement of positively and negatively charged ions across the cell membrane. This movement creates a change in electrical charge across the membrane that constitutes the electrical signal.

Let's first consider the membrane potential when the neuron is at rest and no signal is being received or sent. Under these conditions, the cell's membrane potential is negative on its inside relative to its outside (**Fig. 34.5**). The negative membrane potential results from the buildup of negatively charged ions on the inside surface of the cell's plasma membrane and of positively charged ions on its outer surface. Notice in **Fig. 34.5** that there are many more positively charged ions (colored purple and pink) outside the cell. The negative membrane potential at rest is the cell's **resting membrane potential**. This resting membrane potential ranges from  $-40$  to  $-85$  millivolts (mV) depending on the type of nerve cell. The charge of the cell's interior can be measured with respect to its outside charge by placing small glass electrodes on the inside and outside of the cell.

FIG. 34.5 Neuron resting membrane potential. The resting potential of a neuron is negative and results primarily from the movement of K<sup>+</sup> ions out of the cell.

At rest, nerve (and muscle) cells have a greater concentration of sodium (Na<sup>+</sup>) ions outside the cell than inside, and a greater concentration of potassium (K<sup>+</sup>) ions inside the cell than outside. This distribution of ions results in part from the action of the sodium–potassium pump ([Chapter 5](#)). The pump uses the energy of ATP to move three Na<sup>+</sup> ions outside the cell for every two K<sup>+</sup> ions moved inside the cell ([Fig. 34.5](#)). The action of the pump makes the inside of the cell less positive, and therefore more negative, than the outside of the cell.

The exact value of the resting membrane potential depends on the movement of K<sup>+</sup> ions back out of the cell by passive diffusion through potassium ion channels ([Fig. 34.5](#)). As discussed in [Chapter 5](#), ion channels are protein pores embedded in the cell membrane. The most important ions that move across the cell membrane are sodium (Na<sup>+</sup>), potassium (K<sup>+</sup>), chloride (Cl<sup>-</sup>), and calcium (Ca<sup>2+</sup>). When a nerve cell is at rest, the K<sup>+</sup> ion channels are open and K<sup>+</sup> ions move out of the

cell. As a result, positive ions build up on the outside of the cell. Because negatively charged ions (largely proteins) remain on the inside of the cell, the inside of the nerve cell is more negative than its outside.

The relative proportion of ions does not by itself determine the resting membrane potential. In fact, the number of charged ions that build up at the cell's surface is just a tiny fraction of the total number of charged ions and proteins located inside and outside the cell. Instead, it is the *movement* of  $K^+$  ions relative to other ions, particularly  $Na^+$  ions, that largely determines the resting membrane potential.

## Neurons are excitable cells that transmit information by action potentials.

When a nerve cell is excited, its membrane potential becomes less negative—that is, the inside becomes less negative, or more positive, than the outside of the cell. This increase in membrane potential is referred to as a **depolarization** of the membrane. Depolarization does not occur over the entire cell at once. Rather, it starts at the end of the dendrite, in response to neurotransmitter binding to membrane receptors, and travels to the cell body, losing strength along the way. If the depolarization is strong enough at the axon hillock of the cell body, the cell fires an action potential that carries the signal from the cell body to the ends of the axon.

The nerve fires an action potential at the axon hillock if the membrane at the hillock is depolarized to a voltage of approximately

15 mV above the resting membrane potential (about  $-55$  mV). An action potential is a rapid, short-lasting rise and fall in membrane potential ([Fig. 34.6](#)). The critical depolarization voltage of  $-55$  mV required for an action potential is called the cell's **threshold potential**. Nerve cells in different animals have slightly different resting and threshold potentials, but all operate similarly with respect to firing an action potential. When the threshold potential is exceeded (step 1 in [Fig. 34.6](#)), the nerve fires an action potential in an “all-or-nothing” fashion. As a consequence, once the threshold potential has been exceeded, the magnitude of the action potential is always the same independent of the strength of the stimulating input. At this point, a rapid spike in membrane potential to approximately  $+40$  mV occurs over a very brief time period of 1 to 2 msec.

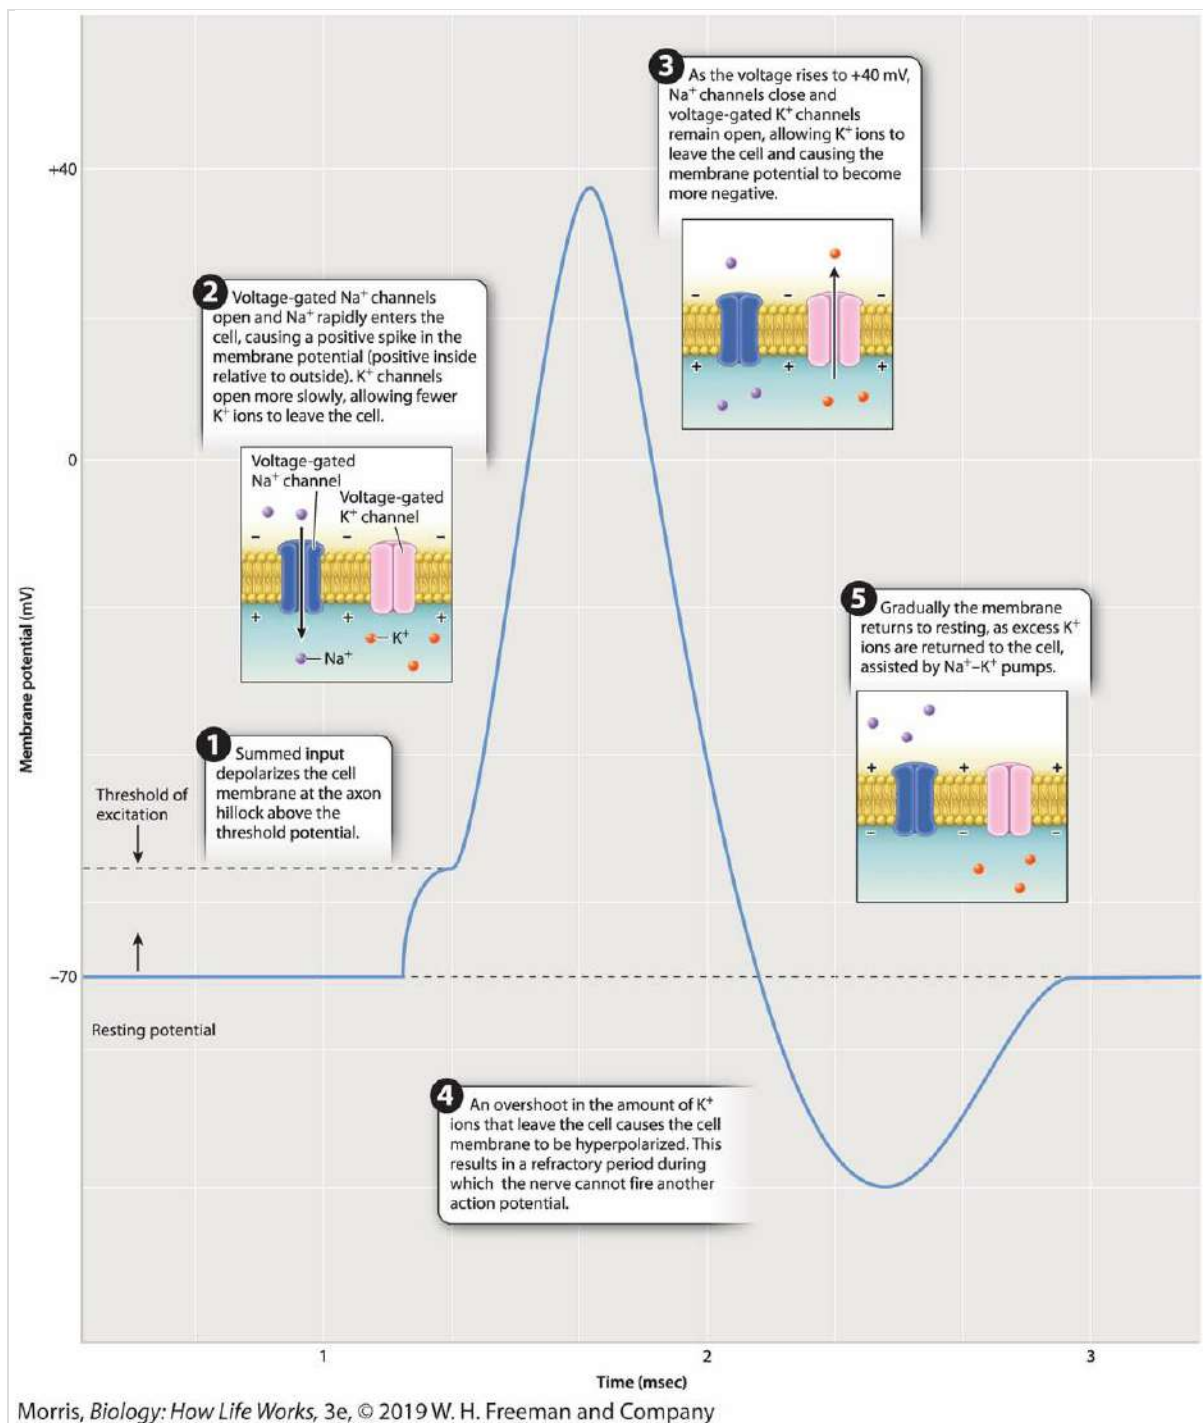

FIG. 34.6 An action potential. An action potential results from the opening and closing of voltage-gated ion channels and results in a positive spike in membrane potential.

How is the action potential generated? As [Fig. 34.6](#) shows, voltage-gated channels play a key role in how neurons fire action potentials.

Recall that [voltage-gated channels](#) open and close in response to changes in membrane potential ([Chapter 9](#)).

As the cell membrane crosses its threshold potential, a dramatic change occurs in the state of the voltage-gated  $\text{Na}^+$  and voltage-gated  $\text{K}^+$  channels in the axon membrane, causing a large number of voltage-gated  $\text{Na}^+$  channels to open suddenly, and allowing  $\text{Na}^+$  ions to rush inside the cell (step 2). This influx of  $\text{Na}^+$  causes a flow of positive charge along the inside of the cell, toward more negatively charged nearby regions. The resulting rise in voltage causes additional, nearby voltage-gated  $\text{Na}^+$  channels to open. This is an example of [positive feedback](#), in which a signal (depolarization) causes a response (open voltage-gated  $\text{Na}^+$  channels) that leads to an enhancement of the signal (more depolarization), which then leads to an even larger response (more open voltage-gated  $\text{Na}^+$  channels).

During the rising phase of the action potential, voltage-gated  $\text{K}^+$  channels also begin to open. These channels are slow to activate relative to the rapidly opening voltage-gated  $\text{Na}^+$  channels. As a result, few  $\text{K}^+$  ions leave the cell, and the cell membrane potential continues to rise due to the large number of  $\text{Na}^+$  ions entering the cell.

As shown in [Fig. 34.6](#), the rising phase of the action potential (rapid depolarization) is followed by the falling phase (rapid repolarization). Two important factors cause this sudden reversal of the membrane potential. First, voltage-gated  $\text{Na}^+$  channels begin to close once the membrane potential becomes positive (step 3). Second, voltage-gated  $\text{K}^+$  channels continue to open in response to the change in membrane

potential. Because they respond more slowly than the voltage-gated  $\text{Na}^+$  channels, the membrane potential peaks and then falls as  $\text{K}^+$  ions diffuse out of the axon through the open voltage-gated  $\text{K}^+$  channels.

The charge inside the axon does not return immediately to resting levels. Instead, it briefly falls below the resting potential in a process known as hyperpolarization or undershoot (step 4). It then returns to the resting potential after another few milliseconds as  $\text{K}^+$  channels close to restore the resting concentration of  $\text{Na}^+$  and  $\text{K}^+$  ions on either side of the cell membrane (step 5). The continuous action of the sodium–potassium pumps also helps to reestablish the resting membrane potential.

The period during which the membrane potential falls below and then returns to the resting potential is called the **refractory period** (Fig. 34.6). During the refractory period, a neuron cannot fire a second action potential. Although the duration of the refractory period varies for different kinds of nerve cells, it serves to limit a nerve cell's fastest firing frequency.

It might seem that many  $\text{Na}^+$  and  $\text{K}^+$  ions need to diffuse across the axon membrane to produce an action potential. In fact, only about 1 in 10 million  $\text{Na}^+$  and  $\text{K}^+$  ions need to cross the membrane. Thus, enough ions are always available to generate repeated action potentials.

Because all action potentials are alike in being all-or-nothing and uniform, the action potential itself contains little information. Instead, most neurons code information by changing the rate and timing of action potentials. Generally, a higher firing frequency codes for a more

intense stimulus, such as a louder noise, or for a stronger signal transmitted by the nerve cell to other cells it contacts.

## Neurons propagate action potentials along their axons by sequentially opening and closing adjacent $\text{Na}^+$ and $\text{K}^+$ ion channels.

Once initiated, an action potential propagates along the axon ([Fig. 34.7](#)). The local membrane depolarization initiated at the axon hillock triggers the opening of neighboring voltage-gated  $\text{Na}^+$  channels farther along the axon. The inward sodium current depolarizes the membrane above its threshold, triggering the opening of nearby voltage-gated  $\text{Na}^+$  channels still farther along the axon. By this means, the depolarization—the location of the action potential spike—spreads down the axon. Notice in [Fig. 34.7](#) that the area of depolarization represented by the three  $\text{Na}^+$  ions (purple spheres) is farther along the axon in the bottom panel. Neighboring voltage-gated  $\text{K}^+$  channels subsequently open and close to reestablish a resting membrane potential after an action potential has fired. In this way, action potentials become [self-propagating](#). They propagate in only one direction, usually from the cell body at the axon hillock to the axon terminal. The refractory period following an action potential prevents the membrane from reaching its threshold and firing an action potential in the reverse direction.

FIG. 34.7 Propagation of action potentials. Local depolarization of the membrane triggers the opening of nearby voltage-gated  $\text{Na}^+$  channels, producing an action potential that spreads along the membrane. The action potential moves in only one direction (shown here as left to right).

The conduction speed of action potentials is limited by the neuron's membrane properties and the diameter of its axon. Yet fast transmission speeds are essential for animals to respond quickly to stimuli. For example, when you inadvertently touch something very hot, your fingers sense and relay this information rapidly to ensure that you withdraw your hand quickly and avoid worse injury.

The neurons of vertebrate animals have an adaptation that lets them respond rapidly to stimuli in their environment. Glial cells form lipid-rich layers or sheaths called [myelin](#) that wrap around the axons of these neurons ([Fig. 34.8](#)). Myelin gives many nerves a glistening white appearance. The myelin sheath insulates the axon's membrane, spreading the charge from a local action potential over a much greater

distance along the axon's length than would be possible in the absence of myelin.

At regular intervals, the axon membrane is exposed at sites called **nodes of Ranvier** that lie between adjacent segments wrapped with myelin (Fig. 34.8). Voltage-gated  $\text{Na}^+$  and  $\text{K}^+$  channels are concentrated at these nodes. As a result, rather than being conducted in a continuous fashion, as is the case for unmyelinated axons, the action

potentials in myelinated axons “jump” from node to node. This **saltatory propagation** (from the Latin *saltus*, “jump”) of action potentials by myelinated axons greatly increases the speed of signal transmission.

The British neurophysiologists Alan Hodgkin and Andrew Huxley first worked out the electrical properties of the axon plasma membrane by studying the giant axons in squid that stimulate contractions of these animals’ body muscles for swimming (**Fig. 34.9**). For this work, they shared the 1963 Nobel Prize in Physiology or Medicine, along with John Eccles.

#### HOW DO WE KNOW?

### FIG. 34.9

## How does electrical activity change during an action potential?

#### BACKGROUND

To record the voltage of the inside of a nerve cell relative to the outside, a small electrical recording device called a microelectrode is inserted into a neuron. This technique is more easily performed with large cells, such as the squid giant axon. As its name suggests, this axon is quite large, measuring 0.5 mm in diameter (**Fig. 34.9a**), about 500 times larger than most vertebrate axons. The large diameter of the giant axon of the squid allows electrical signals to be propagated to the muscles very quickly. Vertebrate neurons (approximately 1  $\mu\text{m}$ ) are much smaller; they rely on myelin sheaths rather than large size for rapid conduction of electrical signals.

### EXPERIMENT

In 1939, British neurophysiologists Alan Hodgkin and Andrew Huxley inserted a microelectrode into a squid giant axon and placed a reference electrode outside the nerve cell ([Fig. 34.9b](#)) to test the hypothesis that action potentials are established across the membrane of a neuron's axon. They then used a separate set of electrodes (not shown) to depolarize the cell to threshold, triggering an action potential.

and Company

### RESULTS

[Fig. 34.9c](#) is a voltage trace as a function of time from Hodgkin and

Huxley's experiment showing the resting membrane potential and the course of an action potential recorded by the electrode inside a giant squid axon. Note that the resting potential is negative on the inside of the axon relative to the outside, and that the action potential is the rapid spike in potential seen in the voltage trace. During the action potential, the inside of the cell quickly becomes positive, then negative again. The large size of the spike was a surprise.

#### FOLLOW-UP WORK

This work was performed before anyone had identified the ion channels responsible for the changes in current across the membrane. Subsequent work focused on identifying these channels and their roles in generating the action potential.

## Neurons communicate at synapses.

As described earlier, nerve cells communicate at specialized junctions called synapses. Synapses can be electrical or chemical. Electrical

synapses provide direct electrical communication through gap junctions that form between neighboring cells ([Chapters 10](#) and [26](#)). Such electrical synapses are found in the giant axons of squids, as well as in the large motor nerves that fishes use for escape. Those found in the mammalian brain likely help to speed up information processing, but their role has not been well studied.

Chemical synapses are by far the more common type of synapse found in animal nervous systems. The signals conveyed at chemical synapses are neurotransmitters contained within small vesicles in the axon terminal. When an action potential reaches the end of an axon ([Fig. 34.10](#), step 1), the resulting depolarization induces voltage-gated  $\text{Ca}^{2+}$  ion channels to open (step 2). These channels are found only in the axon terminal membrane. Because of their higher concentration outside the cell,  $\text{Ca}^{2+}$  ions diffuse through these channels into the axon terminal. In response to the rise in  $\text{Ca}^{2+}$  concentration, the vesicles fuse with the presynaptic membrane and release neurotransmitter molecules into the synaptic cleft by exocytosis (step 3). The neurotransmitters diffuse rapidly across the cleft and bind to postsynaptic membrane receptors of the neighboring cell. The binding of neurotransmitters opens or closes ion channels, causing a change in the postsynaptic cell membrane potential that allows the signal to propagate along the next neuron (step 4).

FIG. 34.10 A chemical synapse. Neurons communicate with other neurons or with muscle cells by releasing neurotransmitters at a synapse.

These postsynaptic membrane receptors are called **ligand-gated ion channels**, because when the neurotransmitter binds as a ligand, it causes the ion channel to open. Specific ions can then enter or leave the postsynaptic cell, changing its membrane potential. Ligand-gated ion channels underlie the signal transmission that occurs at synapses, regulating the activity of nerve and muscle cells.

The neurotransmitter's effect on the postsynaptic membrane ends shortly after binding. Neurotransmitters become unbound from the receptor, causing the ligand-gated ion channels to close, and

neurotransmitters in the synaptic cleft are either rapidly broken down by deactivating enzymes or taken up again by the presynaptic cell and reassembled in newly formed vesicles (step 5). Because the synapse is rapidly cleared of neurotransmitters, the postsynaptic cell is ready to respond to a new action potential signal from the presynaptic cell shortly after responding to the first one.

## Signals between neurons can be excitatory or inhibitory.

Neurotransmitters bound to postsynaptic membrane receptors can either stimulate or inhibit the firing of action potentials in the postsynaptic neuron. The binding of some neurotransmitters depolarizes the postsynaptic membrane by opening ligand-gated  $\text{Na}^+$  channels. As a result,  $\text{Na}^+$  ions diffuse into the cell, making the membrane potential more positive. Such a positive change in membrane potential is termed an **excitatory postsynaptic potential (EPSP)**. Membrane depolarization makes a neuron more likely to respond and transmit an action potential.

In contrast, the binding of other neurotransmitters can make the postsynaptic membrane potential more negative, or hyperpolarized, through the opening of ligand-gated  $\text{Cl}^-$  or  $\text{K}^+$  channels. In this process,  $\text{Cl}^-$  ions diffuse into the cell or  $\text{K}^+$  ions diffuse out of the cell. The negative change in membrane potential is called an **inhibitory postsynaptic potential (IPSP)**. Membrane hyperpolarization inhibits the neuron from sending an action potential.

The postsynaptic nerve cell combines the excitatory and inhibitory

synaptic inputs (the summed EPSPs and IPSPs) that it receives through its dendrites and cell body ([Fig. 34.11](#)). The neuron then fires an action potential only if the sum of synaptic stimulation results in a membrane potential that exceeds its threshold at the axon hillock ([Fig. 34.11a](#)).

FIG. 34.11 Summation of excitatory and inhibitory postsynaptic potentials. (a) Widely spaced EPSPs do not sum. Other EPSPs and IPSPs can be summed (b) in time or (c) in space, or even (d) cancel each other out.

EPSPs and IPSPs can be summed over time and space. When summed over time, the frequency of synaptic stimuli determines whether the postsynaptic cell fires an action potential ([Fig. 34.11b](#)). This is **temporal summation**. When summed over space, the number

of synaptic stimuli received from different regions of the postsynaptic cell's dendrites determines whether the cell fires an action potential ([Fig. 34.11c](#)). This is **spatial summation**. Sometimes, excitatory and inhibitory signals may cancel each other out ([Fig. 34.11d](#)). Temporal and spatial summation of EPSPs and IPSPs are the fundamental forms of information processing carried out by the nervous system. They provide mechanisms for determining whether an organism responds to a particular sensory stimulus or ignores it.

Many different neurotransmitters exist. Although most nerve cells release only one type of neurotransmitter, some release two or more neurotransmitters. The amino acids glutamate (excitatory), glycine (inhibitory), and GABA (inhibitory) are key neurotransmitters that operate at synapses in the brain. The related amino acid derivatives dopamine, norepinephrine, and serotonin are also neurotransmitters acting in the brain. Simple peptides serve as neurotransmitters for sensory neurons. Acetylcholine is one of the key neurotransmitters produced in a variety of nerve cells: this excitatory neurotransmitter is released by motor neurons to cause muscle contraction ([Chapter 35](#)).

Excitatory synapses tend to transmit relevant information between nerve cells, and inhibitory synapses often serve to filter out unimportant information. For example, when a gazelle senses a predator, its nervous system transmits key sensory information about the presence of a predator, but filters out irrelevant information such as flies buzzing around its ears. Inhibitory synapses are also important for controlling the timing of muscle activity required for coordinated movement.

### Self-Assessment Questions

5. Graph an action potential, showing the change in electrical potential on the y-axis and time on the x-axis. Indicate on the graph the phases when voltage-gated  $\text{Na}^+$  and  $\text{K}^+$  ion channels are opened and when they are closed.
6. What is meant by saying that action potentials are “all-or-nothing”?
7. Multiple sclerosis is a disease in which the immune system attacks and destroys the myelin sheath surrounding nerve cells. What effect would you expect the loss of myelin to have on the speed of nerve conduction?
8. How does neurotransmitter binding to receptors on a postsynaptic cell cause inhibition or excitation?
9. Acetylcholinesterase breaks down and inactivates acetylcholine. Some nerve gases used as chemical weapons block acetylcholinesterase. What effect would such nerve gases have on muscle contraction?

## 34.4 NERVOUS SYSTEM ORGANIZATION

The brain is the body's command center: it receives sensory information from the eyes, ears, and skin; from the antennae and legs of an insect; from the nose of a vertebrate, and from internal organs. Based on that information, it then sends signals to the rest of the body. Up to this point, we have examined how individual neurons send signals to other nerve and muscle cells. How are these neurons organized in the body to sense stimuli, process them, and issue an appropriate response? How does the brain coordinate the movement of limbs necessary to walk or run, and adjust heart rate and breathing in response to exercise? In this section, we look at how the nervous system is organized to allow the brain and the rest of the body to communicate with each other.

### Nervous systems are organized into peripheral and central components.

As animals evolved the ability to sense and coordinate responses to increasingly complex stimuli, their nervous systems became organized into peripheral and central components ([Fig. 34.12](#)). Animals' eyes, receptors for the sense of touch, and other sensory organs are located on the surface of the body, where they can receive signals from the environment. In contrast, the brain and a main nerve cord are located in the interior. Among multicellular animals with nervous systems, only the diffuse nerve nets of cnidarians lack central and peripheral components.

FIG. 34.12 Human central (yellow) and peripheral (blue) nervous systems.

Nerves form the lines of communication between these nervous system structures. Nerves are composed mainly of axons and dendrites from many different nerve cells. For example, the optic nerve contains axons that travel from nerve cells in the eye to the brain.

Nerves connecting to sensory organs and muscles make up the **peripheral nervous system (PNS)**. These nerves communicate with the **central nervous system (CNS)**, which is made up of the brain, a main nerve cord, or—in the case of animals such as flatworms that lack a brain—centralized ganglia. Sensory organs at or near the body surface transmit information by afferent neurons, which send information *toward* the CNS. After processing the information, the CNS sends signals through efferent neurons, which send information

away from the CNS. The signals delivered by efferent neurons in peripheral nerves coordinate the activity of muscles and glands in different regions of the animal's body.

The central nervous system of vertebrates includes the brain and **spinal cord** ([Fig. 34.12](#)). The spinal cord is a central tract of neurons that passes through the vertebrae to transmit information between the brain and the periphery of the body. The vertebrate spinal cord is divided into segments, each of which controls body movement in a particular region along the animal's length. Each spinal cord segment contains axons from peripheral sensory neurons, a set of interneurons, and a set of motor neuron cell bodies.

In humans and other vertebrate animals, the peripheral nervous system is organized into left and right sets of **cranial nerves** located within the head, and **spinal nerves** running from the spinal cord to the periphery. Most of the cranial nerves and all of the spinal nerves contain axons of both sensory and motor neurons. Cranial nerves link specialized sensory organs (eyes, ears, taste buds on the tongue) to the brain. Cranial nerves also control eye movement, facial expression, speech, and feeding. Spinal nerves exit from the spinal cord through openings located between adjacent vertebrae and then thread their way through the trunk and limbs of an animal's body. These nerves receive sensory information from receptors in nearby body regions along the length of the body and send motor signals from the spinal cord back to those regions ([Fig. 34.12](#)).

## Peripheral nervous systems have

## voluntary and involuntary components.

As bodies with distinct internal organ systems evolved, two separate components of the peripheral nervous system emerged. When a gazelle senses a predator, some nerve circuits send a signal to run, an action that is under conscious control. Other nerve circuits signal the heart to beat faster and blood vessels supplying muscles to dilate, actions that occur unconsciously. Conscious reactions are under the control of the voluntary component of the peripheral nervous system, and unconscious ones are under the control of the involuntary component. Voluntary components mainly handle sensing and responding to external stimuli, whereas involuntary components typically regulate internal bodily functions. Both nervous system components are found in invertebrate and vertebrate animals.

In insects and crustaceans, for example, nerve circuits from the involuntary component regulate glands and muscles located in the animal's digestive system. Nerve circuits connecting sensory structures such as the antennae and eyes to the animal's brain, and connecting the brain to muscles, are part of the voluntary system.

In vertebrates, the peripheral nervous system is divided into somatic (voluntary) and autonomic (involuntary or visceral) components. The somatic nervous system is made up of sensory neurons that respond to external stimuli and motor neurons that synapse with voluntary muscles. This system is considered voluntary because it is under conscious control. The autonomic nervous system (Fig. 34.13) controls internal functions of the body such as heart rate, blood flow, digestion,

excretion, and temperature. Thus, it is critical to the maintenance of homeostasis. The autonomic nervous system includes both sensory and motor nerves, which usually act without our conscious awareness.

FIG. 34.13 The human autonomic nervous system. The autonomic system, which controls involuntary functions, is divided into sympathetic and parasympathetic systems.

The autonomic nervous system is organized into **sympathetic** and

**parasympathetic** divisions. Both divisions continuously monitor and regulate internal functions of the body. Typically, sympathetic and parasympathetic nerves have opposite effects. For example, sympathetic neurons stimulate the heart to beat more rapidly, whereas parasympathetic neurons cause the heart to beat more slowly.

The sympathetic nervous system generally causes an increase in alertness and activity. This pathway is activated when animals are exposed to threatening conditions, resulting in the “fight or flight” response. As part of this response, the sympathetic nervous system increases heart rate and breathing rate, stimulates the liver to release glucose, and inhibits digestion. In contrast, the parasympathetic nervous system slows the heart and stimulates digestion as well as metabolic processes that store energy; it enables the body to “rest and digest.”

In addition to having different functions, sympathetic and parasympathetic nerves are distributed in different regions of the central nervous system, as shown in [Fig. 34.13](#). Sympathetic nerves leave the CNS from the middle (thoracic and lumbar) region of the spinal cord, forming ganglia along much of the length of the spinal cord that process information and coordinate activity within a local region of the body. Parasympathetic nerves leave the CNS from the brain by cranial nerves and from lower (sacral) levels of the spinal cord.

**Simple reflex circuits provide rapid responses to stimuli.**

An animal that has perceived a predator has an advantage if it can move quickly. Fast responses are made possible by simple reflex circuits that bypass the brain. These circuits connect sensory neurons (detecting a stimulus) directly with motor neurons (providing a quick response to the stimulus). Reflex circuits are common in both the voluntary and involuntary components of the nervous system.

Simple spinal reflex circuits connect sensory and motor neurons directly in the spinal cord of vertebrates. The [knee-extension reflex](#) in humans is an example of a simple nerve circuit that includes only a single synapse between two neurons—a sensory neuron and a motor neuron ([Fig. 34.14](#)). Physicians commonly use this reflex to evaluate the performance of the peripheral nervous and muscular systems. The strike of the physician's hammer activates the extensor muscles on the front of the thigh, including the quadriceps muscle, causing the bent leg to straighten.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 34.14 The knee-extension reflex. The knee-extension reflex involves a sensory neuron, a single synapse, and a motor neuron.

This pathway starts with specialized “stretch” receptors located on the dendrites of a sensory neuron in the extensor muscles of the leg. These dendrites extend to cell bodies in ganglia alongside the spinal cord. Axons extend from these cell bodies into the spinal cord. The stretch receptors sense the stretch of the muscle that occurs during movement or in response to a physician’s strike of a reflex hammer. In response to a stretch, a signal is sent from the stretch receptor, through the dendrite and cell body, to the axon. In the spinal cord, the axon of the sensory neuron forms synapses with motor neurons that travel from the spinal cord back to the muscle where the stretch originated. The signal from the muscle stretch receptor stimulates the motor neurons: the muscle contracts, and the leg extends at the knee.

This reflex arc is composed of just two neurons and one synapse. Transmission is delayed by communication at synapses, but the muscle contracts quickly because just one synapse is required to relay the sensory information back to the muscle.

As well as being a useful medical test, the knee-extension reflex has a normal physiological role. In running or landing from a jump, the knee joint first flexes (bends), stretching the quadriceps muscles. This action sends the same sensory signal to the spinal cord as when a physician’s hammer taps the muscle’s tendon. As a result, after flexing, the knee reflexively extends (straightens). Knee flexion followed by extension allows rapid adjustments in muscle force and knee position that help stabilize the body during running and jumping.

Because muscles only contract, opposing movements such as

flexion and extension require flexor and extensor muscles on either side of the joint ([Chapter 35](#)). These are often activated out of phase (at different times), so that when one set of muscles is activated (contracting), the other is inhibited (relaxed). The alternating extension and flexion of a leg during walking and running provide an example. This pattern of joint and limb movement is achieved by **reciprocal inhibition**: when stretch receptors of the knee extensor muscles are activated, they also inhibit opposing flexor muscles ([Fig. 34.14](#)). Reciprocal inhibition is possible because axons of the stretch receptor neurons synapse not only with motor neurons of extensor muscles, but also with interneurons that inhibit motor neuron stimulation of flexor muscles. This inhibitory pathway contains two synapses: one synapse between the sensory neuron and interneuron, and a second synapse between the interneuron and the motor neuron to the flexor muscle.

#### Self-Assessment Questions

10. Which functions of an animal are controlled by the voluntary component of the nervous system and which by the involuntary component of the nervous system?
11. Diagram a simple circuit that includes a sensory neuron that synapses with a motor neuron to produce a reflex. Indicate where in the nervous system this synapse is found.
12. Why is an interneuron needed to provide reciprocal inhibition of the flexor muscle when an extensor muscle is activated?

## 34.5 SENSORY SYSTEMS

To see, your eyes detect light, which is a form of electromagnetic radiation. To hear, your ears detect sound waves. To smell, your nose detects odor molecules present in the air. In all these cases, your sense organs detect a physical or chemical stimulus in the environment. In this section, we explore how specialized sensory cells detect these signals and code them as information that can be transmitted and processed by the nervous system.

### Sensory receptor cells detect diverse stimuli.

Animals can sense many physical properties of their environment, including light, chemicals, temperature, pressure, and sound. These perceptions are useful to help animals find mates and food, and avoid predators and noxious environments. Early in evolutionary history, organisms evolved specialized protein receptors in the cell membrane that were able to detect these critical features in their environment. For example, bacteria evolved membrane receptors that sensed osmotic pressure that might otherwise rupture their cell membrane. Bacteria also evolved membrane receptors that detect chemicals, including nutrients, in their environment. Single-celled eukaryotes and sponges have these chemical-sensing membrane receptors as well.

Likewise, the senses of smell, taste, and sight in multicellular organisms with a nervous system rely on membrane receptors. These receptors are embedded in specialized [sensory receptor cells](#). These cells either communicate with neurons, as for taste and sight, or are

themselves neurons, as for smell. (The term “sensory receptor” refers to the entire sensory cell or sensory neuron, not just the membrane protein.)

In most multicellular animals, sensory receptors are organized into specialized [sensory organs](#) that convert physical or chemical stimuli into signals that are communicated to the brain. Cnidarians (including jellyfish, corals, and anemones) and roundworms (including the laboratory organism *Caenorhabditis elegans*) evolved sensory receptors that sense physical contact. Cnidarians and flatworms were among the first animals to evolve simple light-sensing organs.

## Sensory transduction converts a stimulus into an electrical impulse.

The conversion of physical or chemical stimuli into nerve impulses is called [sensory transduction](#). For example, receptors located in the ear convert the energy of sound waves into nerve impulses that allow an animal to distinguish loud versus soft sounds and high-pitched versus low-pitched sounds. Although the sense organs of different animals share many similar properties, some differences between them have also evolved. Consequently, different animals perceive the world differently. Many insects, for instance, are sensitive to ultraviolet light; nocturnal snakes can see at night by sensing infrared radiation; and dogs can distinguish odor compounds at concentrations as much as 100 million times lower than the concentration than humans can detect.

How is a physical phenomenon in the world outside an organism transformed into a nerve impulse? The initial transformation takes

place inside the sensory receptor ([Fig. 34.15](#)). In many cases, the sound wave, touch, or other stimulus causes ion channels in the cell's plasma membrane to open. In most cases, the influx of ions depolarizes the membrane potential by altering the distribution of charged ions on either side of the membrane. That depolarization in membrane potential is the first step in firing an action potential. Sensory receptors either fire action potentials themselves or synapse with neurons that fire action potentials, which are then transmitted to the central nervous system.

FIG. 34.15 Sensory transduction, which converts an external stimulus into a change in membrane potential. (a) Chemoreceptors are located in the antennae of the luna moth; (b) mechanoreceptors below the cuticle of a roundworm; and (c) photoreceptors in the eyes of a vertebrate.

Let's look at examples of how three different types of stimuli from the environment—chemicals, physical changes, and light—can be transformed into a nerve signal.

## Chemoreceptors respond to chemical stimuli.

The most ancient type of sensory detection is chemoreception. All organisms respond to chemical cues in their environment. Even bacteria and archaea have protein receptors in their cell membranes that respond to molecules in the environment. Chemoreception underlies the senses of smell ([olfaction](#)) and taste ([gustation](#)).

In animals, [chemoreceptors](#) are sensory receptor cells that respond to molecules that bind to protein receptors on the cell membrane ([Fig. 34.15a](#)). Many animals detect food in their environment by sensing key molecules such as oxygen (O<sub>2</sub>), carbon dioxide (CO<sub>2</sub>), glucose, and amino acids. Female mosquitoes track CO<sub>2</sub> levels to locate prey for blood meals, and coral polyps respond to simple amino acids in the water, extending their bodies and tentacles toward areas of greater concentration to feed. Other arthropods, such as flies and crabs, have chemosensory hairs on their legs and feet. These animals taste potential food sources by walking on them. Salmon detect chemical traces of the home waters of the river where they hatched, and where they will return to mate and spawn.

The sense of smell in mammals depends on specialized sensory neurons that line the nasal cavity ([Fig. 34.16](#)). These neurons have long, hairlike extensions containing membrane receptors that project

into the nasal mucus. Odor molecules are captured by the mucus during inhalation and bind to membrane receptors. Each sensory receptor has one type of membrane receptor, which is able to detect one type of molecule, but there are typically many distinct sensory receptors, each detecting a different molecule. Mice have approximately 1500 genes that express odorant receptor proteins (about 7% of their genome). The olfactory system can detect specific odor molecules in quite low concentrations.

When bound to odor molecules, the sensory receptors produce excitatory postsynaptic potentials (EPSPs). If enough odor molecules bind to the receptor cell, the EPSPs are summed and trigger an action potential. That action potential travels down the axon to an interneuron

in the olfactory bulb that receives information only from sensory receptors sensitive to a particular odor molecule. In [Fig. 34.16](#), sensory neurons that bind the identical odor molecules shown in the nasal passage all synapse on the middle interneuron. The interneurons in the olfactory bulb, in turn, transmit the combined information from a number of chemoreceptors to the brain. These neurons communicate directly with the brain through the olfactory nerve, one of the cranial nerves.

Clusters of chemosensory receptor cells are also located in specialized [taste buds](#), the sensory organs for taste ([Fig. 34.16](#)). Some fishes have taste buds in their skin that sense amino acids in water, helping them to locate food. The taste buds of terrestrial vertebrates are found in the mouth; most of the taste buds in mammals are on the tongue. The human tongue has approximately 10,000 taste buds, which are contained within raised structures called papillae, giving the tongue its rough surface. Fingerlike projections called microvilli extend through a pore in each taste bud. These microvilli contact food items and provide a large surface area that is rich in membrane receptors.

In most cases, the binding of a molecule to a taste membrane receptor causes the receptor to change conformation, which in turn triggers the opening of  $\text{Na}^+$  channels through G protein signal transduction pathways ([Chapter 9](#)). The influx of  $\text{Na}^+$  ions depolarizes the receptor cell. Although no action potential fires, the depolarization travels far enough down the receptor's short axon to trigger the release of neurotransmitters. Taste bud sensory cells synapse with neurons that send axons to the brain. These neurons fire action potentials when

molecules from a bite of food depolarize a sufficient number of sensory cells.

## Mechanoreceptors detect physical forces.

**Mechanoreceptors** respond to physical deformations of their membrane produced by touch, stretch, pressure, motion, and sound. Mechanoreceptors are found in all multicellular animals. Even bacteria have pressure-sensitive protein receptors in their cell membrane.

In both bacteria and multicellular organisms, the protein receptor is a sodium ion channel. Thus, deformation of the receptor membrane opens sodium channels directly, causing the endings of the cell's dendrites to depolarize (see [Fig. 34.15b](#)). Pressure-sensitive protein receptors in bacteria sense internal cell pressure: when water moving into the cell by osmosis increases the risk of bursting ([Chapter 5](#)), the stretching of the membrane opens channels that let water leave the cell. Other mechanoreceptors in roundworms and anemones are linked to externally projecting cilia that sense forces at the animal's body surface.

One well-studied example of a mechanoreceptor is a touch receptor in the roundworm *Caenorhabditis elegans*. Roundworms, also called nematodes, are one of the most diverse and widespread groups of animals. Deformation of the surface of the worm exerts pressure on proteins connected to an ion channel. The mechanical force changes the shape of the ion channel, causing it to open and produce a change in membrane potential.

One mechanoreceptor in humans and other mammals is the sensory receptor found in the skin that senses touch and pressure. The cell bodies of these neurons are located in ganglia near the spinal cord, with extensions going in two directions: to the skin and to the spinal cord. In the skin, these neurons have branched tips containing ion channels sensitive to deformations of the membrane. These branched tips act as the initial sensors of touch and pressure. If the stimulus is strong enough, depolarization at the tips leads to the firing of an action potential that travels to the spinal cord.

A very different group of mechanoreceptors called [hair cells](#) provide the ability to orient the animal's body with respect to gravity, detect motion, and hear. The hair cells of fishes and amphibians detect movement of the surrounding water, and those of many invertebrates sense gravity and other forces acting on the animal. Hair cells are also found in the ears of terrestrial vertebrates, where they sense body orientation, motion, and sound.

In all these cases, hair cells sense mechanical vibrations. Such vibrations move projections from the surface of the hair cell called [stereocilia](#). In turn, the motion of stereocilia causes a depolarization of the cell's membrane by opening or closing ion channels. Hair cells themselves do not fire action potentials. Instead, when they become depolarized, the cells release neurotransmitters that alter the firing rate of adjacent neurons.

Unlike chemoreceptors, hair cells are generally similar in structure; there is not a specific hair cell for a particular body orientation or pitch

of sound. Thus, for hair cells to provide information about mechanical stimuli, they must interact with structures of the sensory organ in which they reside. These structures influence how individual hair cells respond to body movement and sound waves.

For example, gravity-sensing organs called **statocysts** are found in most invertebrates (**Fig. 34.17a**). The statocyst is a chamber lined by hair cells with stereocilia that project into the chamber. Small granules of sand or other material form a dense particle called a **statolith** that is free to move within the statocyst organ. By pressing down on hair cells at the “bottom” of the chamber, the statolith activates those cells.

**FIG. 34.17 Sensing gravity and motion.** (a) The statocyst of invertebrates detects gravity and orientation by means of a statolith that deflects hair cells. (b) The vestibular system of vertebrates senses gravity by two otolith organs and senses angular rotations of the head by movements of fluid that deflect hair cells within

three semicircular canals.

The mammalian inner ear contains organs that sense motions of the head and its orientation with respect to gravity. These organs make up the **vestibular system** ([Fig. 34.17b](#)), which consists of two otoliths and three **semicircular canals**. The otoliths are similar to the statocysts of invertebrates, providing a sense of gravity and body orientation. Hair cells in the semicircular canals sense angular motions of the head in three perpendicular planes, providing a sense of balance. When the head rotates, gelatinous fluid in the semicircular canals is accelerated, deflecting the stereocilia of the hair cells to activate sensory neurons. The brain interprets differences in the motion of the hair cells among the three semicircular canals to resolve angular motions of the head.

Hair cells in the ear also allow mammals to detect sound. What our ears interpret as sound are actually pressure waves traveling through the air. [Fig. 34.18](#) shows the structure of the human ear. The pinna (external ear), auditory canal, and tympanic membrane (eardrum) make up the outer ear ([Fig. 34.18a](#)). Sound waves enter the outer ear and lead to vibrations of the tympanic membrane. The middle ear contains three small bones: the **malleus**, **incus**, and **stapes**. These bones amplify the vibrations of the tympanic membrane and transmit them to a thin membrane (oval window) of the cochlea in the inner ear.

FIG. 34.18 The human ear. (a) The tympanic membrane and bones of the middle ear transmit sound waves to the inner ear. (b) Hair cells with stereocilia in the cochlea respond to the vibrations, sending signals to the brain.

The **cochlea** (which means “snail” in Latin) is a coiled chamber in the skull ([Fig. 34.18b](#)). It contains two fluid-filled canals separated by a basilar membrane that supports hair cells ([Fig. 34.18c](#)). Stereocilia of the hair cells project into a rigid tectorial membrane. Vibrations of the oval window lead to fluid waves in the cochlea. These waves induce motions of the basilar membrane, bending the stereocilia and stimulating the hair cells to release excitatory neurotransmitters. The signal is sent by the auditory nerve to the brain where it is interpreted as sound.

The ability to discriminate different sound frequencies results from differences in the mechanical properties of the basilar membrane along its length. The basilar membrane is wide, thin, and flexible at one end, and narrow, thick, and stiff at the other end. As a result, the membrane responds to different frequencies in different regions.

---

## CASE 7 BIOLOGY-INSPIRED DESIGN: USING NATURE TO SOLVE PROBLEMS

### How do cochlear implants work?

Our ears allow us to detect sound. Sounds are pressure waves traveling through the air that are converted by hair cells into an electrical signal. Many people, however, are unable to detect sounds. Hearing loss, or deafness, affects millions of people worldwide. Deafness ranges from mild to profound, can occur at any age, and has many different causes. One of the most common causes is damaged or defective hair cells in the cochlea.

To make hearing possible for some deaf persons, scientists have developed cochlear implants. Cochlear implants are small neuro-prosthetic devices that bypass damaged hair cells in the cochlea. They work by electrically stimulating the auditory nerve, which transmits these signals to the brain. Sounds are received by an external microphone worn behind the ear (like a hearing aid) and then decoded by a speech processor that analyzes the sounds. The processor transmits the decoded signals to a receiver that is implanted under the skin. The receiver then sends these signals to electrodes that stimulate

the auditory nerve. In this way, the microphone, speech processor, and electrodes mimic the function of the outer, middle, and inner ear that converts sound waves into electrical signals.

The cochlear implant allows deaf individuals to detect sounds, but the quality of the sounds is different from that of normal sounds. As a result, these individuals have to learn to make sense of the sounds they hear. Furthermore, persons who have never heard sounds need to learn how to interpret the sounds they are hearing for the first time. Thus, after undergoing surgery for a cochlear implant, a person must work with audiologists, counselors, and speech-language pathologists over several years. In addition, scientists continue to develop technology to improve the implants.

The cochlear implant is not without controversy. Many people in the Deaf community view deafness as a culture, with a unique identity, language (sign language), and history. From this perspective, the cochlear implant is a threat. Most deaf children have hearing parents, so decisions about inserting a cochlear implant in a child are often made by people with little or no knowledge of the Deaf community. At the same time, cochlear implants are more effective in younger patients, as the ability to hear and speak depends on early exposure to sounds. Some advocate for sign language to be taught alongside spoken language for children who receive an implant so they have the benefit of multiple forms of communication.

## Electromagnetic receptors sense light.

Electromagnetic receptors are sensory cells that respond to electrical,

magnetic, and light stimuli. Of these, light-detecting [photoreceptors](#) are the most common and diverse types (see [Fig. 34.15c](#)). Most animals sense light in their environment. They rely on the same light-sensitive protein, called [opsin](#), to convert light energy into electrical signals in the receptor cell.

Opsins are ancient molecules that evolved early in animal evolution. These receptor proteins are sensitive to many different stimuli, including light. They are G protein-coupled receptors that activate G proteins, leading to a cellular response ([Chapter 9](#)). In this case, the cellular response is a change in membrane potential. The observation that different types of animal eye use a common light-sensitive protein suggests a common evolutionary origin for animal eyes about 500 million years ago.

Photoreceptors respond to individual photons of light energy. In vertebrates, for example, opsin molecules are arranged in cylindrical groups in the plasma membrane of photoreceptor cells. Each opsin protein contains a light-absorbing pigment molecule called [retinal](#). Retinal is a derivative of vitamin A that changes conformation when it absorbs a photon ([Fig. 34.19](#)).

In most invertebrates, light causes  $\text{Na}^+$  channels to open, depolarizing the cell. By contrast, vertebrate photoreceptor cells have leaky  $\text{Na}^+$  channels that let some  $\text{Na}^+$  ions into the cell even at rest. As a result, their resting membrane potential (in the dark) is less negative (about  $-35$  mV) than that of nerve cells. When a photoreceptor is in the dark and its resting potential is  $-35$  mV, it continuously releases the neurotransmitter glutamate. However, when retinal absorbs a photon of light, it undergoes a conformational change from a *cis* to a *trans* configuration, causing  $\text{Na}^+$  channels to close. Without  $\text{Na}^+$  ions entering the cell, the cell membrane becomes hyperpolarized and the cell's release of glutamate is reduced. The reduction in neurotransmitter triggers EPSPs in the dendrites of some connecting neurons, and IPSPs in others. Differences in the firing rates of these neurons provide information about the intensity and location of light.

Although opsins are the universal photoreceptor protein among animals, the way the visual world is perceived—what it looks like to

the organism—depends in part on the structure of the eye in which the receptors are embedded. Here, we look at the three types of eyes shown in [Fig. 34.20: eyecups, compound eyes, and single-lens eyes](#).

In flatworms, two eyecups on the back surface of the head detect the direction and intensity of light sources ([Fig. 34.20a](#)). Each eyecup contains photoreceptors that point up and to the left or right. In response to light, flatworms turn to move directly away from the light source, seeking a dark region that hides them from potential predators. To find a dark region, the flatworm's nervous system compares the light intensity received by photoreceptors of the two eyecups; the organism then moves in the direction of lower light intensity. Many invertebrates use simple light-sensitive photoreceptors in this way.

A key innovation for detecting images was the evolution of a lens. Two major types of image-forming eyes based on lenses evolved in other invertebrates: compound eyes and single-lens eyes. Insects and

crustaceans have compound eyes that consist of individual light-focusing elements, each having a lens, called **ommatidia** (singular, **ommatidium**) (Fig. 34.20b). The number of ommatidia in the eye determines the resolution, or sharpness, of the image. The compound eyes of ants have only a few ommatidia, and those of fruit flies have about 800. In contrast, the eyes of dragonflies have 10,000 or more. Dragonflies are predators, and their high number of ommatidia is an adaptation for detecting motion and visually tracking their prey.

The single-lens eyes of vertebrates and cephalopod mollusks like squid and octopuses produce sharply defined images (Fig. 34.20c). In spite of their similar outward appearance, single-lens eyes evolved independently in vertebrates and in cephalopod mollusks. An advantage of single-lens eyes compared to compound eyes is that the single lens can focus light rays on a particular region of photoreceptors, improving image quality and light sensitivity.

To form an image, light is focused on a thin, light-sensitive tissue called the **retina** located in the back of the eye. The retina contains the photoreceptor cells that sense light stimuli and other nerve cells that initially process those stimuli. Vertebrates have two types of photoreceptor cells: **rod cells** and **cone cells** (Fig. 34.21). Rod cells are sensitive to blue-green light. Because all rod cells have the same opsin (called rhodopsin), the brain interprets the light detected by rod cells as shades of gray, not as blue-green. Rod cells are more numerous and sensitive than cone cells, so they allow animals to see in low light. Cone cells contain opsins sensitive to different wavelengths of light and are responsible for color vision.

FIG. 34.21 Vertebrate photoreceptors: rods and cones.

Cone cells likely evolved from a rod cell precursor. Most non-mammalian vertebrates have four types of cone cells, each with a different opsin. In contrast, most mammals have two types of cone cells, and two opsins. It is likely that two opsins were lost early in mammalian evolution, when mammals were small, nocturnal, and burrowing. Old World primates, apes, and humans, as well as some New World primates, regained trichromatic (three-color) vision by means of gene duplication, likely in response to selection for better ability to locate fruit, a key part of their diet. Each human cone cell therefore has one of three opsins, which absorb light at blue, green, or red wavelengths. Stimulation of cone cells in varying combinations of these three opsins allows humans and other primates to see a full range of color.

13. What are examples of chemosensory, mechanosensory, and electromagnetic sensory cells?
14. Diagram a generalized sensory receptor cell and show how it changes its firing rate in response to a stimulus.
15. State a hypothesis that explains why all animals have chemoreceptors.
16. Why are you unstable when you try to walk after you spin in place or take a ride on a merry-go-round?
17. Compare and contrast the roles of rod cells and cone cells in the retina.

## 34.6 BRAIN ORGANIZATION AND FUNCTION

Up to this point, we have looked at how sensory information, such as smell, taste, hearing, and vision, is detected by sensory receptors. In each case, the sensory information is sent to the brain, where it is processed. Much of what we know about how the brain functions has been learned over many years through studies of patients who suffered brain injuries and through studies in model organisms. The remainder of this chapter explores the functional organization of the vertebrate brain.

### The brain processes and integrates information received from different sensory systems.

The vertebrate brain is organized into a [hindbrain](#), [midbrain](#), and [forebrain](#), with a [cerebral cortex](#) formed from a portion of the forebrain ([Fig. 34.22a](#)). The hindbrain and midbrain control basic body functions and behaviors, whereas the forebrain, particularly the cerebral cortex, governs more advanced cognitive functions. The cerebral cortex of mammals—and particularly of primates and humans—is greatly expanded relative to that of other vertebrates.

FIG. 34.22 Human brain development. (a) The brain develops from the forebrain, midbrain, and hindbrain. (b) Part of the forebrain develops into the limbic system, which controls drives and emotions.

In adult vertebrates, the hindbrain develops into the **cerebellum** and a portion of the **brainstem** (Fig. 34.22a). The remainder of the brainstem develops from the midbrain. The cerebellum coordinates the body's actions for complex motor tasks, such as catching a ball or writing. It integrates both motor and sensory information. The brainstem, consisting of the **medulla**, **pons**, and midbrain, initiates and regulates motor functions such as walking and controlling posture, and coordinates breathing and swallowing. The brainstem activates the forebrain by relaying information from lower spinal levels.

The forebrain consists of an inner brain region that forms the **thalamus** and the underlying **hypothalamus**, and a more anterior region that develops into the **cerebrum**, the outer left and right hemispheres of the cerebral cortex (Fig. 34.22a). The thalamus is a central relay station for sensory information sent to higher brain centers of the cerebrum. The hypothalamus interacts closely with the

autonomic and endocrine systems to regulate the general physiological state of the body. In humans and most other primates, the cerebral cortex is the largest part of the brain, overseeing sensory perception, memory, and learning.

Other inner components of the forebrain constitute the **limbic system**, which controls physiological drives, instincts, emotions, and motivation and, through interactions with midbrain regions, the sense of reward (**Fig. 34.22b**). Stimulation of the limbic system can induce strong sensations of pleasure, pain, or rage. A posterior region of the limbic system, the **hippocampus**, is involved in long-term memory formation, discussed in the next section.

Sensory information reaches the cerebral cortex from the cranial nerves and nerves passing through the spinal cord. This information passes first through the brainstem, and then through the thalamus, the central relay station for sensory information. From the thalamus, information for each of the senses goes to a different region of the brain specialized for further processing that kind of information.

## The brain is divided into lobes with specialized functions.

The cerebral hemispheres are the largest structures of the mammalian brain (**Fig. 34.23**). They contain a highly folded outer layer of **gray matter** that forms the cerebral cortex, which is made up of densely packed neuron cell bodies and their dendrites (**Fig. 34.23a**). The folds greatly increase the surface area of the cortex and are the result of selection for an increased number of cortical neurons within the limited

volume of the skull. Deep inside the cerebral cortex is the **white matter**, which contains the axons of cortical neurons. The fatty myelin produced by glial cells surrounding the axon makes this region of the brain white. Neurons in different regions of the gray matter communicate with each other and with deeper regions of the forebrain, midbrain, and hindbrain.

FIG. 34.23 Human brain organization. (a) The folding of the brain and (b) the lobes of the cerebrum.

Major regions of the cerebral hemispheres are defined by clearly visible anatomical lobes separated in most cases by deep crevices called **sulci** (singular, **sulcus**) (Fig. 34.23b). The **frontal lobe** is located in the front region of the cerebral cortex (behind your forehead). It is important in decision making and planning. The **parietal lobe** is located behind the frontal lobe and is separated from the frontal lobe by the central sulcus. The parietal lobe controls body awareness and the ability to perform complex tasks, such as animal courtship or human

dressings. The [temporal lobe](#) lies below the parietal lobe. It is involved in processing sound, as well as performing other functions discussed later in this section. Located at the back of the brain is the [occipital lobe](#), which processes visual information.

The central sulcus separates the [primary motor cortex](#) of the frontal lobe from the [primary somatosensory cortex](#) of the parietal lobe ([Fig. 34.23b](#)). “Command” neurons in the primary motor cortex produce complex coordinated behaviors by controlling skeletal muscle movements. The primary somatosensory cortex integrates information about pressure and touch from specific body regions and relays this information to the motor cortex. Both cortices make connections to the opposite side of the body by sending axons that cross over in the brainstem and spinal cord. As a result, the right cortex controls the left side of the body and the left cortex controls the right side of the body.

## Information is topographically mapped into the vertebrate cerebral cortex.

The primary somatosensory cortex and motor cortex are organized as topographic maps that represent different body regions, as shown in [Fig. 34.24](#). For example, the neurons that sense pressure and touch sensation of the foot and lower limb are located near the mid-axis of the somatosensory cortex. Those that sense motions of the face, jaws, and lips map to the side and farther down in the primary motor cortex. A similar topographic map exists in the motor cortex. Notice how large the hand and face are on the map: regions such as those representing

the fingers, hands, and face, which must distinguish fine sensations or control fine motor movements, are represented by larger areas of the cortex.

FIG. 34.24 Somatosensory topographic map.

The auditory cortex in the temporal lobe is similarly organized as a map. This region processes sound information transmitted from the cochlea of the ear. Neurons in the auditory cortex are organized by pitch: neurons sensitive to low frequencies are located at one end, while neurons sensitive to high frequencies are found at the other end.

The occipital lobe topographically maps visual information received from the optic nerves. The topographic mapping of information enables the brain to relate patterns and motion to precise regions of the visual field. As a result, highly visual animals, such as primates and birds, are able to detect complex patterns and movements in their environment.

## The brain allows for memory,

# learning, and cognition.

Memory is the basis for learning. An animal that can remember its encounter with a predator or noxious plant will avoid that danger in the future. A memory is formed by changes in the synaptic connections between neurons in a neural circuit.

In humans and other primates, the hippocampus plays a special role in memory formation. We can remember much of the information we receive for several minutes. However, unless it is reinforced by repetition or by paying particular attention, this information is typically forgotten. The hippocampus transforms reinforced short-term memories into long-term memories.

The hippocampus forms long-term memories by repetitively relaying information to regions of the cerebral cortex. Although the details of these processes remain uncertain, memory and learning depend on establishing particular neural circuits in the hippocampus and cerebral cortex. These circuits can be activated to recall a memory by a particular sound, sight, or other relevant stimulus. Establishing a neural circuit requires establishing a particular set of connections between neurons. Thus, the formation of a memory circuit requires changes in synapses. Some synapses are weakened or removed altogether, whereas others are formed or strengthened. Synapses in the pathways that are repeatedly activated by the hippocampus are likely to be formed or strengthened.

Although the brain regions involved in memory and learning vary among different animals, the basic features of how memories are

constructed through changes in synapses are likely broadly shared across animals capable of forming memories. For example, octopuses rival certain vertebrates in their ability to learn and remember motor tasks. Even the roundworm *C. elegans* is capable of memory and learning.

Human brains are able to process and integrate complex sources of information, interpret and remember past events, solve problems, reason, and form ideas. Collectively, these abilities are called **cognition**. Cognitive brain function ultimately gives rise to a state of consciousness—an awareness of oneself in relation to others.

The study of the brain is challenging because its circuits are so complex. Nevertheless, considerable progress is being made through the use of non-invasive neuroimaging techniques. Using these techniques, scientists observe the interactions of different brain regions within human and other animal subjects while the subjects perform a particular mental or motor task. The results of such neuroimaging studies can then be linked to studies of the molecular and cellular properties of nerve cells. Taken together, these studies advance our understanding of how nerve cells form and maintain neural circuits among different brain regions, and of how these circuits are linked to particular behaviors and cognitive processes.

#### Self-Assessment Questions

18. Draw the brain, label the lobes, and describe their primary functions.

19. What is topographic mapping of sensory input in the cortex? Use the primary somatosensory cortex as an example.

## CORE CONCEPTS SUMMARY

### **34.1 NERVOUS SYSTEM FUNCTION AND EVOLUTION:**

Nervous systems allow animals to sense and respond to the environment, coordinate movement, and regulate internal functions of the body.

Nerve cells, or neurons, receive and send signals and are the functional unit of the nervous system. [page 753](#)

Animal nervous systems include three types of neurons: sensory neurons that respond to signals, interneurons that integrate and process sensory information, and motor neurons that produce a response from muscle. [page 753](#)

Ganglia are localized collections of nerve cell bodies that integrate and process information. [page 754](#)

Simply organized animals, such as cnidarians, have a nerve net to coordinate sensory and motor function. [page 754](#)

Forward locomotion favored the evolution of specialized sense organs in the head, along with concentrated groupings of nerve cells to form ganglia and a brain. [page 754](#)

**34.2 NEURON STRUCTURE:** The functional unit of the nervous system is the neuron, which has dendrites that receive information and axons that transmit information.

Neurons share a common organization: they have dendrites that receive inputs, a cell body that receives and sums the inputs, and axons that transmit signals to other nerve cells. [page 755](#)

Glial cells provide nutritional and physical support for neurons.

[page 757](#)

**34.3 SIGNAL TRANSMISSION:** The electrical properties of neurons allow them to communicate rapidly with one another.

Neurons have electrically excitable membranes that code information by changes in membrane potential and transmit information in the form of electrical signals called action potentials.

[page 758](#)

Ion channels open and close in response to changes in the membrane potential, underlying the production of action potentials in nerve cells. [page 758](#)

Action potentials fire in an all-or-nothing fashion; a brief refractory period follows their firing. [page 758](#)

In vertebrates, glial cells produce the myelin sheath that insulates axons, increasing the speed of nerve impulses. [page 761](#)

Action potentials are conducted in a saltatory fashion in myelinated axons, firing at nodes of Ranvier, where the axon membrane is exposed and not insulated by myelin. [page 761](#)

Most neurons communicate by chemical synapses formed between an axon terminal and a neighboring nerve or muscle cell. [page 763](#)

Communication across the synapse occurs when an arriving action potential triggers the release of neurotransmitters from vesicles within the axon terminal. [page 763](#)

Neurotransmitters released from presynaptic vesicles bind to receptors in the postsynaptic membrane, causing either an excitatory stimulus or an inhibitory stimulus. [page 764](#)

Excitatory stimuli depolarize the membrane, producing an excitatory postsynaptic potential (EPSP), whereas inhibitory stimuli hyperpolarize the membrane, producing an inhibitory postsynaptic potential (IPSP). [page 764](#)

EPSPs and IPSPs can be summed over time (temporal summation) and space (spatial summation). [page 765](#)

**34.4 NERVOUS SYSTEM ORGANIZATION:** Nervous systems are organized into peripheral and central components, and include voluntary and involuntary functions.

Nervous systems are divided into the peripheral nervous system (PNS) and central nervous system (CNS). [page 765](#)

The peripheral nervous system is distributed throughout the animal's body and is composed of sensory and motor nerve cells. [page 765](#)

The central nervous system includes the brain and one or more main trunks of nerve cells, such as the spinal cord. [page 765](#)

In many invertebrates and vertebrates, the peripheral nervous system is divided into voluntary and involuntary components. [page 766](#)

In vertebrates, the voluntary component is referred to as the somatic nervous system, and the involuntary component is referred to as the

autonomic nervous system. [page 766](#)

The autonomic system regulates body functions through opposing actions of its sympathetic and parasympathetic divisions. [page 767](#)

Simple reflex circuits can involve as few as two neurons: a sensory neuron from the periphery, which synapses with a motor neuron in the spinal cord that sends a signal to a muscle. [page 768](#)

**34.5 SENSORY SYSTEMS:** Animal sensory receptors detect chemical, physical, and electromagnetic stimuli by changes in membrane potential.

Sensory receptors convert chemical or physical stimuli into nerve impulses in the process of sensory transduction. [page 769](#)

Chemoreceptors detect chemical stimuli and allow for the senses of taste and smell. [page 769](#)

Mechanoreceptors respond to physical deformations produced by touch, stretch, pressure, motion, and sound, and are important for the senses of balance, detecting the direction of gravity, and hearing. [page 771](#)

Hair cells are specialized mechanoreceptors that detect motion and vibration. [page 772](#)

Electromagnetic receptors are sensory cells that respond to electrical, magnetic, and light stimuli and provide the sense of vision. [page 774](#)

Opsin is a G protein-coupled receptor and the universal

photoreceptor protein in animal eyes. [page 774](#)

Opsin converts light energy into chemical signals, altering the firing rate of neurons. [page 774](#)

Three types of eyes are the eyecups of flatworms, the compound eyes of many arthropods, and the single-lens eyes of vertebrates and cephalopod mollusks. [page 774](#)

Photoreceptor cells of the retina include rod cells, which detect light intensity, and cone cells, which detect different wavelengths of light and allow color vision. [page 776](#)

**34.6 BRAIN ORGANIZATION AND FUNCTION:** The brain integrates information from diverse sources and is organized into distinct regions with specialized functions.

The vertebrate brain is organized into a hindbrain, midbrain, and forebrain. The forebrain is elaborated into the cerebral cortex in birds and mammals. [page 776](#)

The cerebrum is divided into frontal, parietal, temporal, and occipital lobes, which are specialized for different functions. [page 777](#)

Somatosensory, motor, auditory, and visual information is topographically mapped to specific areas in the cerebral cortex. [page 778](#)

The brain stores memories of past experiences and enables learning through the creation of long-lasting neural circuits. [page 778](#)

# CHAPTER 35 Animal Movement: Muscles and Skeletons

SPL/Science Source

---

## CORE CONCEPTS

**35.1 HOW MUSCLES WORK:** Muscles are biological motors composed of actin and myosin that generate force and produce movement

for support, locomotion, and control of internal physiological functions.

**35.2 MUSCLE CONTRACTILE PROPERTIES:** The force generated by a muscle depends on muscle size, degree of actin–myosin overlap, shortening velocity, and stimulation rate.

**35.3 ANIMAL SKELETONS:** Hydrostatic skeletons, exoskeletons, and endoskeletons provide animals with mechanical support and protection.

**35.4 VERTEBRATE SKELETONS:** Vertebrate endoskeletons allow for growth and repair and transmit muscle forces across joints.

---

The ability to move is a defining feature of animal life. Movement allows animals to explore new environments and avoid inhospitable ones, escape predators, mate, feed, and play. An animal's motor and nervous systems work together to enable it to sense and respond to its environment. How are movements produced, and how are they controlled? What determines an athlete's performance? How do muscles and the skeleton work together to provide movement and support? How do muscles convert the chemical energy of ATP into force and movement during a contraction? This chapter explores the organization and function of the muscles and skeletons that power the movements of larger multicellular animals and provide mechanical support of their bodies ([Fig. 35.1](#)).

*Photo source: Tom Brakefield/Alamy.*

**FIG. 35.1 Muscles and bones.** Muscles and bones work together to produce movement.

## 35.1 HOW MUSCLES WORK

We rely on our muscles for all kinds of movement. Muscles function as biological motors within the body because they generate force and produce movement. Some of these movements are obvious—running, climbing stairs, raising your hand, and playing the piano. We are less aware of others—moving food through the digestive tract, breathing in and out, pumping blood through the body. A muscle's ability to produce movement depends on electrically excitable muscle cells containing proteins that can be activated by the nervous system. As we will discuss, the geometry and organization of these proteins largely determine how muscles contract (shorten) to produce force and movement.

The contractile machinery of muscles has an ancient history. The proteins underlying muscle contraction have been found in eukaryotes that lived more than 1 billion years ago, and the first muscle fibers common to all animals are found in cnidarians (the group that includes jellyfish, corals, and sea anemones), which evolved at least 600 million years ago. Thus, basic features of muscle organization and function are conserved across the vast diversity of eukaryotes. Nevertheless, recent genetic analysis shows that certain features of muscle evolved independently in cnidarians, possibly ctenophores (comb jellies), and all other animals.

### Muscles use chemical energy to produce force and movement.

Muscles are composed of elongated cells called muscle **fibers**. Muscle

fibers use ATP generated through cellular respiration ([Chapter 7](#)) to generate force and change length during a contraction. This conversion of chemical energy into muscle work underlies much of the energy cost of animal movement discussed in [Chapter 38](#).

A **force** is a push or pull by one object interacting with another object. Skeletal muscles, for example, generate pulling forces at specific sites of the skeleton. As a muscle shortens, it pulls against the part of the skeleton to which it is attached. The work performed by a muscle is equal to force times length change. For example, work is increased when either the force produced or the distance the skeleton is moved increases. Similarly, a muscle that produces a pulling force twice as great as another muscle but moves the skeletal segment only half the distance does the same work as that other muscle.

Because muscles exert only pulling forces, pairs of muscles are arranged to produce movements in two opposing directions at specific joints of the skeleton. For example, muscles pull on the bones of your leg and foot to swing them forward when you kick a ball. Opposing sets of muscles pull on the leg in the opposite direction to swing your leg back and flex your knee before and after the kick.

Muscles can shorten very quickly, and they can produce large forces for their weight. These forces can be many times an animal's body weight, allowing animals to move quickly. Some small muscles contract extremely quickly. For example, the muscles of many flying insects contract 200 to 500 times per second. Even in vertebrate animals, muscles can contract as many as 50 to 100 times per second.

Other muscles, such as the closing muscle of a clam, contract slowly, but can continue contracting for prolonged periods without tiring. To see how muscles produce forces and contract to change length, we now consider how muscle fibers are organized at the molecular level.

## Muscles can be striated or smooth.

All muscle fibers contain the same contractile proteins that enable them to shorten and produce force, namely actin and myosin ([Chapter 10](#)). These proteins are organized into long, narrow bundles called [filaments](#) that interact with one another to cause muscle fibers to shorten. Although all muscle fibers have filaments of actin and myosin, the filaments are arranged differently in different types of muscle.

Muscles are organized into two broad groups on the basis of their function and appearance under a light microscope ([Fig. 35.2](#)). As their name suggests, [striated muscles](#) appear striped under a light microscope because the actin and myosin filaments are arranged in a regularly repeating pattern. Striated muscles include [skeletal muscles](#) ([Fig. 35.2a](#)), which connect to the body skeleton to move the animal's limbs and torso, and [cardiac muscle](#) in the heart ([Fig. 35.2b](#)), which contracts to pump blood. Skeletal muscle cells are elongated and have many nuclei in each cell. By comparison, cardiac muscle cells are typically less elongated than skeletal muscle cells, often branched, and contain one or more nuclei per cell.

Sources: a. Innerspace Imaging/Science Source; b. Manfred Kage/Science Source; c. SPL/Science Source.

FIG. 35.2 Light micrographs of (a) skeletal muscle, (b) cardiac muscle, and (c) smooth muscle. Skeletal and cardiac muscles have a striated, or striped, appearance; smooth muscle does not.

In contrast to skeletal and cardiac muscle, **smooth muscles** appear unstriated under the light microscope because the organization of actin and myosin filaments is irregular ([Fig. 35.2c](#)). In many vertebrates and invertebrates, smooth muscles are found in the walls of arteries to regulate blood flow, in the respiratory system to control air flow, and in the digestive and excretory systems to help transport food and waste products. Smooth muscles contract slowly compared with cardiac and skeletal muscles. Consequently, bivalve mollusks rely on smooth muscle fibers to keep their shells closed for long periods without having to expend much energy.

## Skeletal and cardiac muscle fibers are organized into repeating contractile units called sarcomeres.

The visible bands in skeletal and cardiac muscles are an important clue to the mechanism that produces muscle contractions. Whole muscles are made up of parallel bundles of individual muscle fibers ([Fig. 35.3](#)).

Recall that a muscle fiber is a muscle cell. Each muscle fiber, in turn, contains hundreds of long, rodlike structures called **myofibrils**. Myofibrils contain parallel arrays of actin and myosin filaments that cause a muscle to contract.

FIG. 35.3 Skeletal muscle organization. Muscles are made up of bundles of muscle fibers (cells), each of which contains myofibrils.

Let's consider the organization of actin and myosin filaments in skeletal muscles in more detail ([Fig. 35.4](#)). Actin molecules polymerize to create two long polypeptide chains, which are arranged as a double helix to form a [thin filament](#). The protein [tropomyosin](#) runs in the grooves formed by the actin helices. Each myosin molecule consists of two long polypeptide chains coiled together, with each chain ending with a globular head. Consequently, the myosin molecule resembles a double-headed golf club. The myosin molecules are arranged in parallel to form a [thick filament](#), with the numerous myosin heads extending out from their flexible necks along the myosin filament.

FIG. 35.4 Thin and thick filaments. A thin filament is made up of two actin subunits arranged in a double helix. A thick filament is made up of numerous myosin molecules arranged in parallel.

The thin filaments are attached to protein backbones called [Z discs](#) that are regularly spaced along the length of the myofibril ([Fig. 35.5a](#)). The region from one Z disc to the next is called the [sarcomere](#). Sarcomeres are the functional units of muscles. In other words, the shortening (contraction) of a muscle is ultimately the result of the

shortening of thousands of sarcomeres along a myofibril.

Sarcomeres are arranged in series along the length of the myofibril. Sets of actin thin filaments extend from both sides of the Z discs toward the midline of the sarcomere ([Fig. 35.5a](#)). In the middle of the sarcomere, but not directly contacting the Z discs, are myosin thick filaments. The thin filaments overlap with the myosin thick filaments, forming two regions of overlap within a sarcomere. Toward either end

of the sarcomere, as well as in the middle, are regions where the actin and myosin filaments do not overlap. The regions that overlap appear dark under an electron microscope, while the regions of non-overlap appear lighter in color. A third large protein, called titin, links the myosin filaments to the Z discs at the ends of the sarcomere. Titin is believed to help with assembly and protect the sarcomeres from being overstretched. Because it acts as a spring, titin also contributes to muscle elasticity.

As mentioned earlier, the regular pattern of actin and myosin filaments within sarcomeres along the length of the fiber gives skeletal muscles their striated appearance (see [Fig. 35.2a](#)). In cross section, thick and thin filaments are arranged in a hexagonal lattice. This arrangement allows each thick filament to interact with six adjacent thin filaments ([Fig. 35.5b](#)). The precise geometry of thin and thick filaments is critical to their interaction, as we discuss next.

## Muscles contract by the sliding of myosin and actin protein filaments.

Using high-resolution light microscopy, two independent teams (physiologists Hugh Huxley and Jean Hanson in the United States and Andrew Huxley and Rolf Niedergerke in England) were able to quantify the changing banding patterns of sarcomeres when rabbit or frog myofibrils were stimulated to contract to different lengths. Their results led them to hypothesize that muscles change length and produce force by the sliding of actin filaments relative to myosin filaments. Their theory is known as the [sliding filament model](#) of muscle contraction.

The banding patterns of sarcomeres revealed the extent of overlap between actin and myosin filaments. When myofibrils contracted to short lengths, the sarcomeres were observed to have increased actin–myosin overlap. When myofibrils were stretched to longer lengths, actin–myosin overlap decreased ([Fig. 35.6](#)). However, the lengths of the myosin and actin filaments never varied. Consequently, nearly all of the length change during a muscle contraction results from the sliding of actin filaments with respect to myosin filaments within individual sarcomeres. The length change of the whole muscle fiber, therefore, is a sum of the fractions by which each sarcomere shortens along the fiber’s length.

**FIG. 35.6 Sliding filament model.** Muscle contraction, or shortening, results from the sliding of actin thin filaments relative to myosin thick filaments. Filament sliding changes the sarcomere banding pattern between Z discs.

A muscle’s ability to change length and generate force is largely determined by the properties of its sarcomeres. Whereas sarcomere length is quite uniform in vertebrate animals (approximately 2.3  $\mu\text{m}$  at rest), it is highly variable in invertebrate animals (ranging from as short as 1.3  $\mu\text{m}$  to as long as 43  $\mu\text{m}$ ). Longer sarcomeres allow a greater

degree of shortening. Thus, length changes are more limited in vertebrate muscles compared to those in some invertebrate muscles with long sarcomeres. For example, when the sarcomeres in an octopus tentacle contract, they can produce large motions of the tentacle. However, because vertebrates have shorter sarcomeres than an octopus, vertebrate muscles can shorten to produce movements more quickly.

Interactions between the myosin and actin filaments cause the muscle fiber to shorten and produce force. Along the myosin filament, one of the two heads of a myosin molecule at a given point in time binds to actin at a specific site to form a [cross-bridge](#) between the myosin and actin filaments. The myosin filaments pull the actin filaments toward each other by means of these cross-bridges.

The key to making the filaments slide relative to each other is the ability of the myosin head to undergo a conformational change and, therefore, pivot back and forth. The myosin head attaches to the actin filament and pivots forward, sliding the actin filament toward the middle of the sarcomere. The myosin head then detaches from the actin filament, pivots back, and reattaches, and the cycle repeats. The movement of the myosin head is powered by ATP. Together, these events constitute the [cross-bridge cycle](#).

The cross-bridge cycle is just that—a cycle ([Fig. 35.7](#)). Let's look at it in more detail:

1. The myosin head binds ATP. Binding of ATP allows the myosin head to detach from actin and readies it for attachment to actin again.

2. The myosin head hydrolyzes ATP to ADP and inorganic phosphate ( $P_i$ ). Hydrolysis of ATP results in a conformational change in which the myosin head is cocked back. ADP and  $P_i$  remain bound to the myosin head. Because ADP and  $P_i$  are bound rather than released, the myosin head is in a high-energy state.
3. The myosin head binds to actin, forming a cross-bridge.
4. When the myosin head binds to actin, the myosin head releases ADP and  $P_i$ . The result is another conformational change in the myosin head, called the **power stroke**. During the power stroke, the myosin head pivots forward and generates a force, causing the myosin and actin filaments to slide relative to each other over a distance of approximately 7 nm. The power stroke pulls the actin filaments toward the sarcomere midline.

The myosin head then binds a new ATP molecule (step 1 again), allowing it to detach from actin, and the cycle repeats, as the myosin binds to a new site farther along the actin filament.

Individual muscle contractions are the result of many successive cycles of cross-bridge formation and detachment among many myosin and actin filaments. During these cycles, muscle cells convert the chemical energy released by ATP into force and the kinetic energy of movement. Muscle fibers that contract especially quickly, such as those that power insect wing flapping or produce the sounds of cicadas and rattlesnake tails, express myosin molecules that have high rates of ATP hydrolysis. The muscle fibers have faster rates of cross-bridge cycling, force development, and shortening. Thus, myosin functions as both a structural protein and an enzyme.

Each thick filament can interact with as many as six actin filaments. Thus, at any one time numerous cross-bridges anchor the lattice of myosin filaments, while other myosin heads are detached to find new

binding sites. When summed over millions of cross-bridges, these molecular events generate the force that shortens the whole muscle.

## Calcium regulates actin–myosin interaction through excitation–contraction coupling.

We have discussed *what* makes muscles contract. We now consider *when* they contract. Skeletal and smooth muscle fibers are both activated by the nervous system. Whereas vertebrate skeletal muscles are activated by the somatic nervous system, smooth muscles are activated by the autonomic nervous system, as are cardiac muscles ([Chapter 34](#)).

Like nerve cells, muscle fibers are electrically excitable. Skeletal muscle fibers are activated by impulses transmitted by motor nerves ([Fig. 35.8](#)). Motor neuron axons have branches that allow each axon to synapse with multiple muscle fibers. When action potentials traveling down a motor neuron arrive at the neuromuscular junction, the neurotransmitter acetylcholine is released into the synaptic cleft. The neurotransmitter binds with postsynaptic receptors on the muscle cell at a region called the [motor endplate](#), triggering the opening of  $\text{Na}^+$  channels. The resulting influx of  $\text{Na}^+$  ions initiates a wave of membrane depolarization that passes from the neuromuscular junction toward both ends of the muscle fiber ([Chapter 34](#)).

FIG. 35.8 Excitation–contraction coupling. Depolarization (excitation) leads to shortening (contraction) of the muscle.

How does membrane depolarization lead to the cross-bridge cycle? Actin and myosin filaments can form cross-bridges only when the myosin-binding sites on actin are exposed. At rest, these binding sites are blocked by the protein tropomyosin. The wave of depolarization in the muscle cell initiates a chain of events that moves tropomyosin away from these binding sites, allowing cross-bridges between actin and myosin to form and the muscle to contract ([Fig. 35.8](#)).

Let's look at the chain of events that concludes with the exposure of the myosin-binding sites. You saw in [Chapter 5](#) that eukaryotic cells contain several types of membrane-bound internal organelles. The myofibrils of muscle cells are surrounded by a highly branched membrane-bound organelle called the [sarcoplasmic reticulum \(SR\)](#), a modified form of the endoplasmic reticulum. When the muscle is at rest, the SR contains a large internal concentration of calcium ( $\text{Ca}^{2+}$ ) ions that are transported into the cell by calcium pumps in its membranes.

Depolarization initiated in the plasma membrane is conducted to the SR through infoldings of the plasma membrane ([Fig. 35.8](#)). A muscular contraction is initiated when depolarization reaches the SR and causes it to release  $\text{Ca}^{2+}$ . The  $\text{Ca}^{2+}$  diffuses into the myofibrils and binds to a protein called [troponin](#), causing the troponin molecule to change shape. This conformational change of troponin, in turn, causes tropomyosin to move, exposing myosin-binding sites along the actin

filament. Myosin cross-bridges then form with actin, producing a contraction.

Note that at this stage in the cross-bridge cycle, the myosin head has already hydrolyzed ATP, is bound to ADP and  $P_i$ , and is in the cocked-back “ready” position. Binding to actin then allows the power stroke to occur. In this way, contraction is initiated immediately following depolarization and release of  $Ca^{2+}$ .

The process by which membrane depolarization leads to  $Ca^{2+}$  release from the SR and the formation of myosin-actin cross-bridges is called **excitation–contraction coupling** because excitation of the muscle cell is coupled to contraction of the muscle. Together, these events are the molecular “switch” that causes a muscle to contract. The muscle relaxes when neural stimulation ends. Acetylcholine is broken down or reabsorbed, and  $Ca^{2+}$  is actively transported back into the sarcoplasmic reticulum. With  $Ca^{2+}$  gone, tropomyosin molecules can once again block myosin-binding sites along the actin filaments.

## Calmodulin regulates calcium activation and relaxation of smooth muscle.

Smooth muscle controls many internal organs. How is the contraction of smooth muscle regulated? Smooth muscle can be activated by the autonomic nervous system, but it also responds to other factors. These include hormones, stretch of the muscle, and local factors such as pH, oxygen, carbon dioxide, and nitric oxide. For example, smooth muscle

in the walls of arteries contracts when stimulated by the release of epinephrine to reduce blood flow to a body region ([Chapter 37](#)), and smooth muscle within the mammalian uterus contracts when oxytocin is released to stimulate labor ([Chapter 40](#)).

As in skeletal muscle, contraction of smooth muscle is regulated by  $\text{Ca}^{2+}$ . However, there are two sources of  $\text{Ca}^{2+}$  for smooth muscle contraction: intracellular (release of  $\text{Ca}^{2+}$  from the SR, as in skeletal muscle) and extracellular (opening of calcium channels in the plasma membrane). In addition, whereas release of  $\text{Ca}^{2+}$  in skeletal muscle is coupled to depolarization,  $\text{Ca}^{2+}$  channels in smooth muscle also open in response to intracellular signaling pathways triggered by hormones and other factors, as well as to stretch of the muscle cell.

Smooth muscle lacks the troponin–tropomyosin mechanism for regulating contraction. Instead, smooth muscle cells are activated when the protein [calmodulin](#) binds with  $\text{Ca}^{2+}$  released from the SR or entering through the cell's membrane. The calmodulin– $\text{Ca}^{2+}$  complex activates a myosin kinase that phosphorylates the smooth muscle myosin heads, causing them to bind actin and begin the cross-bridge cycle. Once the muscle has finished contracting, a second enzyme dephosphorylates the myosin heads, disrupting their ability to bind to actin, and the muscle relaxes.

Smooth muscle contracts slowly compared with skeletal muscle, using less ATP per unit time. The SR of smooth muscle cells is less extensive and has many fewer calcium pumps than the SR of skeletal muscle cells. As a result, calcium is returned more gradually from the

myofibrils back to the SR, or pumped back out through the cell's membrane, slowing the relaxation of smooth muscle. Through these kinds of slow contractions of smooth muscle, clams are able to hold their shells closed for long periods, arteries can contract and restrict blood flow to particular body regions, and the gut can move the digestive contents through the gastrointestinal tract.

#### Self-Assessment Questions

1. Diagram a sarcomere, showing the basic organization of thin (actin) and thick (myosin) filaments. Indicate on your diagram the regions where myosin cross-bridges form with actin.
2. What is the sequence of events involved in the cross-bridge cycle? How do these events explain how muscles generate force and shorten when they are stimulated to contract?
3. When an animal dies, its limbs and body become stiff because its muscles go into *rigor mortis* (a term that means “stiffness of death”). Why would the loss of ATP following death cause this to happen?
4. What is the sequence of events that occurs when an action potential arrives at a muscle fiber's motor endplate, causing the muscle to be depolarized?
5. Curare is a paralyzing compound that blocks the action of the neurotransmitter acetylcholine at the muscle fiber's motor endplate. What effect does curare have on the release of calcium ions from the sarcoplasmic reticulum of the muscle cell?

## 35.2 MUSCLE CONTRACTILE PROPERTIES

Actin and myosin are evolutionarily conserved across all animal life, so all muscles have similar force-generating properties. The huge muscles of a weight lifter as well as the large closing muscle of a lobster claw are evidence that larger muscles can exert more force. Why is that? The force exerted by the whole muscle is the sum of the forces produced by the individual myofibrils of activated muscle fibers. As a consequence, larger muscles with more fibers produce greater forces than smaller muscles with fewer fibers. However, the force that a muscle produces also depends on its contraction length and the speed of contraction.

### Antagonist pairs of muscles produce reciprocal motions at a joint.

Muscles can generate force only by pulling, not by pushing, on the skeleton. As described earlier, to produce reciprocal joint and limb movements, they are arranged as pairs of **antagonist muscles** that pull in opposite directions. **Flexion** is the joint motion that moves bone segments closer together, and **extension** is the joint motion that moves them farther apart. For example, muscles at the elbow joint are organized as flexors (the biceps muscle) that contract to bring the arm toward the shoulder, and extensors (the triceps muscle) that contract to extend the arm away from the shoulder (**Fig. 35.9**).

FIG. 35.9 Antagonist muscles. Skeletal muscles can produce force only by pulling on a skeletal attachment, so they are arranged as antagonists to produce opposing motions at a joint.

Antagonist muscles also control flexion and extension of the leg joints of jumping grasshoppers and locusts, as well as the muscles that elevate and depress the wings of flying insects. Additional pairs of antagonist muscles are present for movements in other directions. Muscles in the body wall of cnidarians (jellyfish and sea anemones) and segmented annelid worms are organized in longitudinal (lengthwise) and circumferential (circular) layers, as are the smooth muscles in the walls of intestines. These two muscle layers function as muscle antagonists that control movement and shape.

In contrast, when muscles combine to produce similar motions, they are termed muscle **agonists**. Muscles arranged as agonists increase the strength and improve the control of joint motion. For example, the

three heads of the triceps are agonists of one another.

## Muscle length affects actin–myosin overlap and generation of force.

Why is it difficult to jump while standing on your toes? A muscle's ability to generate force depends in part on how much it is stretched before contraction begins. The sliding filament model for muscle contraction, like any good model, makes specific predictions. In this case, it predicts that the amount of overlap between actin and myosin filaments within the sarcomere will determine the number of cross-bridges that can form. The more overlap, the more force that can be produced. Conversely, when a muscle fiber is pulled to long lengths and then contracts, it generates less force because the overlap between myosin and actin filaments is reduced. When a muscle fiber contracts at short lengths, it also produces less force because myosin filaments begin to run into the Z disc at each end of the sarcomere, disrupting the geometry of the myosin filament lattice and hindering cross-bridge formation. At intermediate lengths, the muscle fiber generates its maximum force because actin–myosin filament overlap is greatest. These predictions have been tested by experiments ([Fig. 35.10](#)).

### HOW DO WE KNOW?

#### FIG. 35.10

How does actin myosin filament overlap affect force generation in muscles?

### BACKGROUND

From the 1930s through the 1960s, British and American muscle

physiologists studied the properties of striated frog muscle fibers. In one set of studies, American physiologists Albert Gordon and Fred Julian, together with British physiologist Andrew Huxley, studied how a contracted muscle's length relates to the muscle's force-generating ability.

#### HYPOTHESIS

Gordon, Huxley, and Julian hypothesized that changes in overlap between myosin and actin affect the number of cross-bridges, thereby determining the amount of force the muscle can produce.

#### EXPERIMENT

The three scientists isolated a single muscle fiber and used optical microscopy to measure sarcomere length. They kept this length constant while stimulating the fiber to produce force. They then obtained measurements of force at various other sarcomere lengths. The length at which the muscle fiber generated the maximum force is indicated on the graphs as 100%. Other lengths are expressed relative to this length.

## RESULTS

The top graph shows the data obtained by Gordon, Huxley, and Julian for a single sarcomere of a single muscle fiber, and the bottom graph reinterprets their data for a whole muscle. Note that these graphs have different x-axes. The lower left graph shows force (% maximum) plotted versus absolute length of the sarcomeres. The upper right graph shows force (% maximum) plotted against the percentage of muscle length, with 100% being the length at which the muscle generates maximum force. The researchers' results indicate that the muscle fiber produces its maximal force at an intermediate sarcomere length (approximately 2.3  $\mu\text{m}$ ). It is at this length, they hypothesized, that the greatest number of cross-bridges form, generating maximal force. As the sarcomere length is decreased or stretched, and the muscle fiber is then stimulated to contract, force declines. These results are consistent with a decrease in the number of cross-bridges that form as a result of decreased actin myosin filament overlap.

## FOLLOW-UP WORK

Other studies confirmed that changes in myosin cross-bridge formation are linked to changes in actin and myosin filament overlap at different

sarcomere lengths, supporting the sliding filament model of muscle contraction.

SOURCE Gordon, A. M., A. F. Huxley, and F. J. Julian. 1966. "The Variation in Isometric Tension with Sarcomere Length in Vertebrate Muscle Fibres." *Journal of Physiology* 184:170-192.

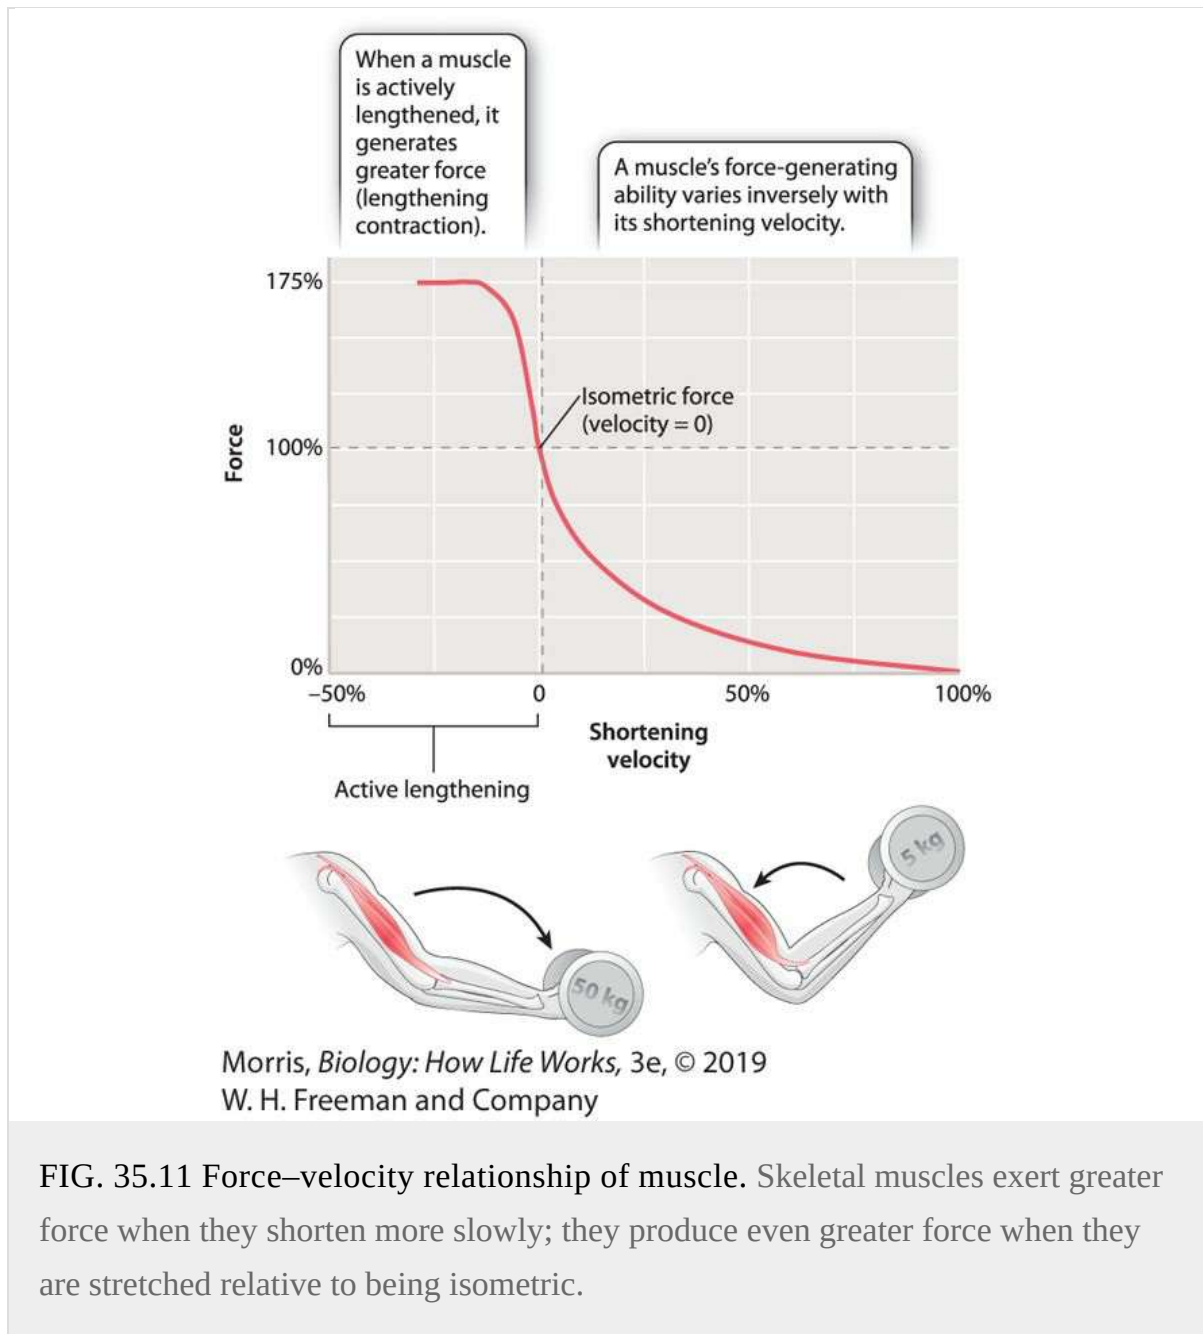

You can't jump well if you are on your toes and your ankles are fully extended because this position shortens your calf muscle fibers. Conversely, you also can't jump well if your ankles are overly flexed and your calf muscles are lengthened. Through training, athletes and dancers learn techniques, such as bending the knees before jumping, so that their leg muscles contract at intermediate lengths to maximize muscle-force output.

The relationship between force and length of striated muscle also explains Starling's law for the function of the heart as a pump (discussed in [Chapter 37](#)). This law explains the fact that the heart contracts more strongly when it is filled with larger amounts of blood returning from the veins.

## Muscle force and shortening velocity are inversely related.

In experiments carried out in the 1930s, A. V. Hill (who won the 1922 Nobel Prize in Physiology or Medicine for his work on muscle energy use) observed that a muscle shortens fastest when producing low forces ([Fig. 35.11](#)). To produce larger forces, the muscle must shorten at progressively slower velocities. For example, your arm moves faster when you throw a lightweight ball than when you throw a heavy one.

The reason is that the faster a muscle fiber shortens, the fewer cross-bridges that can form within it, reducing the force that each fiber and the muscle as a whole can produce.

The term “muscle contraction” suggests that muscles shorten when stimulated to generate force. In reality, muscles may also exert force and remain a uniform length or even be lengthened. Consequently, the

term “contraction” needs to be broadened beyond its familiar reference to muscle shortening to include those instances when a muscle exerts force while remaining the same length or being actively stretched. In the last section, we looked at what happens when you contract a muscle that has been stretched or shortened before the contraction begins. Now we look at what happens when you lengthen a muscle during the contraction or keep it the same length rather than shortening it.

When you carry a heavy bucket of water, your arm muscle exerts force, yet it stays the same length and does not shorten. In this case, the muscle’s shortening velocity is zero and it generates an **isometric** force (*iso* means “same” and *metric* refers to “measure”) that is greater than the force generated when it shortens. Isometric exercises take advantage of this type of muscle contraction: holding a weight in a fixed position or exerting force against an immovable object helps maintain muscle strength and may be beneficial in rehabilitation after injury by minimizing joint motion.

Muscles can be lengthened during a contraction when the external load against which they contract exceeds the force the muscle produces. This action is known as an active **lengthening contraction**. During a lengthening contraction, the muscle generates more force (as much as 75% more; [Fig. 35.11](#)) than when it remains isometric or shortens. When you lower a box from a shelf, your biceps muscle lengthens as it exerts force, and when you land a jump, your calf and quadriceps muscles lengthen to support your body. During every stride you take during a run, contracting leg muscles stretch as your leg joints

flex when the leg contacts the ground. Active muscle lengthening reduces the muscle's energy consumption because fewer fibers are recruited to generate a given level of force.

Stretching a muscle too rapidly or repetitively however can cause injury. Rapid and repetitive stretching often occurs during prolonged downhill hiking, causing muscle damage and soreness, particularly in the quadriceps muscles in the front of the thigh. Suitable training and warm-up exercises can help muscles to stretch without damage.

## Muscle force is summed by an increase in stimulation frequency and the recruitment of motor units.

How do animals vary the amount of force exerted by a muscle? As we have seen, skeletal muscles are stimulated by motor neurons, which conduct action potentials to the neuromuscular junction. The force exerted by a muscle depends on the frequency of stimulation by the motor neuron, as well as the number of motor neurons that activate the muscle. As action potentials become more frequent, the amount of calcium that is released to activate cross-bridge formation in the muscle fibers also increases. Thus, the more frequent the action potentials, the more cross-bridges form.

A single action potential results in a **twitch** contraction of a certain force (**Fig. 35.12a**). If sufficient time is allowed for the muscle to pump  $\text{Ca}^{2+}$  back into the sarcoplasmic reticulum, the contraction ends, force falls to zero, and a second stimulus can elicit a twitch contraction

of the same force. However, if a second action potential arrives before the muscle has relaxed, a greater force is produced because  $\text{Ca}^{2+}$  remains within the myofibrils to activate more cross-bridges. As the frequency of stimulation increases, muscle force increases as well (Fig. 35.12b). This property of muscle contraction is called force summation.

FIG. 35.12 (a) Twitch and (b) fused tetanus muscle contractions.

At a sufficiently high stimulation frequency, muscle force reaches a plateau and remains steady as stimulation continues. This muscle contraction of sustained force is called a **tetanus**. Measurements in animal muscles indicate that tetanic contractions are common, and that they generate steady and large forces. Tetanus is a normal physiological response of a muscle, but it can also be induced by a toxin from the bacterium *Clostridium tetani*, so named because it causes severe muscle spasms, particularly of the jaw, chest, back, and abdomen.

A motor neuron and the population of muscle fibers that it

innervates are collectively termed a **motor unit** ([Fig. 35.13](#)). The number of muscle fibers in a motor unit can range from relatively few to several hundred. Invertebrate muscles typically have few motor units. Force is adjusted mainly by graded activation of the muscle's fibers rather than by adjusting the stimulation frequency of multiple motor units. In contrast, a vertebrate muscle's force output depends on the number of motor units (and therefore the number of muscle fibers) that are activated, as well as their stimulation frequency. The number of muscle fibers innervated by a given motor neuron, and hence the size of the motor unit, affects how finely force can be controlled. For example, finger muscles have small motor units allowing fine adjustments in muscle force, whereas leg muscles have large motor units providing larger adjustments in force. Within each motor unit, muscle fibers generally share similar contractile and metabolic properties. Differences in these properties can give muscles very different capabilities, as discussed in the next section.

FIG. 35.13 Motor units. A motor unit consists of the motor neuron and the population of cells (fibers) it innervates.

## Skeletal muscles have slow-twitch and fast-twitch fibers.

The difference between a sprinter and a marathoner is not just due to training; it also reflects the properties of their muscles. Different types of muscle fibers exist, allowing for greater variation in endurance and in the speed of muscle contraction. In vertebrates, such muscle fibers are classified as red [slow-twitch](#) fibers and white [fast-twitch](#) fibers ([Fig. 35.14](#)). Slow-twitch fibers are found in muscles that contract slowly and consume ATP slowly. An animal uses slow-twitch fibers to control its posture or move slowly and economically. Fast-twitch fibers generate force quickly, producing rapid movements, but they consume ATP more quickly. An animal depends on fast-twitch fibers to sprint or lunge at its prey. A key difference between the two types of fibers is that slow-twitch fibers obtain their energy through oxidative phosphorylation (aerobic respiration), whereas fast-twitch fibers obtain their energy mainly through glycolysis ([Chapter 7](#)).

FIG. 35.14 Slow-twitch (darkly stained) and fast-twitch (lightly stained) skeletal muscle fibers. These two types of fibers provide differences in endurance and the speed of contraction. (a) Mammalian limb muscle; (b) muscles of two different fish species.

Although slow-twitch fibers develop force more slowly, they have greater resistance to fatigue in response to repetitive stimulation; that is, their loss of force over time is less. Their greater endurance is explained by the ability of their mitochondria to supply ATP to muscle fibers by aerobic respiration. Slow-twitch fibers have many mitochondria and are well supplied by capillaries. They contain an abundance of [myoglobin](#), an oxygen-binding protein related to hemoglobin that helps deliver oxygen to the mitochondria ([Chapter 37](#)). The iron in myoglobin gives muscles with these fibers their red appearance. Slow-twitch muscle fibers express a chemically “slow” form of myosin with a relatively low rate of ATP hydrolysis, limiting their speed of cross-bridge cycling and force development.

White fast-twitch muscle fibers have fewer mitochondria and

capillaries, contain little myoglobin, and rely heavily on glycolysis to produce ATP. Fast-twitch fibers express a chemically “fast” form of myosin with a high rate of ATP hydrolysis, favoring rapid force development and movement. However, fast-twitch fibers also fatigue quickly. Because white fibers are larger than red fibers, they generate more force. In general, most skeletal muscles are composed of mixed populations of red and white fiber types, providing a broad range of speed, force, and endurance.

Athletes who have more oxidative slow-twitch fibers excel at endurance and long-distance competitions. In contrast, athletes who have larger numbers of fast-twitch fibers perform better in sprint races and weight-lifting competitions. Because the distribution and properties of muscle fiber types are strongly inherited, it is largely true that champions are born and not made. Nevertheless, aerobic training can significantly increase the energy output through oxidative phosphorylation of an individual’s muscle fibers, just as weight lifting and speed training can enhance an individual’s strength and sprinting ability. A popular belief is that weight lifting places strain on the muscle that builds new fibers. This is a myth: it actually increases the size of existing muscle fibers through the synthesis of additional myosin and actin filaments. This synthesis increases the cross-sectional area of the fiber and, in turn, its force-generating capacity.

## How do different types of muscle fibers affect the speed of animals?

We have just seen that slow-twitch muscle fibers provide endurance for sustained activity, whereas larger fast-twitch fibers produce greater

speed and strength but fatigue quickly. The relative distribution of these fiber types in the muscles of different animals is influenced mainly by genetic heritage. It affects the locomotive behavior and capacities of both predator and prey animals. Whereas cheetahs have exceptional speed, their muscles tire quickly. As their prey, antelope have muscles that enable endurance for long-distance running and contract rapidly for maneuvering.

Highly aerobic animals such as dogs and antelope have large fractions of slow-twitch fibers *and* specialized fast-twitch muscle fibers that have a high oxidative capacity and use glycolysis for rapid ATP synthesis. These muscle fibers allow the animals to move for extended periods of time at relatively fast speeds. In contrast, cats have mainly fast-twitch fibers, enabling them to sprint and pounce quickly. Nevertheless, cats and other animals use particular muscles with high concentrations of slow-twitch fibers (these are the dark-staining fibers shown in [Fig. 35.14a](#)) for slower postural movements and stealth. Animals such as sloths and lorises that move slowly have mostly oxidative slow-twitch fibers and few glycolytic fast-twitch fibers.

More generally, animals with high body temperatures and high metabolic rates (birds and mammals) have larger numbers of oxidative fibers compared with animals that have lower body temperatures and lower metabolic rates (reptiles). As a result, lizards use glycolytic fast-twitch fibers to sprint for brief periods but must then recover from the acid buildup produced by their muscles' anaerobic activity by resting for longer periods ([Chapter 38](#)). In contrast, birds and mammals can sustain activity over longer time periods because they have oxidative

muscle fibers supported by an aerobic ATP supply.

Most fish have a narrow band of slow-twitch red muscle fibers that runs beneath their skin, which they use for slow, steady swimming. Tuna and some sharks have evolved deeper regions of red muscle that they can keep warm ([Fig. 35.14b](#)), enabling their muscles to contract longer and faster to enhance their swimming. When escaping from a predator or attacking prey, fish recruit their larger fast-twitch white trunk musculature for rapid swimming.

The evolutionary arms race between predators and prey has resulted in selection for particular muscle fiber types and other musculoskeletal specializations for rapid movement and maneuvering. Features of the skeleton that contribute to these specializations are discussed next.

#### Self-Assessment Questions

6. Why can you lift a larger load when your elbow is slightly flexed and your biceps muscle is at an intermediate length than you can when your elbow is fully extended?
7. Draw a graph of the isometric force–length relationship of striated muscle, indicating where maximal overlap between actin and myosin filaments occurs.
8. Draw a graph of the force–shortening velocity relationship of striated muscle.
9. Compare the force produced by a muscle over time when it is stimulated by a single twitch stimulus with the force produced by multiple stimuli at low frequency, and then with the force

produced when the stimulation frequency is increased.

10. What are two mechanisms by which the force of contraction can be increased in vertebrate muscles?

## 35.3 ANIMAL SKELETONS

Most animal skeletons provide a rigid set of elements that meet at joints (articulate). These rigid elements transmit forces generated by muscles for movement and body support. They also enable many animals to manipulate their environment by digging burrows, building nests, or constructing webs to catch food. Animals have evolved three types of skeletal systems: [hydrostatic skeletons](#), [exoskeletons](#), and [endoskeletons](#). All three types of skeletons have rigid elements that resist the pull of antagonist sets of muscles.

### Hydrostatic skeletons support animals by muscles that act on a fluid-filled cavity.

Hydrostatic skeletons evolved early in multicellular animals, with the first cnidarians (jellyfish and sea anemones) approximately 600 million years ago. Today they are found in nearly all multicellular animals as well as in many vascular plants. In animals that depend on a hydrostatic skeleton, fluid contained within a body cavity serves as the supportive component of the skeleton. Muscles exert pressure against the fluid to produce movement.

Two sets of opposing muscles surround the fluid. By contracting and relaxing these opposing muscle sets, an animal can control the width and length of the body cavity and, in many cases, of the whole animal ([Fig. 35.15a](#)). Circular muscles reduce the diameter of the body cavity, and longitudinal muscles reduce its length. A sea anemone, for example, can bend its body in various directions to feed or to resist

water currents by closing its mouth to keep its fluid volume constant and contracting its circular and longitudinal muscles. It extends itself into the water column by contracting its circular muscles and relaxing its longitudinal muscles. The sea anemone can also adjust its shape by altering the amount of fluid in its body cavity. For example, when threatened, a sea anemone rapidly retracts by contracting its longitudinal muscles and allowing water to escape from its body cavity.

FIG. 35.15 Diverse examples of hydrostatic skeletal support. (a) In sea anemone; (b) in earthworm; (c) intervertebral discs; (d) articular cartilage.

Similarly, an earthworm burrows through the soil by causing movement in a series of hydrostatic segments along its body ([Fig. 35.15b](#)). By contracting longitudinal muscles in a few segments, the earthworm shortens those segments and also widens them to anchor those segments against the soil. It then extends intervening segments between anchor points by contracting circular muscles, causing the segments to lengthen and move the animal's body through the soil.

Because of their simple but effective organization, hydrostatic skeletons are well adapted for many uses. In animals such as squid and jellyfish, the hydrostatic skeleton has become specialized for jet-propelled locomotion. Large circular muscles contract to eject fluid from the body cavity, propelling the animal in the opposite direction. The muscles of other mollusks also exert pressure against a hydrostatic skeleton. By this means, for example, a clam uses its muscular "foot" to burrow into the sediment, and an octopus adeptly manipulates its flexible tentacles. (Clams also have shells that form an exoskeleton to protect the body.) These same principles allow an elephant to control its trunk, and the human tongue to manipulate food and assist in speech.

Even vertebrate animals with rigid endoskeletons have hydrostatic elements that provide flexibility and cushion loads transmitted by the skeleton. These elements include [intervertebral discs](#) and [cartilage](#). Intervertebral discs are sandwiched between the bony vertebrae of the backbone ([Fig. 35.15c](#)). Each disc has a wall reinforced with connective tissue that surrounds a jelly-like fluid. Intervertebral discs enable the backbone to twist and bend. Disc walls damaged by

repeated stress can rupture, causing significant lower back pain. Articular cartilage, another fluid-filled tissue, forms the joint surfaces between adjacent bones ([Fig. 35.15d](#)). The fluid within the cartilage resists the pressure between the ends of articulating bones, cushioning forces transmitted across the joint.

## Exoskeletons provide hard external support and protection.

The first skeletons, consisting of needle-like elements called spicules hardened by calcium carbonate or silica, arose with sponges approximately 650 million years ago. Exoskeletons, rigid skeletons that lie outside the animal's soft tissues, subsequently evolved in other invertebrate groups adapted for life in aquatic and terrestrial environments ([Fig. 35.16](#)). Because exoskeletons are on the exterior of the animal, the muscles attach from the inside. Exoskeletons provide hard external support and protection. However, a main disadvantage is that exoskeletons limit growth of the organism.

Sources: a. Rita van den Broek/AGE Fotostock; b. Reinhard Dirscherl/Getty Images; c. Jim Simmen/Getty Images.

FIG. 35.16 Examples of exoskeletons. The shells of (a) a bivalve mollusk and (b) *Nautilus*, made of calcium carbonate, surround and protect internal soft body parts. The exoskeleton of arthropods, such as (c) a grasshopper, is made of stiff cuticle that surrounds internal muscles and tendons and other internal body parts.

---

Different invertebrates have different kinds of exoskeleton, but all types have relatively few cells for their volume of tissue. The shells of bivalve mollusks, such as clams and mussels, form a hard, mineralized calcium carbonate exoskeleton ([Fig. 35.15a](#)). So does the shell of the cephalopod mollusk *Nautilus*, a creature that has existed largely unchanged for nearly 500 million years ([Fig. 35.15b](#)). Mineralization is the process in which a mineral, in this case calcium carbonate, is laid down on an organic matrix, in this case a small amount of protein. The mixture of calcium carbonate and protein is an example of a composite material, one that combines substances with different properties. Its composite nature means the resulting shell is less brittle and more difficult to break than if it were made of just calcium carbonate. The shell expands as the organism grows and epidermal cells deposit new layers of mineralized protein in regular geometric patterns. Indeed, you can see these growth rings if you examine a mollusk shell. Although some marine bivalves achieve large size over many years, growth is limited by the rate at which new skeletal material can be deposited on the outside of the shell.

Arthropods have more complex exoskeletons. More than half of all known animal species, including insects and crustaceans, are arthropods. Arthropods are defined in part by their jointed legs and in part by a type of rigid exoskeleton called a [cuticle](#) that covers their entire body ([Fig. 35.16c](#)). Arthropod exoskeletons, which first evolved in aquatic crustaceans, protect animals from desiccation and physical insults. Consequently, exoskeletons were key to the success and diversification of insects in terrestrial environments approximately 450

million years ago.

The cuticle of insects is composed mainly of [chitin](#), nitrogen-containing polysaccharide [fibers](#) that are reinforced by proteins. When initially formed, the cuticle of arthropods is soft, so the animal can grow before the cuticle hardens. Mature cuticle consists of two layers. A thin outer, waxy layer minimizes water loss. Water loss is especially dangerous for terrestrial arthropods, given their small size. The much thicker inner layer, whether flexible or stiff, is tough and hard to break. The cuticle remains flexible at joints, allowing motion between body segments. Because the rigid exoskeleton restricts their growth, arthropods shed their cuticle at intervals, a process called [molting](#). After molting, arthropods expand and grow for a period before forming a new rigid exoskeleton.

Marine crustaceans, such as crabs and lobsters, incorporate calcium carbonate into their cuticle. Calcium carbonate makes the exoskeleton hard and stiff, much like the hardened cuticle of terrestrial insects, helping to protect these crustaceans from predators.

While offering several protective benefits, exoskeletons pose risks as well. Animals are vulnerable when the newly formed exoskeleton has not yet hardened. Exoskeletons are also hard to repair. If a skeleton is damaged while growing, the animal must produce an entirely new one. Because the exoskeleton is a thin-walled structure, it is prone to breaking if its surface area is very large. Consequently, the imperviousness of the monstrous insects depicted in science-fiction films is improbable—they would easily break from a sharp blow to

their exoskeleton.

## The rigid bones of vertebrate endoskeletons are jointed for motion and can be repaired if damaged.

Endoskeletons first evolved approximately 350–500 million years ago, when the first vertebrates evolved endoskeletons made of cartilage, a gel-like tissue reinforced by protein and sugar polymer fibers.

Lampreys are descendants of these early vertebrates. The cartilage endoskeleton became stiffened in other vertebrates through the incorporation of calcium phosphate mineral, or was replaced by bone. The calcium phosphate skeletons that evolved in marine vertebrates stand in contrast to the calcium carbonate skeletons that evolved in marine invertebrates.

An endoskeleton, made of either bone or calcified cartilage, lies internal to most of a vertebrate's soft tissues. In contrast to exoskeletons, vertebrate endoskeletons can grow extensively and, when broken, can be repaired. Endoskeletons also provide protection for certain key internal organs, such as the brain, lungs, and heart.

The bones of vertebrate skeletons consist of a variety of tubular, rodlike, and platelike elements that form a scaffold to which the muscles attach. Because bones are rigid and hard, there are joints between adjacent bones to enable movement. Muscles attach to the skeleton by connective tissue, often specialized as [tendons](#) made of collagen. Tendons transmit muscle forces, allowing the forces to be

redirected and transmitted over a wide range of joint motion. Tendons, like a spring, also store and recover elastic energy.

The vertebrate skeleton can be divided into **axial** and **appendicular** regions (**Fig. 35.17**). The axial skeleton consists of the skull and jaws of the head, the vertebrae of the spinal column, and the ribs. Bones of the skull protect the brain and sense organs of the head. The appendicular skeleton consists of the bones of the limbs, including the shoulder and pelvis. The axial and appendicular regions reflect the evolutionary ancestry of vertebrates. The axial skeleton formed first, to protect the head and provide support and movement of the animal's body by bending its body axis. As a result, the axial skeleton is the main skeletal component of fishes. The appendicular skeleton includes the pectoral and pelvic fins of fishes, which evolved into limbs when vertebrate animals first moved onto land. In a special group of lobe-finned fishes, the fin bones became adapted for an amphibious lifestyle, evolving into the limb bones that terrestrial vertebrates use for support against gravity and for movement on land.

Skeletal tissues have relatively few cells compared to their volume because they consist mostly of an extensive **extracellular matrix** that is secreted by specialized cells. Thus, most of a skeletal tissue is connective tissue external to the cells ([Chapter 10](#)). Five main extracellular tissues are produced in the formation of the vertebrate skeleton: bone, tooth enamel, dentine, tendon, and cartilage.

Bone tissue is formed by cells called **osteoblasts**. These cells synthesize and secrete calcium phosphate as **hydroxyapatite** mineral crystals in close association with the protein **collagen**. Mineralized bone is removed by **osteoclasts** when necessary to reshape a bone or repair damaged regions. Generally, bone consists of two-thirds hydroxyapatite mineral and one-third type I collagen protein. The combination of mineral and protein makes bone a composite material,

like an exoskeleton. Bone is rigid (because of the properties of the mineral), but also hard to break because it absorbs much energy before fracture (because of the properties of the collagen). During the normal process of aging, bone gradually becomes more mineralized and brittle. The genetic bone disorder osteogenesis imperfecta leads to bones that are brittle and fragile because the osteoblasts produce insufficient collagen in the extracellular matrix.

Articular cartilage is located at the joint surfaces of a bone. It forms a cushion between the bones meeting at a joint. As a gel-like matrix, cartilage resists fluid being squeezed out when forces press on the cartilage during movement. Articular cartilage consists of 70% water; 15% large, branched molecules called proteoglycans that bond with water molecules; and 15% type II collagen. The collagen fibers reinforce the cartilage, allowing the cartilage to cushion and distribute loads as the joint moves. Cartilage may degenerate for a variety of reasons, including rheumatoid arthritis and repetitive physical injury, but in general it lasts over an individual's lifetime.

#### Self-Assessment Questions

11. What are the two basic structural elements common to all animal musculoskeletal systems?
12. How are exoskeletons and endoskeletons alike? How are they different?
13. Glass is strong and rigid, but can be easily broken. In contrast, a bone is strong and rigid, but hard to break. How can this be?
14. What are the two primary components of bone tissue? How does

each contribute to a bone's strength, stiffness, and resistance to fracture?

## 35.4 VERTEBRATE SKELETONS

Although both vertebrate skeletons and invertebrate exoskeletons are rigid and have flexible joints, certain features distinguish them.

Vertebrate skeletons are adapted to grow quickly in the fetus and grow continuously, without molting, until adulthood. Even after bones stop growing, they can be repaired if damaged. Here we explore the biology of vertebrate skeletons, focusing on how bones develop and grow and how they are repaired and remodeled.

### Vertebrate bones form directly or by forming a cartilage model first.

Vertebrate bones form and develop by two distinct processes: either they are produced directly as bone or they are generated by way of a cartilage model. Bones of the skull and the ribs form when precursor cells differentiate into osteoblasts that immediately begin producing bone as a skeletal sheet or membrane. These bones are often referred to as membranous bones. This method of forming bone is very slow, however. Indeed, if most bones in the body formed this way, the fetus would take a very long time to develop.

Most other bones of the body—the vertebrae, shoulder, pelvis, and limb bones—are first formed as cartilage ([Fig. 35.18](#)). The precursor cells initially become cartilage-producing cells, known as chondroblasts, which in the embryo produce cartilage models of most bones of the developing body ([Fig. 35.18a](#)). For example, at approximately 9 weeks of development, a human fetal hand consists

mainly of cartilage models of the hand bones ([Fig. 35.18b](#)). Embryonic cartilage is the same as the articular cartilage that remains at the ends of bones to form the joint surfaces. Because cartilage is a pliable, fluid-filled matrix, it grows by expansion within the structure as well as at the surface, enabling the fetal skeleton to grow rapidly. As the fetus grows and its skeleton matures, the cartilage model of the bone is invaded by blood vessels. The presence of blood vessels triggers the transformation of cartilage into hard, mineralized bone tissue.

**FIG. 35.18** Bone formation from a cartilage model. (a) Most bones other than the skull and ribs are formed as cartilage first, followed by invasion by blood vessels and the transformation into bone tissue by osteoblasts. (b) Cartilage model of a human fetal hand, showing initial sites of bone tissue formation at about 9 weeks of embryonic development.

## The two main types of bone are compact bone and spongy bone.

The cartilage template of a bone is replaced by one of the two main types of bone: compact or spongy ([Fig. 35.19](#)). Both types contribute

to the overall form of many bones in the body.

**Compact bone** forms the walls of the bone's shaft. It consists mainly of dense, mineralized bone tissue containing bone cells derived from osteoblasts and the network of blood vessels supplying these cells with oxygen and nutrients.

A second type of bone, called **spongy bone**, consists of small plates and rods known as **trabeculae** with spaces between them. Spongy bone is found internally at the ends of limb bones and within the vertebrae. It reduces the weight of bone in these regions, but is also

stiff so that forces are transmitted effectively from the joint to the bone shaft. **Bone marrow** is a fatty tissue found between trabeculae and also within the bone's central cavity. It contains many important cells, including blood-forming cells, other stem cells ([Chapter 19](#)), immune system cells ([Chapter 41](#)), and fat cells.

## Bones grow in length and width, and can be repaired.

Bones can grow in length, at least until an animal reaches maturity. Growth in length occurs at the **growth plate** (see [Fig. 35.18](#)), a region of cartilage between the middle region of the bone, called the **diaphysis**, and the end, called the **epiphysis**. The growth plate remains in place when the rest of the cartilage is transformed into bone. It adds new cartilage toward the bone's diaphysis, enabling bone length to continue to increase after birth (see [Fig. 35.18](#)). At maturity, each growth plate fuses as the remaining cartilage is replaced with bone, preventing further growth in length. The fusion of growth plates is typical of most mammals and birds. In amphibians and reptiles, the growth plates often do not fuse and growth may continue, albeit at a slower pace, over much of their lifetime.

Limb bones grow in diameter when osteoblasts deposit new bone on the bone's external surface. At the same time, bone is removed from the inner surface by osteoclasts, expanding the marrow cavity. Bone removal is slower than bone growth, thickening the walls during growth. Osteoclasts secrete digestive enzymes and acid to dissolve the calcium mineral and collagen. The dissolved compounds are reabsorbed and recycled for use in bone formation in other regions of

the skeleton. Through this process, the vertebrate skeleton serves as an important store of calcium and phosphate ions. For example, in female birds, calcium removed from the skeleton is regularly used to form the eggshell.

Generally, physically active younger adults have thicker bones than less active younger adults because physical loading stimulates osteoblasts to produce more bone during growth. However, in older adults, bone tissue is gradually lost as osteoclasts remove more bone than is produced by osteoblasts. Bone loss is particularly severe in women after menopause, in part because of hormone shifts as well as reduced physical activity. This bone loss can lead to osteoporosis, a condition that significantly increases the risk of bone fracture.

A great advantage of endoskeletons compared with exoskeletons is that a damaged endoskeleton can be repaired. Osteoblasts and osteoclasts form and remove mineralized tissue as needed in damaged regions of the bone.

## CASE 7 BIOLOGY-INSPIRED DESIGN: USING NATURE TO SOLVE PROBLEMS

# Can we design smart materials to heal bones that are damaged and improve artificial joints?

Despite their elegant organization, which helped inspire the design of

the Eiffel Tower, bones are often damaged due to fracture from accidents, extreme physical activity, and disease. Damaged bone is a major health problem for people of all ages, but particularly for older individuals.

New bone tissue engineering techniques that make use of three-dimensional printing hold promise to solve this problem. The strategy is to create artificial polymer–ceramic scaffolds that incorporate stem cells, growth factors, and bioactive molecules. With the help of recent advances in three-dimensional printing, such as solid free-form printing, researchers create complex geometries of multicomponent materials at microscopic scales that mimic the structure and chemical composition of bone tissue. After being implanted in the body, this scaffold is infiltrated with stem cells and growth factors to stimulate bone formation. Once the artificial scaffold is remodeled into natural bone tissue, the scaffold degrades.

As we have seen, the structure of bone is complex: it consists of a compact shell that is supported by plates and struts consisting of a more porous inner spongy bone. The challenge for bone tissue engineers and material scientists is to create three-dimensional scaffolds that mimic this complex structure. The scaffolds need to provide similar mechanical support when initially grafted to a damaged region of a bone, induce the formation of blood vessels for nutrient supply, and stimulate the cellular activity of osteoblasts. These processes of bone healing are critical to the remodeling of the artificial scaffold into natural bone tissue. An advantage of bioengineering artificial bone tissue, rather than relying on a bone graft from another

donor, is that the risk of infection during surgical implantation is greatly reduced.

In addition to repairing damaged regions of bone, bone tissue engineering techniques are improving the long-term viability of joint prostheses, such as artificial hips and knees, which are commonly used in both humans and their pets. Often a joint prosthesis fails because its connection to the surrounding bone tissue loosens. By coating the surface of the prosthesis base with bioactive components, such as growth factors and stem cells, and by utilizing a three-dimensional porous surface, osteoblasts can be stimulated to form new bone tissue that grows into the prosthesis, reinforcing its interface to bone and greatly increasing the useful lifetime of an artificial joint.

## Joint shape determines range of motion and skeletal muscle organization.

The shapes of the bone surfaces that meet at a joint determine the range of motion at that joint. Joints range from simple [hinge joints](#) to [ball-and-socket joints](#) ([Fig. 35.20](#)). The human elbow joint and the ankle joint of a dog are examples of hinge joints. The shoulder and hip joints are examples of ball-and-socket joints, which allow the widest range of motion. The joints at the base of each finger are intermediate: they allow you to flex and extend your fingers as well as spread them laterally or move them together when making a fist or grasping objects.

Joints with a larger range of motion are generally less stable than joints with a smaller range of motion. The shoulder is the most mobile joint in the human body, yet one of the joints that is most often dislocated or injured. In contrast, the ankle joint of dogs, horses, and other animals is a stable hinge joint that is unlikely to be dislocated, but its range of motion is limited to flexion and extension. Because muscles are arranged as paired sets of antagonists to move a joint in opposing directions, hinge joints may be controlled by as few as two

antagonist muscles (generally referred to as a flexor and an extensor). In contrast, ball-and-socket joints have at least three sets of muscle antagonists to control motion in many different planes. As a result, a more complex organization of muscles is needed to control the movements of the arm at the shoulder joint or the leg at the hip joint.

#### Self-Assessment Questions

15. Diagram a limb bone, such as the tibia, showing the regions of articular cartilage, spongy trabecular bone, compact bone tissue, and marrow cavity.
16. The shoulder joint provides a good example of a trade-off, where a benefit comes with a cost. What is the trade-off?

## CORE CONCEPTS SUMMARY

**35.1 HOW MUSCLES WORK:** Muscles are biological motors composed of actin and myosin that generate force and produce movement for support, locomotion, and control of internal physiological functions.

There are two main types of muscles: striated (skeletal and cardiac) and smooth. [page 788](#)

Skeletal and cardiac muscle fibers appear striated when viewed under the microscope because of the regular spacing of sarcomeres along their length. [page 788](#)

Smooth muscle fibers, which regulate air flow for breathing, blood flow through arteries, and the passage of food through the gut, lack regular sarcomere organization and appear smooth when viewed under the microscope. [page 788](#)

Skeletal muscle fibers are long, thin cells composed of parallel sets of myofibrils built up from smaller parallel arrays of actin and myosin filaments. [page 789](#)

The sarcomere is the basic contractile unit of a skeletal muscle. Sarcomeres are arranged in series along the length of a myofibril. [page 789](#)

Muscles change length and produce force by forming actin–myosin cross-bridges, which cause myosin and actin filaments to slide relative to each other. [page 791](#)

Muscles are stimulated by motor neurons at the fiber's motor

endplate, leading to depolarization of the muscle cell that triggers the release of  $\text{Ca}^{2+}$  ions from the sarcoplasmic reticulum.  $\text{Ca}^{2+}$  binds troponin, which moves tropomyosin off the myosin-binding sites on actin, allowing myosin heads to form cross-bridges with actin. [page 792](#)

Excitation–contraction coupling is the process by which depolarization of the muscle cell leads to its shortening. [page 793](#)

**35.2 MUSCLE CONTRACTILE PROPERTIES:** The force generated by a muscle depends on muscle size, degree of actin–myosin overlap, shortening velocity, and stimulation rate.

Because muscles can transmit force only by pulling on the skeleton, they are arranged as antagonist pairs to produce reciprocal motions of a joint or limb. [page 794](#)

Muscles exert their greatest force when actin–myosin filaments have maximal overlap, allowing the largest number of cross-bridges to form. [page 794](#)

Muscles exert more force when they contract at slow velocities, compared with when they contract at high velocities. [page 796](#)

In vertebrates, a motor unit consists of a single motor neuron and the muscle fibers (cells) it innervates. [page 797](#)

Muscle force is increased by increasing the motor neuron firing rate and, in vertebrates, by increasing the number of motor units that are activated. [page 797](#)

Vertebrate muscles contain two types of fibers: red slow-twitch

fibers that contract slowly over longer time periods and white fast-twitch fibers that contract rapidly but fatigue quickly. [page 798](#)

**35.3 ANIMAL SKELETONS:** Hydrostatic skeletons, exoskeletons, and endoskeletons provide animals with mechanical support and protection.

The rigid element of a hydrostatic skeleton is an incompressible fluid within a body cavity, used to support the body and change shape. [page 799](#)

Invertebrate exoskeletons form an external rigid support system, which protects the animal and limits water loss, but also limits growth and repair. [page 801](#)

Vertebrates have a bony endoskeleton that provides rigid support and protection of body organs, and that can grow and be repaired. [page 802](#)

The vertebrate endoskeleton is organized into axial (central) and appendicular (limb) components. [page 802](#)

Vertebrate endoskeletons consist of bone, which is a composite tissue of calcium phosphate mineral and type I collagen, and cartilage, which is a fluid-based gel that provides cushioning at joint surfaces. [page 803](#)

**35.4 VERTEBRATE SKELETONS:** Vertebrate endoskeletons allow for growth and repair and transmit muscle forces across joints.

Vertebrate bones develop by one of two processes: either directly or by way of a cartilage model. [page 803](#)

Cartilage forms much of the embryonic skeleton and remains as growth plates within the bone to provide rapid growth after birth, as well as forming the bone's joint (articular) surfaces. [page 803](#)

Bone has two basic structures: compact bone forms the solid walls of a bone's shaft, and spongy bone forms a mesh that supports the cartilage at the bone's ends. [page 803](#)

Bone formation by osteoblasts and removal by osteoclasts is a continuing process of growth, shape change, and repair. [page 804](#)

The shape of a bone's joint surfaces largely determines the range of motion and stability of a joint. [page 805](#)

## CHAPTER 36 Animal Endocrine Systems

FLPA/Chris Mattison/AGE Fotostock

---

### CORE CONCEPTS

**36.1 ENDOCRINE FUNCTION:** Animal endocrine systems release hormones into the bloodstream that respond to environmental cues,

regulate growth and development, and maintain homeostasis.

**36.2 HORMONES:** Hormones bind to receptors on or inside target cells, and their signals are amplified to exert strong effects on target cells.

**36.3 THE VERTEBRATE ENDOCRINE SYSTEM:** In vertebrates, the hypothalamus and pituitary gland control and integrate diverse physiological functions and behaviors.

### **36.4 OTHER FORMS OF CHEMICAL COMMUNICATION:**

Chemical communication can occur locally between neighboring cells or between individuals, coordinating social interactions.

---

We have seen how the nervous system allows an animal to sense and respond to its environment, coordinating the animal's movement and behavior ([Chapters 34](#) and [35](#)). The nervous system also works closely with the [endocrine system](#) to regulate an animal's internal physiological functions. The endocrine system is an interacting set of secretory cells, glands, and organs, located in different regions of the body, which communicates using chemical signals. It responds to signals sent from the nervous system as well as to blood-borne signals from other organs to regulate internal bodily functions.

The signals communicated by the nervous and endocrine systems differ greatly in their modes of transmission and in the times over which they act. The nervous system sends signals rapidly by action potentials running along nerve axons, and adjacent nerve cells communicate by means of neurotransmitters. In contrast, cells and glands of the endocrine system secrete chemical signals called [hormones](#), which influence the actions of other cells in the body.

Whereas some hormones act locally, many others are released into the bloodstream. Circulating throughout the body, these hormones can influence distant target cells. As a result, endocrine communication is generally slower and more prolonged than the rapid and brief signals transmitted by nerve cells.

Hormones bind to receptors on or in target cells. Once bound, each hormone exerts a specific effect on those cells. Hormonal signals are amplified in a series of steps, so that even a small amount of hormone can have dramatic effects in the body ([Chapter 9](#)).

In this chapter, we explore the properties and actions of hormones that help to coordinate and maintain a broad set of physiological functions of the organism. In particular, we examine the mechanisms by which hormones trigger cellular responses in their target organs. Because most hormones are evolutionarily conserved, their chemical structure is similar across a diverse array of animals. However, their functions often evolve rapidly, enabling hormones to serve new and broader roles.

## 36.1 ENDOCRINE FUNCTION

The word “hormone” often popularly connotes teenagers and the changes that occur to their bodies as they grow and mature. Hormones do play a key role in animal growth and development, but that is just one of their many diverse roles. In particular, hormones regulate an organism’s physiological response to the environment and help maintain stable physiological conditions within cells or within the animal as a whole. We start by highlighting these functions, before addressing the molecular mechanisms of how hormones work in [section 36.2](#).

### The endocrine system helps to regulate an organism’s response to its environment.

Organisms face constant changes in their environment. These changes often present physiological challenges or stresses that the organism must respond to by altering the functional state of its body. Changes in light or temperature, the threat of a predator, or the presence of a potential mate stimulate responses of an animal’s nervous system and endocrine system. Environmental cues activate the nervous system, which relays signals to the endocrine system, triggering a response. The endocrine system, with its slower and more prolonged signaling, reinforces physiological changes in the animal’s body that better suit environmental conditions.

When a gazelle sees or smells a predator, its endocrine system helps to ready its body for rapid escape. When a female cardinal sees a bright

red, singing male early in spring, endocrine signals released from within the female cardinal's brain initiate changes in its reproductive organs and increase its behavioral responsiveness, encouraging it to select the male as its mate. And when particular smells stimulate a sense of hunger and digestive function in animals such as dogs and humans, those animals are attracted to food. In each of these cases, the endocrine system helps the animal respond appropriately to environmental cues.

## The endocrine system regulates growth and development.

Growth and development require broad changes in many different organ systems. The release of circulating hormones from the endocrine system accomplishes these changes, regulating how animals develop and grow. For example, in [Chapter 40](#), we discuss the importance of the sex hormones estrogen and testosterone in determining female or male sexual characteristics both in the embryo and during puberty.

As another example, consider how the well-studied endocrine system of insects regulates their growth and development. Insects produce a rigid exoskeleton ([Chapter 35](#)), which must be periodically shed and replaced by a larger new one to enable the insect to grow ([Fig. 36.1](#)). Shedding of the exoskeleton is referred to as [molting](#). Each molting produces a new larval stage. In some insects, such as moths, the animal's body also changes dramatically, undergoing [metamorphosis](#) at a key stage in development ([Fig. 36.1a](#)). In other insects, such as grasshoppers and crickets, the animal grows larger after each molt, but with little change in body form ([Fig. 36.1b](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 36.1 Growth and development in (a) moths and caterpillars and in (b) grasshoppers.

Molting and metamorphosis are regulated by hormones released from tissues in the insect's head. British physiologist Vincent Wigglesworth studied the effects of hormones on the blood-sucking insect *Rhodnius*. Normally, *Rhodnius* goes through five juvenile stages before developing into its final adult body form. Like grasshoppers and crickets, it does not undergo metamorphosis. Each of the developmental stages is triggered by a blood meal. Wigglesworth showed that he could prevent molting if the head of the insect were removed shortly after a blood meal ([Fig. 36.2](#)). *Rhodnius* can survive for long periods despite having its head removed. If the insect takes a blood meal and the head is removed a week later, the animal's body undergoes a molt and grows into its adult form. Wigglesworth hypothesized that a substance diffusing from the animal's head controls its molt. If the head is removed shortly after a blood meal, this

substance does not have time to reach the insect's body to trigger a molt; if the removal is delayed, it does.

#### HOW DO WE KNOW?

### FIG. 36.2

## How are growth and development controlled in insects?

#### BACKGROUND

During the 1930s, British physiologist Vincent Wigglesworth studied how a blood meal taken by the bug *Rhodnius* triggered molting and growth. This work pioneered the discovery of hormonal substances that stimulate the bug's growth. *Rhodnius* goes through five successive larval stages (called nymphs) before becoming a winged adult, as illustrated in [Fig. 36.2a](#). Each developmental step is triggered by a blood meal.

#### HYPOTHESIS

Wigglesworth hypothesized that a substance (specifically, a hormone) that diffuses from the head triggers molt in *Rhodnius*.

#### EXPERIMENT 1 AND RESULTS

Wigglesworth decapitated juvenile bugs at different intervals of time after a blood meal and observed whether molting occurred. (Decapitation does not kill the insect.) He showed that if a bug is decapitated less than an hour after a blood meal, it fails to molt. If a bug is decapitated a week after the blood meal, it molts (Experiment 1; [Fig. 32.2b](#)).

#### EXPERIMENT 2 AND RESULTS

Wigglesworth also found that if he used a fluid tube to join the body of a bug decapitated immediately after a blood meal with the body of one that wasn't decapitated until a week after feeding, the bodies of both bugs molted (Experiment 2; [Fig. 32.2b](#)). This experiment demonstrated that the diffusing hormone triggers molting in a bug that lacks the hormone because of an immediate decapitation.

#### CONCLUSION

A substance diffuses from the head in *Rhodnius* and triggers the molting process.

#### FOLLOW-UP WORK

In 1936, the German endocrinologist Alfred Kuhn confirmed Wigglesworth's result in experiments performed on moth caterpillars. More recently, Japanese molecular endocrinologists Atsushi Nagasawa and colleagues (1984) and Hiromichi Kawakami and colleagues (1990) isolated and sequenced the structure of the hormone from silkworm moths. It is now known as prothoracicotropic hormone (PTTH), because it acts on the prothoracic gland of the insect to release the molting hormone, ecdysone.

SOURCES Wigglesworth, V. B. 1934. "The Physiology of Ecdysis in *Rhodnius prolixus* (Hemiptera). II. Factors Controlling Moulting and 'Metamorphosis.'" *Quarterly Journal of Microscopical Sciences* 77:191–223; Nagasawa, H., et al. 1984. "Amino-Terminal Amino Acid Sequence of the Silkworm Prothoracicotropic Hormone: Homology with Insulin." *Science* 226:1344–1345; Kawakami, A., et al. 1990. "Molecular Cloning of the *Bombyx mori* Prothoracicotropic Hormone." *Science* 247:1333–1335.

The German endocrinologist Alfred Kuhn obtained a similar result in experiments performed on moth caterpillars. Tying the caterpillar's head off from the rest of the body prevented the body from molting. Wigglesworth and Kuhn considered the diffusing substance to be a brain hormone. Subsequent work showed that cells in a specialized region of the insect brain secrete the peptide now known as prothoracicotropic hormone (PTTH) ([Table 36.1](#)). In *Rhodnius*, PTTH is released after a blood meal and acts to trigger the animal's molt by stimulating the release of a second hormone from the prothoracic gland.

|                      | hormone<br>(peptide)       |                    | squid, cuttlefish)                                                                       |
|----------------------|----------------------------|--------------------|------------------------------------------------------------------------------------------|
| Brain and eye stalks | Chromatotropins (peptides) | Chromatophores     | Stimulates pigmentation changes in crustaceans                                           |
| Reproductive gland   | Androgen (peptide)         | Reproductive tract | Regulates development of testes and male secondary sexual characteristics of crustaceans |

Two decades later, the German endocrinologist Peter Karlson isolated and purified this second hormone, termed ecdysone. PTH triggers molting by stimulating the release of ecdysone, a steroid hormone that coordinates the growth and reorganization of body tissues during a molt. The action of ecdysone is a good example of how a hormone can precisely coordinate broad changes in body organization and function, in contrast to the specific regulation that nerves provide. Karlson was able to purify a small amount of ecdysone from large numbers of silk moth *Bombyx* caterpillars. He ultimately isolated a mere 25-mg sample from 500 kg of moth larvae! This tiny amount highlights the general principle that relatively few hormone molecules can have a large effect on an organism.

In his studies of *Rhodnius*, Wigglesworth also noted that, whatever the larval stage, the decapitated bug always molted into an adult after its blood meal. By removing just the region behind the brain, Wigglesworth was able to show that paired endocrine glands, called corpora allata, in this region of the head release a hormone that normally prevents the earlier larval stages from molting into the adult form. This hormone, called juvenile hormone, is released in decreasing amounts during each successive larval molt. After the fifth and final

stage, the level of juvenile hormone is so low that it no longer blocks maturation; thus, at the final molt the insect undergoes its final growth into the adult form ([Fig. 36.3](#)).

FIG. 36.3 Hormonal control of growth and development in *Rhodnius*.

The brains of insects, similar to the nervous systems of other invertebrate and vertebrate animals, contain [neurosecretory cells](#). These cells are neurons that release hormones, which act on endocrine glands or other targets within the insect, instead of secreting neurotransmitters that bind to another neuron or to muscle. In the case of insects, peptide hormones released from neurosecretory brain cells act on the corpora allata and the prothoracic gland ([Fig. 36.3](#)). The neurosecretory cells stimulate the corpora allata to produce juvenile hormone so that molting larvae retain their juvenile characteristics. At appropriate times, other neurosecretory brain cells secrete the peptide hormone PTTH, which stimulates the release of ecdysone from the prothoracic gland, triggering the transition from larval to pupal and adult forms.

These studies reveal how small amounts of hormones released from key glands within the animal's body regulate major stages of growth

and changes in body form during metamorphosis. When an animal's body requires coordinated changes in multiple organ systems, hormonal regulation by the endocrine system plays a critical role.

Hormones also regulate growth in humans and other vertebrate animals. Growth hormone controls the growth of the skeleton and many other tissues in the human body. This hormone is produced by the [pituitary gland](#), which is located beneath the brain. Tumors of the pituitary that cause an overproduction of growth hormone lead to gigantism, whereas tumors that result in too little growth hormone cause pituitary dwarfism. The role of the pituitary gland in regulating body function is described later in the chapter.

## The endocrine system underlies homeostasis.

Endocrine control of internal body functions is also central to [homeostasis](#), the maintenance of a steady physiological state within a cell or an organism ([Chapters 5](#) and [33](#)). Without some way to maintain a stable internal environment, changing environmental conditions would lead to dangerous shifts in an animal's physiological function. For example, an animal's body weight depends on the regulation of its energy intake relative to energy expenditure.

Disruption of hormones that regulate appetite and food intake can lead to obesity on the one hand or to weakness and lethargy on the other hand. Similarly, hormones that regulate the concentrations of key ions in the body, such as  $\text{Na}^+$  and  $\text{K}^+$ , are fundamental to healthy nerve and muscle function ([Chapters 34](#) and [35](#)) and fluid balance within the body ([Chapter 39](#)).

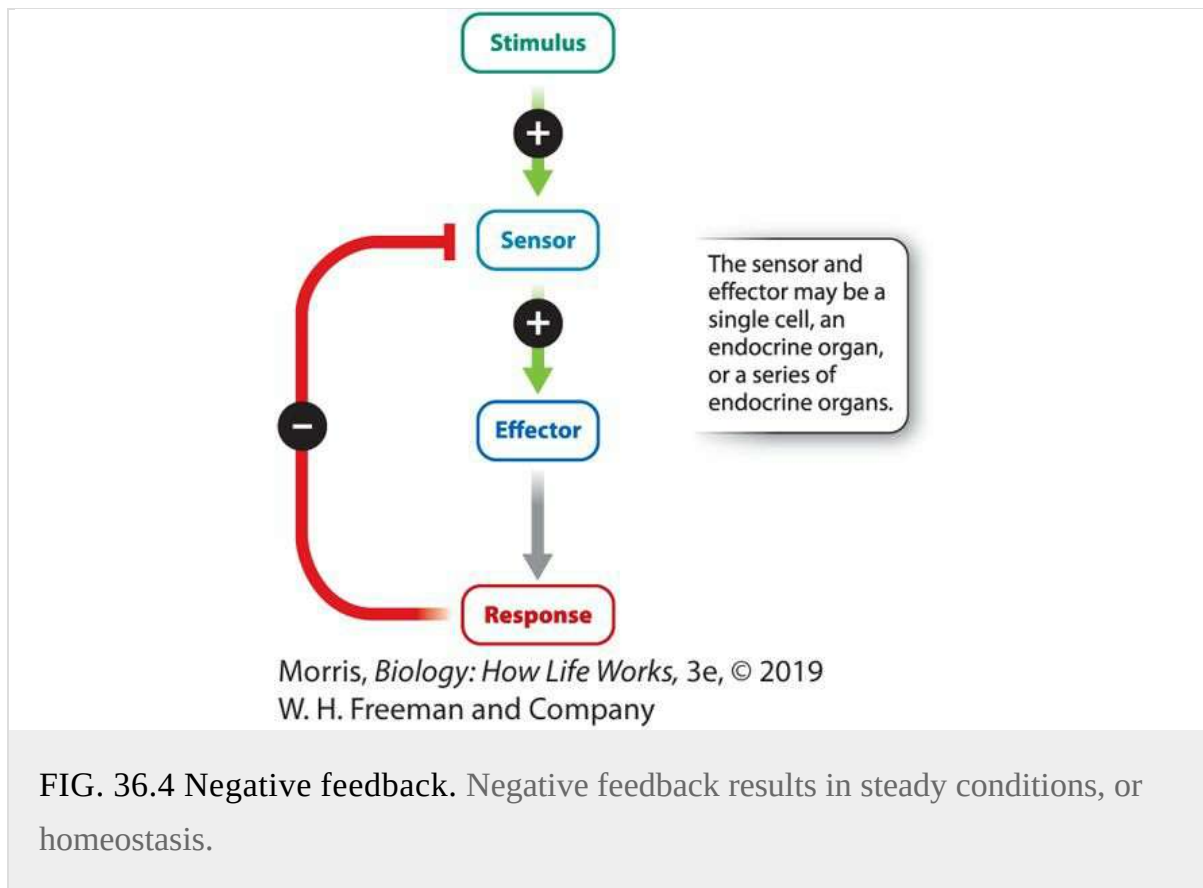

How does the body, and in particular the endocrine system, maintain homeostasis? Maintaining homeostasis depends on feedback from the target organ to the endocrine gland that secretes the hormone. Because hormones are transmitted through the bloodstream, this feedback can occur over varying distances within the body, coordinating the functions of several organs at any one time. In response to this feedback, the endocrine gland modifies its own subsequent production of hormone, either increasing or decreasing it. Two general types of feedback are provided: **negative feedback** and **positive feedback**.

Homeostasis typically depends on negative feedback, in which a stimulus produces a response that in turn counteracts the initial stimulus. In [Chapter 33](#), we saw how both the temperature in a house and the core body temperature of an animal are maintained at a constant level by this type of control.

Many physiological parameters—such as blood glucose and calcium levels—are maintained at relatively steady levels by negative feedback. For example, a change in the glucose or calcium level causes a response that brings the level back to the starting point, called the set point. In these cases, a change in level (the stimulus) is detected by a sensor in the endocrine organ ([Fig. 36.4](#)). The endocrine organ (the effector) releases a hormone, and the hormone causes a response that opposes the initial stimulus, so that the glucose or calcium level moves back toward the set point. As levels return to the set point, secretion of the hormone decreases, and there is a limit to further change. Constant feedback between the response and sensor maintains a set point. That

is, the maintenance of homeostasis is an active process.

Let's examine the example of blood glucose levels in more detail. The amount of glucose in the blood of animals is maintained at a steady level ([Fig. 36.5](#)). If glucose levels are too low, cells of the body do not have a ready source of energy. Conversely, if glucose levels are too high for too long, they can damage organs. Maintaining steady blood glucose levels is challenging because glucose levels rise immediately after a meal when glucose is absorbed into the bloodstream from the intestine, then fall as glucose is taken up by cells to meet their energy needs.

FIG. 36.5 Control of glucose levels in the blood by negative feedback.

Immediately after a meal, when blood glucose rises,  $\beta$  (beta) cells of the pancreas secrete the hormone insulin, which circulates in the blood ([Fig. 36.5a](#)). The presence of insulin triggers muscle and liver cells to take up glucose from the blood and either use it or convert it to a storage form called glycogen ([Chapter 7](#)). In this way, insulin guards against high levels of glucose in the blood.

Several hours after a meal, as blood glucose levels fall, a different population of cells in the pancreas, called  $\alpha$  (alpha) cells, secrete the hormone glucagon. Its effects are roughly opposite to those of insulin ([Fig. 36.5b](#)): glucagon stimulates the breakdown of glycogen into glucose and its release from muscle and liver cells. The result is that blood glucose levels rise.

In both cases, the stimulus (either high or low blood glucose levels) is sensed by cells of the pancreas ( $\beta$  cells or  $\alpha$  cells) and triggers a response (secretion of insulin or of glucagon) that brings blood glucose levels back to the set point. Note that in each case the response feeds back to the secreting cells (negative feedback) to reduce further hormone secretion.

When insulin fails to control blood glucose levels, a disease called diabetes mellitus results. When this disease is untreated, individuals with diabetes excrete excess glucose in their urine because their blood glucose levels are too high. Diabetes causes cardiovascular and neurological damage, including loss of sensation in the extremities, particularly the feet.

In some instances, it is necessary to accelerate the response of target cells for a period of time. That is the role of positive feedback ([Fig. 36.6](#)). In positive feedback, a stimulus causes a response in the same direction as the initial stimulus, which leads to a further response, and so on. In the endocrine system, positive feedback to a stimulus leads to secretion of a hormone that causes a response, and the response causes the release of more hormone. The result is an escalation of the response. A positive feedback loop reinforces itself until it is interrupted or broken by some sort of external signal outside the feedback loop but from within the body.

FIG. 36.6 Positive feedback. In positive feedback, a stimulus causes a response, and that response causes a further response in the same direction.

Positive feedback occurs in mammals during birth ([Chapter 40](#)). In response to uterine contractions (the stimulus), the pituitary gland releases the hormone oxytocin. The release of oxytocin causes the uterine muscles (the effector) to contract more forcefully. The uterine contractions, in turn, stimulate (positive feedback) the pituitary gland to secrete more oxytocin, causing the uterine muscles to contract still more forcefully and frequently.

#### Self-Assessment Questions

1. What are three general functions of the endocrine system?  
Provide an example of each.
2. Diabetes mellitus is a disease characterized by high blood glucose levels. Given what you know about how insulin usually prevents

high blood glucose levels, can you think of two different ways that diabetes can result?

3. Diagram an endocrine pathway, such as oxytocin regulation of labor during birth, that relies on positive feedback.

## 36.2 HORMONES

Because hormones are released into the bloodstream, they have the potential to affect many organ systems. How do hormones circulating in the blood target specific tissues? How can one hormone exert its effect on one cell type and another hormone exert its effect on a different cell type? The answer lies in the presence of receptors on cells within target organs—receptors that bind specific hormones.

### Hormones act specifically on cells that bind the hormone.

Hormones circulating in the bloodstream bind to receptors located either on the surface of or inside target cells. Therefore, it is the presence or absence of a receptor for a given hormone that determines which cells respond and which do not. For example, when the hormone oxytocin is released into the bloodstream of mammals, it affects only cells that express a receptor on the cell surface capable of binding oxytocin as it flows by in the bloodstream, namely uterine muscle cells and secretory cells in breast tissue. When oxytocin binds to these cell-surface receptors, uterine muscle cells are stimulated to contract, and secretory cells in breast tissue release milk during breastfeeding. The cells of other organs do *not* express the receptor, so the hormone can exert its effect only on these specific tissues and no others.

The binding of a hormone to its receptor triggers changes in the target cell, resulting in a cellular response ([Chapter 9](#)). The specific action of a hormone depends on the kind of response that it triggers in the target cell. For example, the binding of a hormone can alter ion

flow across the cell membrane, change the biochemical activity of a target cell, or initiate changes in gene expression.

## Two main classes of hormones are peptide and amines, and steroid hormones.

Some hormone receptors are located on the cell surface; others are located inside the cell. Where a receptor is located depends on characteristics of the hormone molecules themselves. Hormones can be grouped into two general classes: hydrophilic molecules, which cannot diffuse across the plasma membrane, and hydrophobic molecules, which can. The hydrophilic hormones are [peptide hormones](#) and [amine hormones](#), and the hydrophobic hormones are [steroid hormones](#). [Fig. 36.7](#) shows examples of both types.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 36.7 (a) Peptide, (b) amine, and (c) steroid hormones.

---

Peptide hormones and amine hormones are both derived from amino acids ([Figs. 36.7a](#) and [36.7b](#)). Peptide hormones are short chains of amino acids, whereas amine hormones are derived from a single aromatic amino acid, such as tyrosine or phenylalanine ([Chapter 4](#)). Steroid hormones are derived from cholesterol ([Fig. 36.7c](#)). Whereas peptide hormones (which are sometimes large enough to be considered proteins) can evolve through changes in their amino acid sequence, steroid hormones cannot. Evolutionary changes in steroid hormone function depend instead on changes in their synthetic enzymes or changes in the receptors they bind and the cellular responses they trigger.

Peptide and amine hormones are more abundant than steroid hormones and are more diverse in their actions. Because most peptide and amine hormones are hydrophilic and cannot diffuse across the plasma membrane (exceptions are thyroid hormones), nearly all of these hormones bind to receptors on the surface of the cell ([Fig. 36.8a](#)). Peptide and amine hormones alter the activity of the target by initiating signaling cascades within the target cell, as discussed in [Chapter 9](#). The bound receptor activates an enzyme or other molecule within the cell, and it in turn activates another, and so on. Typically, the activated enzymes are protein kinases, which phosphorylate other proteins. These signaling cascades can alter metabolism by activating or inhibiting enzymes, or they can lead to changes in gene expression. For example, a peptide or amine hormone could trigger a cell to grow, divide, change shape, or release another hormone. Peptide and amine hormones act on timescales of minutes to hours.

**a. Cell-surface receptors**

**b. Intracellular receptors**

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 36.8 Mechanism of action of (a) peptide and (b) steroid hormones.

There are many examples of peptide hormones. In vertebrates, for instance, growth hormone stimulates protein synthesis and the growth of many body tissues, particularly those in the musculoskeletal system ([Table 36.2](#)). As we saw, insulin and glucagon are peptide hormones released by the pancreas that regulate glucose metabolism by the liver,

muscles, and other tissues. Gastrin and cholecystokinin are peptide hormones that regulate mammalian digestive function ([Chapter 38](#)). In addition to serving as a neurotransmitter released by the sympathetic nervous system ([Chapter 34](#)), epinephrine and norepinephrine (also known as adrenaline and noradrenaline, respectively) are amine hormones that support an animal's fight-or-flight response.

Because steroid hormones are hydrophobic, they diffuse freely across the cell membrane. Steroid hormones bind with receptors in the cytoplasm or nucleus, forming a steroid hormone–receptor complex ([Fig. 36.8b](#)). Hormone–receptor complexes that form in the cytoplasm are transported into the nucleus of the cell. These complexes most commonly act as transcription factors: they stimulate or repress gene expression, thereby altering the proteins produced by the target cell. Consequently, steroid hormones typically have profound and long-lasting effects on the cells and tissues they target, on timescales of days to months.

The sex hormones estrogen, progesterone, and testosterone ([Table](#)

[36.2](#)) are steroid hormones that regulate the development of the vertebrate reproductive organs. Cortisol is a steroid hormone that regulates a vertebrate animal's response to stress and inhibits inflammation. Steroid hormones similar to cortisol are used medically to reduce the symptoms of certain inflammatory disorders. However, they also carry risks; namely, they suppress the immune system, increasing the chance of infection and diminishing wound healing.

## Hormonal signals are amplified to produce a strong effect.

Hormones are typically released in small amounts. As mentioned earlier, they can exert strong effects on the overall physiology of an organism by amplification ([Chapter 9](#)). Amplification occurs during two series of signaling steps, both before the hormone binds to a cell receptor and inside the cell afterward. The first set of signaling steps is the passing of a signal from one endocrine gland to the next in a hormonal pathway. The second set is signal transduction in the target cell. Signals are amplified at each step of the pathway, resulting in a large effect on the target cell or organ.

Some hormonal signaling pathways involve the release of a hormone by one gland that acts on another gland as its target. The target gland, in turn, releases another hormone that acts on a second gland or tissue in the pathway, and so on. Hormone signaling pathways between endocrine glands and tissues are often referred to as endocrine axes. In vertebrates, hormonal signals are amplified along a pathway called the hypothalamic–pituitary axis that goes from the hypothalamus to the anterior pituitary gland, and then from the anterior pituitary

gland to target glands or tissues in the body. The hypothalamus initially releases trace amounts of peptide hormones called **releasing hormones** (**Fig. 36.9**). These releasing hormones bind to receptors on cells in the anterior pituitary gland, leading that organ to release a much larger amount of the associated hormones. For example, the hypothalamus secretes a corticotropin-releasing hormone, which stimulates the anterior pituitary gland to release a larger amount of adrenocorticotrophic hormone (ACTH).

FIG. 36.9 Amplification of a hormonal signal.

Hormones released by the anterior pituitary gland subsequently bind cell receptors in the target organ. For example, ACTH acts on cells of the adrenal cortex, stimulating their secretion of the hormone cortisol. Cortisol acts on many different cells and tissues in the body, causing an acute stress response. Among its effects, it causes the liver to convert glycogen and amino acids to glucose. This action yields a weight of glucose that is 56,000 times heavier than the initial weight of releasing hormones secreted by the hypothalamus.

We can see an example of amplification in invertebrates in the regulation of insect molting and metamorphosis (see [Fig. 36.3](#)). This pathway has two signaling steps in which an endocrine gland releases a hormone. First, the brain releases the hormone PTTH. In turn, PTTH signals the prothoracic gland, leading to the release of a much larger amount of ecdysone, the hormone that regulates growth and metamorphosis of the insect's body. Ecdysone then binds to cell receptors in the target organ. Signaling cascades within these cells further amplify the hormone signal. Thus, amplification applies both to signal transduction cascades within a cell and to the transmission of endocrine hormones between glands and tissues.

## Hormones are evolutionarily conserved molecules with diverse functions.

Most hormones have an ancient evolutionary history and are

evolutionarily conserved. For example, some vertebrate hormones can also be found in many invertebrates. Given that the first vertebrate animals diverged from invertebrates more than 500 million years ago, some animal hormones must be even older. Their roles in many invertebrate animals have yet to be discovered.

Typically, the same hormone serves different functions in vertebrates and in invertebrates. The same hormone may even serve different functions within distinct groups of vertebrates. For example, thyroid-stimulating hormone (TSH) is released by the anterior pituitary gland and targets the thyroid gland. It regulates metabolism in mammals but triggers metamorphosis in amphibians and feather molt in birds. It has even been found in snails and other invertebrates that lack a thyroid gland. Its function in snails appears to be stimulation of sperm or egg production.

Recent genomic analysis has shown that the receptors for many hormones evolved long before the hormones with which they now interact. Even though the structure of a hormone or its receptor is often largely unchanged across diverse groups of organisms, hormones and their receptors can readily be selected to take on new roles as organisms evolve new behaviors and exploit new environments. An example is the shift in function of TSH from its role of stimulating sperm or egg production in snails to regulating metabolism in mammals and feather molt in birds.

Another intriguing finding is that many peptides originally identified as hormones in various tissues also function as

neurotransmitters in the nervous system. For example, oxytocin, which stimulates uterine contraction and the release of milk during breastfeeding, also serves as a neurotransmitter in the brain. It is believed to influence social behavior, as well as to stimulate sexual arousal in mammals. Similarly, antidiuretic hormone, a peptide hormone that regulates water uptake in the kidneys ([Chapter 39](#)), also functions as a neurotransmitter in the brain, influencing mammalian mating and pair-bonding behavior. Hence, the same compound, expressed in two different cell types, may have entirely different functions in each cell type. The roles of hormones as chemical messengers are varied within an organism and easily changed over the course of evolution.

#### Self-Assessment Questions

4. How can hormones act specifically on only some cells or organs although they are transported by the bloodstream throughout the body?
5. What are the two general classes of hormone? Provide an example of each.
6. Where are receptors for peptides and steroid hormones located, and how does the difference in their location affect the resulting signaling pathways in the target cell?
7. How are hormones able to exert substantial and broad effects on their target cells even though they are released in small amounts by the initial cell, tissue, or gland?

## 36.3 THE VERTEBRATE ENDOCRINE SYSTEM

The vertebrate endocrine system responds to sensory cues received by its nervous system. Whereas certain sensory signals may be communicated directly to endocrine glands or tissues in the body, many are processed in the brain. After processing, these signals are transmitted to the endocrine system by the hypothalamus, a structure located in the forebrain. The hypothalamus is the main route by which nervous system signals are transmitted to the vertebrate endocrine system. The hypothalamus relays these signals to the pituitary gland, which lies just below it. The pituitary gland acts as a control center for many other endocrine glands in the body.

**The pituitary gland integrates diverse bodily functions by secreting hormones in response to signals from the hypothalamus.**

The pituitary gland is a central regulating gland of the vertebrate endocrine system. It releases several hormones that coordinate the action of many other endocrine glands and tissues. These glands, which are illustrated in [Fig. 36.10](#), control the growth and maturation of the body, regulate reproductive development and metabolism, and control water balance. These effects reflect the broad range of roles that the endocrine and nervous systems perform in regulating body maturation and maintaining homeostasis.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 36.10 The hypothalamus–pituitary axis. The hypothalamus sends signals to the pituitary gland, which in turn sends signals to diverse cells and organs throughout the body.

---

The pituitary gland communicates with many cells, tissues, and organs of the body. Some of these, such as the thyroid and adrenal glands, secrete hormones in response to signals from the pituitary gland and, therefore, have exclusively endocrine functions. Others, such as the lungs, kidneys, and digestive tract, harbor endocrine cells that secrete hormones and also have other physiological roles in the body. Consequently, the vertebrate endocrine system is not localized in one part of the body, but rather is present throughout.

The pituitary gland is divided into anterior and posterior regions ([Fig. 36.11](#)). This division is not arbitrary: the two regions have distinct functions, organizations, and embryonic origins. The [anterior pituitary gland](#) forms from epithelial cells that develop and push up from the roof of the mouth, whereas the [posterior pituitary gland](#) develops from neural tissue at the base of the brain. Both sets of cells form pouches that develop into glands, which come to lie adjacent to each other. As a consequence of this development pathway, the anterior and posterior pituitary glands should be thought of as two distinct glands, not one.

FIG. 36.11 The anterior and posterior pituitary glands. The hypothalamus communicates with the anterior pituitary gland by secreting releasing hormones into the blood. The hypothalamus communicates with the posterior pituitary gland by extending axons of neurosecretory cells into it.

Because of their developmental differences, the anterior and posterior pituitary glands receive input from the hypothalamus in different ways. Like the brain of arthropods, the vertebrate hypothalamus contains neurosecretory cells, which are part of the brain and therefore neurons. Like the invertebrate neurosecretory cells, these cells release hormones into the bloodstream. Some of the neurosecretory cells communicate with the anterior pituitary gland. In this case, they secrete releasing hormones into small blood vessels that travel to and supply the anterior pituitary gland ([Fig. 36.11](#)). In response, cells of the anterior pituitary gland release hormones into the bloodstream. These hormones circulate throughout the body and bind

to receptors on target cells, tissues, and organs.

In contrast, the hypothalamus and the posterior pituitary gland communicate without the use of releasing hormones. Instead, cell bodies of neurosecretory cells located in the hypothalamus extend axons into the posterior pituitary gland. These axons release hormones directly into the bloodstream for transport to distant sites ([Fig. 36.11](#)). Consequently, the posterior pituitary gland is part of the nervous system itself.

In response to signals from the hypothalamus, the anterior and posterior pituitary glands secrete distinct sets of hormones ([Table 36.2](#)). The hormones released by the anterior pituitary gland act on an endocrine gland to cause release of other hormones. Hormones that control the release of other hormones are called **tropic hormones**. For example, in response to thyroid-stimulating hormone, the thyroid gland releases thyroid hormones that regulate the metabolic state of the body. In response to follicle-stimulating hormone (FSH) and luteinizing hormone (LH), the ovaries release estrogen and progesterone and the testes release testosterone. In response to adrenocorticotrophic hormone, the adrenal glands release cortisol.

The anterior pituitary gland also secretes two other hormones: growth hormone (GH) and prolactin. Growth hormone acts generally on the muscles, bones, and other body tissues to stimulate their growth. Prolactin stimulates milk production in the breasts of female mammals in response to an infant's suckling at the mother's nipple.

The hormones released by the posterior pituitary gland include

[oxytocin](#) and [antidiuretic hormone](#) (ADH; also called [vasopressin](#)).

These two evolutionarily related peptide hormones have similar structures. As discussed earlier, oxytocin plays several roles related to female reproduction. It causes uterine contraction during labor and stimulates the release of milk during breastfeeding. Antidiuretic hormone acts on the kidneys, regulating the concentration of urine that an animal excretes, which is critical to maintaining water and solute balance in the body ([Chapter 39](#)).

In addition to their roles in reproduction and kidney function, oxytocin and antidiuretic hormone are released by cells in the brain and may play roles in social behaviors. These hormones are able to act directly on the brain by binding to receptors on neurons. Recent evidence indicates that oxytocin may have important roles in regulating maternal behavior toward infants and in creating trust as a prelude to mating in certain groups of vertebrate animals. These functions reflect the long evolutionary history of oxytocin, which also plays a role in the social behavior of insects.

Recent evidence suggests that antidiuretic hormone plays a parallel role in regulating male social behavior and parental behavior in mammals. This is not surprising because oxytocin and antidiuretic hormone have very similar chemical structures (see [Fig. 36.7](#)). The integration of reproductive function with behavior for the care of young is likely favored strongly by natural selection.

**Many targets of pituitary hormones are endocrine tissues that also secrete**

## hormones.

As we have seen, some of the hormones released by the anterior pituitary gland act on endocrine organs, which then release hormones of their own. These tropic hormones are TSH, FSH and LH, and ACTH (see [Fig. 36.10](#); [Table 36.2](#)). Here, we look at their target organs in more detail.

TSH acts on the [thyroid gland](#), which is located in the front of the neck (see [Fig. 36.10](#); [Table 36.2](#)). In response to TSH, the thyroid gland releases two peptide hormones, triiodothyronine ( $T_3$ ) and thyroxine ( $T_4$ ), that diffuse into cells and bind to intracellular receptors. These two hormones act to increase the resting metabolic rate of cells throughout the body. As levels of  $T_3$  and  $T_4$  rise, these hormones act as a brake on the release of TSH by the anterior pituitary gland. This regulation of TSH by negative feedback is critical to keeping TSH levels stable and maintaining the body as a whole in a stable metabolic state. Individuals who overproduce thyroid hormones (hyperthyroidism) experience increased appetite and weight loss caused by an overly active metabolic state. In contrast, individuals with thyroid hormone deficiency (hypothyroidism) experience fatigue and sluggishness caused by a metabolic state that is too low. Both conditions are diagnosed by blood tests that monitor circulating levels of thyroid hormones.

Because the thyroid hormones  $T_3$  and  $T_4$  require iodine for their production, individuals who do not acquire enough iodine from their diets produce too little thyroid hormone. In such a case, the anterior pituitary gland increases its production of TSH because it is no longer

receiving negative feedback. Over time, in response to TSH the thyroid gland expands to form an enlargement of the throat called a goiter. The introduction of iodized salt has largely eliminated goiter formation and hypothyroidism in many countries, but in some underdeveloped areas these conditions remain significant public health problems.

The gonadotropic hormones are FSH and LH. They target the female and male gonads: the [ovaries](#) and [testes](#), **respectively** (see [Fig. 36.10](#); [Table 36.2](#)). In response to FSH and LH, both the ovaries and the testes secrete specific sex hormones that regulate their own development as well as the development of secondary sexual characteristics. Female sex hormones include the steroids estrogen and progesterone. The principal male sex hormone is the androgen testosterone. These sex hormones are common to a vast majority of vertebrates, regulating sexual differentiation, gonadal maturation, and reproductive behavior. The role of these sex hormones in regulating reproductive function is discussed in greater detail in [Chapter 40](#).

Testosterone is a naturally occurring anabolic steroid that promotes protein synthesis to build body tissues and anabolic metabolism to store energy within cells. Thus, one role of testosterone is to stimulate male body tissue growth, particularly in muscles. A variety of synthetic anabolic steroids that mimic the action of testosterone have been developed to treat muscle wasting due to loss of appetite and diseases such as cancer and AIDS. Some male and female athletes use anabolic steroids illegally to promote muscle strengthening, undermining fair competition in their sports. The risks to health of continued use of anabolic steroids are considerable, including liver damage, heart

disease, and high blood pressure. Tissues become damaged because the elevated circulating levels of testosterone produced by anabolic steroids inhibit the normal synthesis of tropic hormones by the anterior pituitary gland.

ACTH released by the anterior pituitary gland is also a tropic hormone. As noted in [section 36.1](#), ACTH acts on the cortex (the outer portion) of the paired **adrenal glands** (see [Fig. 36.10](#); [Table 36.2](#)). The adrenal glands are located adjacent to the kidneys (*ad-*, meaning “near”; *renal*, referring to the kidneys). In humans, each small adrenal gland lies just above each kidney. During times of stress, such as starvation, fear, or intense physical exertion, ACTH stimulates adrenal cortex cells to secrete cortisol. The release of cortisol affects a broad range of bodily functions. For example, it raises blood glucose levels, suppresses immune function ([Chapter 41](#)), and increases blood pressure ([Chapter 37](#)). Whereas acute (short-term) episodes of elevated cortisol are healthy physiological responses that enable animals to respond to stressful situations, chronic (long-term) stress often leads to a broad range of unhealthy conditions that include impaired cognitive and immune function, sleep disruption, and fatigue.

## Other endocrine organs have diverse functions.

Although many endocrine organs receive signals from the hypothalamic–pituitary axis, some respond instead to internal physiological states of the body or to external environmental cues. One of these organs is the **parathyroid gland**, which is located on the thyroid gland. The parathyroid gland secretes parathyroid hormone

(PTH). Working together with calcitonin secreted by the thyroid gland, PTH controls the level of calcium in the blood ([Table 36.2](#)). The two hormones act by regulating the actions of bone cells (osteoblasts and osteoclasts; [Chapter 35](#)) that control bone formation and bone removal.

When circulating levels of calcium fall too low, the parathyroid gland releases PTH. The release of PTH stimulates osteoclasts to reabsorb bone mineral, halting bone formation and triggering the release of calcium into the bloodstream. When calcium levels are too high, the production of PTH is inhibited and calcitonin is released. The release of calcitonin shifts bone metabolism toward net bone formation, building bone that stores calcium in the skeleton. As is true for blood glucose levels, calcium levels are maintained in a narrow range by negative feedback. The response to the hormone (increasing or decreasing the level of calcium in the blood) is in the opposite direction to the stimulus (low or high level of calcium in the blood), so that a stable set point is maintained.

Several organs of the digestive system, including the pancreas, stomach, and duodenum, produce hormones that regulate appetite and digestion. Three of these hormones are discussed in [Chapter 38](#).

The **pineal gland** is located in the brain. In response to darkness, the pineal gland secretes melatonin, a hormone that helps control an animal's state of wakefulness ([Table 36.2](#)). Melatonin secretion is inhibited by light. Environmental light cues sensed by the retina are conveyed to the gland by the autonomic nervous system. In some vertebrates, such as lampreys, some fishes, and reptiles, the pineal

gland responds to light sensed by a “third eye” composed of photosensitive cells that are located at the skull’s surface between the animal’s actual eyes. In both cases, melatonin levels rise at night. In diurnal animals (those that are active during the day), the rise in melatonin levels at night causes the animals to sleep. In nocturnal animals (those that are active during the night), the rise in melatonin levels at night causes the animals to become active.

The release of melatonin in response to daily (and seasonal) light cycles helps to maintain the body’s circadian rhythms. Circadian rhythms are cycles of approximately 24 hours in which an animal’s biochemical, physiological, and behavioral state shifts in response to changes in daily and seasonal environmental conditions. To overcome jet lag, travelers are advised to seek sunlight and often to take melatonin before sleeping to help reset their 24-hour circadian rhythm.

In several animals, including ground squirrels, bats, bears, and rattlesnakes, the pineal gland regulates hibernation, controlling the animal’s metabolic state over longer time periods. In many animals, release of melatonin also regulates seasonal breeding cycles.

## The fight-or-flight response represents a change in set point in many different organs.

The endocrine system works closely with the nervous system to enable animals to respond to external cues in the environment. In [Chapter 34](#), we discussed how prey animals, such as gazelles, use visual and

olfactory cues processed by the nervous system to detect the distant movement of a predator, such as a cheetah. We also saw how the sympathetic nervous system, in the fight-or-flight response, can trigger broad physiological changes, such as increased heart and breathing rates and changes in metabolism that ready the predator to attack or the prey to respond.

These actions are coordinated by the endocrine system. The sympathetic nervous system sends axons to the [adrenal medulla](#) (see [Fig. 36.10](#)), the inner part of the adrenal gland. In response to stimulation by the sympathetic nervous system, cells of the adrenal medulla secrete two hormones, epinephrine and norepinephrine (also known as adrenaline and noradrenaline, respectively). These hormones released by the adrenal gland have targets throughout the body, and they trigger the physiological changes of the fight-or-flight response. Interestingly, epinephrine and norepinephrine also act as neurotransmitters in the brain. In fact, cells of the adrenal medulla are modified nerve cells that have lost their axons and dendrites.

The same set of responses occurs when, walking along a deserted sidewalk, we note a shadowy movement or hear a footstep behind us. The perceived threat sets in motion a coordinated physiological reaction, mediated by the combined action of the nervous and endocrine systems. These changes make us alert and ready for action to avoid or resist a perceived threat. They also inhibit digestion and eliminate a sense of appetite.

Earlier, we considered the importance of homeostasis in maintaining

a variety of parameters, such as temperature and blood glucose levels, at a steady level. In this case, there is an adjustment of the set points of different organs, which is critical in enabling an animal to respond to external cues and adjust its physiological response appropriately. When the real or perceived threat is gone, the body is able to return to its prior state by reestablishing earlier set points.

Set points are also changed when an animal acclimatizes to a new environment, such as when it moves from fresh water to a marine environment or to a new altitude. An adaptive change in body function to a new environment is referred to as **acclimatization**. Examples of acclimatization are the increase in the number of red blood cells and their capacity to carry more oxygen that occurs at higher altitude ([Chapter 37](#)) and the seasonal changes in the fur of mammals that achieve the insulation required to maintain a stable body temperature ([Chapter 38](#)). These physiological changes result from establishing new set points in a process coordinated by the endocrine system.

#### Self-Assessment Questions

8. What is the difference in how the hypothalamus controls the anterior pituitary gland and how it controls the posterior pituitary gland?
9. What is a tropic hormone? Give two examples, identifying which endocrine gland releases the tropic hormone and which endocrine gland or organ is its target.
10. Diagram an endocrine pathway, such as parathyroid regulation of blood calcium levels, that maintains homeostasis of a bodily

function by means of negative feedback.

## 36.4 OTHER FORMS OF CHEMICAL COMMUNICATION

As we have seen, hormones enter the circulation and act on distant cells, namely those having receptors that bind the hormones. However, other chemical signals act over short distances, and still others are released into the environment to signal other individuals of the same species. In this section, we explore additional modes of chemical communication and the compounds that produce them.

### Local chemical signals regulate neighboring target cells.

Unlike hormones, some chemical compounds act locally only, on neighboring cells ([Fig. 36.12](#)). These cells must have receptors that bind to the compound before it degrades or diffuses into the bloodstream.

**a. Long-distance signaling**

**b. Local signaling**

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 36.12 Modes of chemical signaling. Chemical signaling can occur (a) over long distances (endocrine) or (b) locally (paracrine and synaptic).

Chemical compounds that act locally are said to have paracrine function ([Fig. 36.12b](#)). If a compound acts on the secreting cell itself, it is said to have autocrine function; that is, the chemical signal may stimulate or inhibit its own secretion. Growth factors (also referred to as cytokines and distinct from the growth hormone released by the anterior pituitary gland) and histamine are examples of paracrine chemical compounds released in small amounts that act locally on neighboring cells.

Growth factors ([Chapter 9](#)) enhance the differentiation and growth of particular kinds of tissues. For example, bone morphogenetic proteins (BMPs) promote the formation of bone in growing skeletons, and fibroblast growth factors (FGFs) stimulate the formation of connective tissue. Similarly, nerve growth factors (NGFs) promote the survival and growth of nerve cells.

When tissues are damaged, specialized cells nearby release histamine as a paracrine signaling molecule. This chemical triggers the dilation of blood vessels, allowing blood proteins and white blood cells to move into the region to fight infection and induce repair ([Chapter 41](#)). The release of histamine causes the swelling, redness, and warmth that we commonly associate with inflammation.

Another form of short-range chemical signaling is the release of neurotransmitters into the synapse between directly communicating

nerve cells or between nerve cells and muscles at neuromuscular junctions ([Fig. 36.12b](#)). Synaptic signaling is extremely rapid and brief compared to the other modes of chemical communication.

## Pheromones are chemical compounds released into the environment that signal physiological and behavioral changes.

Many animals release small chemical compounds into the environment to send a signal to other members of their species. These water-borne or airborne compounds, known as [pheromones](#), influence the physiology and behavior of other members of the species. For example, bees and wasps release pheromones to signal the location of a nest or food and to regulate the development and activities of other colony members. Even plants, such as orchids, release pheromones. Some plant pheromones attract pollinating bees or wasps by mimicking the chemical signals released by females of these species. There are many different pheromones, which serve very different functions, as shown in [Fig. 36.13](#).

Sources: a. Krzysztof Bisztyga/AGE Fotostock; b. Jorg & Petra Werner/Animals Animals/Earth Scenes; c. Darios/Shutterstock.

FIG. 36.13 Pheromone action. (a) Mating ladybugs are attracted by pheromones. (b) Wolves secrete pheromones in their urine that mark their territory. (c) Honeybees swarm to defend their nest after a bee that stings a threatening animal releases an alarm pheromone.

One of the most common types of pheromone signaling is the release of sex pheromones ([Chapter 43](#)). These pheromones play a key role in the mating behavior of many invertebrate and vertebrate species: they attract mates and trigger ritualistic social and mating behaviors. For example, the sex pheromone bombykol, released from a gland in the abdomen of the female silk moth, signals her location to males looking for a mate. In most mammals, amphibians, and reptiles, pheromones are detected by a vomeronasal organ with chemosensory neurons in the nasal region of the skull. Humans and nonhuman primates lack a vomeronasal organ, and most studies indicate that they do not produce pheromones.

Other pheromones signal territorial boundaries. Dogs and other canids (this family includes wolves and coyotes), as well as cats, secrete pheromones in their urine that mark their territories. Social seabirds, such as cormorants and boobies, mark their nesting sites with pheromones.

In many species, an animal under attack releases an alarm pheromone, warning its neighbors. Ants and other social insects deploy alarm pheromones to warn of an attack by an advancing army from another colony. The release of alarm pheromones from a stinging bee causes other bees to swarm and join the attack to defend their nest.

Similarly, social mammals such as deer warn of an approaching predator by means of alarm pheromones.

Social insects, such as ants, deploy trail pheromones that provide chemical cues that other worker ants can follow to a food source ([Fig. 36.14](#)). An ant returning to the colony from a food source releases trail pheromones from its abdomen onto the soil. Other worker ants then detect this trail with their antennae and track the concentration of trail pheromone, guiding them along the trail. If you have watched ants marching in line across a sidewalk, along a trail, or into and out of your house, you have seen worker ants using pheromone cues that serve as signposts for the way to food.

*Source: LatitudeStock–Patrick Ford/Getty Images.*

FIG. 36.14 Trail pheromones in ants. Here, a chemical trail has been laid down by worker ants signaling a food source for the colony.

Aquatic species also depend on pheromone signaling. Fishes, salamanders, and tadpoles release alarm pheromones into the water to warn of a threatening predator. Prey species that share the same habitat may even sense and respond to the release of another species' alarm pheromone.

Fishes also release pheromones to coordinate mating and to regulate

social interactions. In dense populations of cichlid fish living in Lake Tanganyika in central Africa, the ratio of brightly colored breeding males ([Fig. 36.15](#)) to females is highly regulated. Only approximately 10% of males are brightly colored and defend their territory to attract and mate with females. This restriction on the number of dominant breeding males is regulated by behavioral cues and chemical pheromones. When a dominant male dies, subordinate males fight for the vacated territory. When a new male assumes dominance, it becomes brightly colored to attract females. The color change is triggered by hormones released from the male fish's pituitary gland, which act on pigment cells called melanocytes that are located in the epidermis of its scales. The dominant breeding male reinforces its dominance by releasing pheromones in its urine that signal females and subordinate males in its breeding area. Thus, the fish makes use of both endocrine and pheromone signals to change its own behavior and the behavior of other members of its species.

FIG. 36.15 A brightly colored male cichlid fish. The behavior and markings of this fish are under hormonal control and triggered by social context.

---

### Self-Assessment Questions

11. How do hormones, paracrine signaling molecules, neurotransmitters, and pheromones differ?
12. The brown marmolated stink bug (*Halyomorpha halys*) emits at least two kinds of chemical compounds: one emits a noxious smell (explaining its name) that is used to ward off predators, and the other attracts other brown marmolated stink bugs. Which of these two chemicals is a pheromone and why?

## CORE CONCEPTS SUMMARY

**36.1 ENDOCRINE FUNCTION:** Animal endocrine systems release hormones into the bloodstream that respond to environmental cues, regulate growth and development, and maintain homeostasis.

The nervous system responds rapidly to sensory information, providing immediate physiological responses, whereas the endocrine system acts more slowly and over prolonged periods to effect broad changes in the physiological and behavioral state of an animal. [page 809](#)

The endocrine system helps an animal respond to its environment. [page 809](#)

The endocrine system is involved in growth and development. [page 810](#)

The nervous and endocrine systems regulate physiological functions to maintain homeostasis. [page 812](#)

Homeostasis is often achieved by negative feedback, in which the response opposes the stimulus. [page 813](#)

A stimulus can be amplified by positive feedback, in which the response amplifies the initial stimulus. [page 814](#)

**36.2 HORMONES:** Hormones bind to receptors on or inside target cells, and their signals are amplified to exert strong effects on target cells.

Hormones are chemical compounds that are secreted and

transported by the circulatory system, often to distant targets. [page 815](#)

Hormones bind to specific receptors located on the surface or inside the target cells that receive their signals. [page 815](#)

Two main classes of hormone are peptides and amines, and steroid hormones. [page 815](#)

Peptide and amine hormones are hydrophilic and bind to cell-membrane receptors, stimulating second-messenger pathways to alter the biochemical function of target cells. [page 815](#)

Steroids are hydrophobic and bind to intracellular or nuclear receptors, which function as transcription factors to regulate gene expression and protein synthesis. [page 816](#)

Hormones communicate by signaling cascades to amplify the strength of their downstream effects on target cells. [page 816](#)

The hypothalamic–pituitary axis forms the central endocrine pathway by which vertebrates regulate and integrate diverse bodily functions. [page 816](#)

Hormones are evolutionarily conserved molecules that are common to diverse groups of animals, but that have evolved novel functions. [page 817](#)

**36.3 THE VERTEBRATE ENDOCRINE SYSTEM:** In vertebrates, the hypothalamus and the pituitary gland control and integrate diverse functions and behaviors.

The anterior pituitary gland secretes hormones in response to releasing hormones secreted by the hypothalamus. [page 821](#)

Hormones released by the anterior pituitary gland include thyroid-stimulating hormone (TSH), the gonadotropic hormones follicle-stimulating hormone (FSH) and luteinizing hormone (LH), adrenocorticotrophic hormone (ACTH), growth hormone (GH), and prolactin. [page 821](#)

The posterior pituitary gland contains the axons of neurosecretory cells that release the peptide hormones oxytocin and antidiuretic hormone into the bloodstream. [page 821](#)

Tropic hormones are hormones that act on endocrine glands to produce additional hormones. TSH acts on the thyroid gland to release thyroid hormones; FSH and LH act on the female ovaries to produce estrogen and progesterone and the male testes to produce testosterone; and ACTH acts on the adrenal gland to release cortisol. [page 822](#)

Some endocrine glands do not respond to signals from the pituitary gland. These include the parathyroid gland, which releases parathyroid hormone that helps to control calcium levels; the pancreas, which secretes insulin and glucagon to regulate blood glucose levels; and the pineal gland, which secretes melatonin in response to light and dark cycles. [page 822](#)

### **36.4 OTHER FORMS OF CHEMICAL COMMUNICATION:**

Chemical communication can occur locally between neighboring cells or between individuals, coordinating social interactions.

Paracrine signals act locally to affect neighboring cells, compared with the more distant signals transmitted by blood-borne hormones.

[page 824](#)

Pheromones are chemical signals released into the air or water, signaling behavioral cues between individuals of a species.

[page 824](#)

Sex pheromones attract mates and coordinate ritualized mating behavior; alarm pheromones signal predatory threats; trail pheromones signal the location of food sources; and territorial pheromones signal a male's dominance and breeding area.

[page 825](#)

# CHAPTER 37 Animal Cardiovascular and Respiratory Systems

Power and Syred/Science Source

## CORE CONCEPTS

**37.1 DELIVERY OF OXYGEN AND ELIMINATION OF CARBON DIOXIDE:** Respiration and circulation depend on diffusion over short

distances and bulk flow over long distances.

**37.2 RESPIRATORY GAS EXCHANGE:** Respiration provides oxygen and eliminates carbon dioxide in support of cellular metabolism.

**37.3 OXYGEN TRANSPORT BY HEMOGLOBIN:** Red blood cells produce hemoglobin, greatly increasing the amount of oxygen transported by the blood.

**37.4 CIRCULATORY SYSTEMS:** Circulatory systems have vessels of different sizes that facilitate bulk flow and diffusion.

**37.5 STRUCTURE AND FUNCTION OF THE HEART:** The evolution of animal hearts reflects selection for a high metabolic rate, achieved by increasing the delivery of oxygen to metabolically active cells.

---

As animals evolved to be larger and more complex, they faced the challenge of obtaining an adequate supply of oxygen (O<sub>2</sub>) and nutrients and, at the same time, eliminating carbon dioxide (CO<sub>2</sub>) and other waste products. In this chapter, we explore how animal respiratory and circulatory systems evolved to meet the metabolic needs of an animal's cells. In particular, we focus on the uptake of O<sub>2</sub> and the release of CO<sub>2</sub>, key gases in cellular respiration ([Chapter 7](#)).

Gases, nutrients, and wastes are continually being exchanged between an organism and its environment. Because of their small sizes or thin bodies, single-celled organisms and simple multicellular animals exchange compounds with the environment by diffusion. Diffusion works effectively only over very short distances, so larger and more complex animals cannot rely on diffusion as the sole means

of exchanging compounds ([Chapter 26](#)). Instead, these animals evolved respiratory structures at the body's surface for taking up  $O_2$  and releasing  $CO_2$ , and internal circulatory systems for long-distance transport to different body regions.

Because similar physical laws govern gas and liquid movement, the respiratory and circulatory systems of different animals have many features in common. However, fishes and other aquatic animals obtain  $O_2$  from water, whereas land animals breathe air. Water and air have very different physical properties. Thus, aquatic and terrestrial environments pose distinct challenges for obtaining  $O_2$ . Because life first began in the water, the evolution of life on land required substantial changes in how animals exchange gases, take up nutrients, and eliminate wastes.

# 37.1 DELIVERY OF OXYGEN AND ELIMINATION OF CARBON DIOXIDE

Eukaryotic cells use  $O_2$  to burn organic fuels—carbohydrates, lipids, and proteins—for adenosine triphosphate (ATP) production ([Chapter 7](#)). The increase in atmospheric  $O_2$  with the evolution of photosynthesis was key to the evolution of  $O_2$ -based cellular respiration, which in turn contributed to the diversification of multicellular animal life during the Cambrian Period, approximately 500 million years ago. In the process of burning fuel by aerobic respiration,  $CO_2$  is produced. Animals have evolved mechanisms to acquire  $O_2$  from their environment and eliminate excess  $CO_2$  from their bodies. These mechanisms make up the process known as animal respiration—or “breathing.”

## Diffusion governs gas exchange over short distances.

The transport of  $O_2$  and  $CO_2$  between an organism and its environment is referred to as **gas exchange**, and it is fundamental to all eukaryotic animals as well as to photosynthetic plants. Single-celled organisms and simple animals and plants exchange gases by diffusion. **Diffusion** is the random movement of individual molecules ([Chapter 5](#)). If there is a difference in the concentration of a substance between two regions, diffusion results in the net movement of molecules from regions of higher concentration to regions of lower concentration until the molecules are evenly distributed.

Given a large enough surface, diffusion is an extremely effective way to exchange gases and other substances over short distances between two compartments, such as between the lungs and the blood vessels supplying the lungs. The rate of diffusion is directly proportional to the surface area over which exchange occurs and to the concentration difference. It is inversely proportional to the distance over which the molecules move (or the thickness of the barrier). Diffusion is generally ineffective over distances exceeding about 100  $\mu\text{m}$  (0.1 mm). Consequently, respiratory and circulatory structures have large surface areas and thin interfaces.

Because effective transport by diffusion is limited to short distances, some of the earliest and simplest invertebrate animals were, and still are, composed of thin sheets of cells with a large surface area. For example, sponges and sea anemones have a thin body with a central cavity through which water circulates, and flatworms have a flattened body surface ([Fig. 37.1](#)).

Morris, *Biology: How Life Works*, 3e, © 2019

W. H. Freeman and Company

Photo source: Amar and Isabelle Guillen/SeaPics.com.

FIG. 37.1 The thin body of a flatworm. Gases can be exchanged by diffusion in flatworms because their bodies are only a few cell layers thick.

Diffusion results in the net movement of a substance when there is a concentration difference between two regions. When considering the diffusion of a gas, however, we usually refer to its partial pressure rather than its concentration. The **partial pressure ( $p$ )** of a gas is defined as its fractional concentration relative to other gases present, multiplied by the overall (that is, the atmospheric) pressure ([Fig. 37.2](#)). Pressure is measured in units of millimeters of mercury (mmHg). Oxygen makes up approximately 21% of the gases in air (nitrogen contributes about 78%, carbon dioxide about 0.03%, and the remainder

consists of trace gases). At sea level, atmospheric pressure is approximately 760 mmHg, which means that  $O_2$  in the atmosphere exerts a partial pressure ( $pO_2$ ) of about  $0.21 \times 760 = 160$  mmHg. For  $O_2$  to diffuse from the air into cells, the partial pressure of  $O_2$  inside the cells must be lower than the partial pressure of  $O_2$  in the atmosphere.

## Bulk flow moves fluid over long distances.

Larger, more complex animals transport  $O_2$  and  $CO_2$  over longer distances to cells within their bodies. These animals rely on **bulk flow** in addition to diffusion for this transport. Bulk flow is the physical movement of fluids, either a liquid or a gas, as a result of pressure

differences. Specialized pumps, like the heart, generate the pressure that is required to move fluids.

Bulk flow occurs in two steps to meet the gas exchange needs of cells in larger animals. The first step is **ventilation**. Ventilation is the movement of the animal's respiratory medium—water or air—past a specialized respiratory surface. The second step is **circulation**. Circulation is the movement of a specialized body fluid that carries O<sub>2</sub> and CO<sub>2</sub>. The circulatory fluid is called **hemolymph** in invertebrates and **blood** in vertebrates. This fluid delivers O<sub>2</sub> to cells within different regions of the body and carries CO<sub>2</sub> back to the respiratory exchange surface.

Both ventilation and circulation require a pump to produce a pressure ( $P$ ) that drives flow ( $Q$ ) against the resistance to flow ( $R$ ). The rate of flow is governed by the following simple equation:

$$Q = P/R$$

Resistance to flow measures the difficulty of pumping the fluid through a network of chambers and vessels located within the respiratory and circulatory systems. If the resistance to flow doubles, the flow rate is halved. The longer the network of vessels and the narrower the vessels within that network, the greater the vessels' resistance to the fluid (whether air, water, or blood) moving through them. As an illustration of that relationship, consider how much harder it is to blow fluid out of a long thin tube than a short wide one.

In summary, we can view gas exchange in complex multicellular

organisms as four steps that are linked in series ([Fig. 37.3](#)). To deliver  $O_2$  to the mitochondria in an animal's cells, (1) fresh air or water moves over the respiratory exchange surface in the process of ventilation (by bulk flow). Ventilation maximizes the concentration of  $O_2$  in the air or water on the outside of the respiratory surface. (2) The buildup of  $O_2$  then favors the diffusion of  $O_2$  into the blood or hemolymph across its respiratory surface. (3)  $O_2$  is transported by the circulation (by bulk flow) to the tissues. Internal circulation serves to maximize the concentration of  $O_2$  outside cells. (4) Oxygen diffuses from the blood across the cell membrane and into the mitochondria, where fuel molecules are oxidized for ATP production.

FIG. 37.3 The four steps of gas transport and exchange.

The same four steps occur in reverse to remove  $CO_2$  from the body:  $CO_2$  (4) moves from cells to the blood or hemolymph by diffusion, (3) is carried in the circulation to the respiratory surface by bulk flow, (2) moves across the respiratory surface by diffusion, and (1) moves out of the animal by bulk flow. Because diffusion and bulk flow are coupled, it is important that each step in the transport chain (whether for a gas,

nutrient, or waste) has a similar capacity—that is, the same amount of  $O_2$  enters the blood through diffusion as is transported by the circulation.

#### Self-Assessment Questions

1. Which two structural features favor diffusion?
2. Individuals who experience an asthma attack have difficulty breathing. From the discussion of bulk flow, what do you think happens to these individuals' airways that makes it difficult for them to breathe?
3. Diagram the four basic steps of  $O_2$  transport from an animal's respiratory medium (air or water) to its cells.

## 37.2 RESPIRATORY GAS EXCHANGE

All animals obtain O<sub>2</sub> from the surrounding air or water. Aquatic animals such as lobsters, aquatic salamanders, and fishes that take in O<sub>2</sub> from water breathe through **gills**, highly folded delicate structures that allow gas exchange with the surrounding water (**Fig. 37.4a**). Some animals, such as aquatic frogs and terrestrial adult salamanders, breathe through their skin. In contrast, most terrestrial vertebrates, such as reptiles, certain terrestrial salamanders, birds, and mammals, have internal **lungs** that perform gas exchange (**Fig. 37.4b**). Internal respiratory exchange surfaces are adaptations that protect the lung surfaces from drying out in a terrestrial environment. Instead of lungs, terrestrial insects evolved a system of air tubes called **tracheae** that branch from openings along their abdominal surface into smaller airways. These smaller airways, termed tracheoles, supply air directly to the cells within their bodies.

**FIG. 37.4 Animal gas exchange organs.** Gas exchange organs are shaped and folded to provide large surfaces for gas exchange.

For both aquatic and terrestrial animals, ventilation supplies  $O_2$  to gas exchange surfaces, and then  $O_2$  crosses the surface through diffusion. How does the rate of diffusion through the gas exchange surface in lungs or gills keep up with the rate of  $O_2$  supplied by ventilation? The respiratory surfaces of many animals are highly folded, creating a very large surface area. These surfaces are also exceedingly thin, just one or two cell layers thick, providing a diffusion distance of as little as 1 to 2  $\mu m$ . In fact, this short distance is all that separates the air you breathe into your lungs from the bloodstream into which  $O_2$  diffuses.

## Many aquatic animals breathe through gills.

Most large aquatic animals (with the notable exception of marine mammals like dolphins and whales) breathe  $O_2$ -containing water through gills. Some sessile invertebrates have external gills; these organisms include tube worms and sea urchins, as well as nudibranch mollusks and aquatic amphibians (see [Fig. 37.4a](#)). However, external gills are easily damaged or may be eaten by predators. Most mollusks, crustaceans, and fishes have evolved internal gills that, although still formed as outfoldings of the body surface, are contained within protective cavities. Whereas the external gills of invertebrates often rely on the natural motions of the water to move water past the gills, invertebrates with internal gills often have cilia that direct water over the gill's surface.

The gills of fishes are located in a chamber behind the mouth cavity. Fishes need sufficient  $O_2$  to meet the energy demands of swimming.

To meet this need, they actively pump water through their mouth and over the gills ([Fig. 37.5](#)). The effort required to ventilate the gills could be high because of the density and viscosity of water, but fishes greatly reduce the energy cost of moving water by maintaining a continuous, unidirectional flow of water past their gills. In bony fishes, a protective flap overlying the gills, called the operculum, expands laterally to draw water over the gills while the mouth is refilling before its next pumping cycle.

FIG. 37.5 Respiration by fish gills. Fish gills extract  $O_2$  from water efficiently through a unidirectional flow of water and countercurrent flow.

The gills of fishes typically consist of a series of gill arches located on either side of the animal behind the mouth cavity and, in bony fishes, beneath the operculum. Each gill arch includes two stacked rows of flat leaf-shaped structures called gill filaments. Numerous

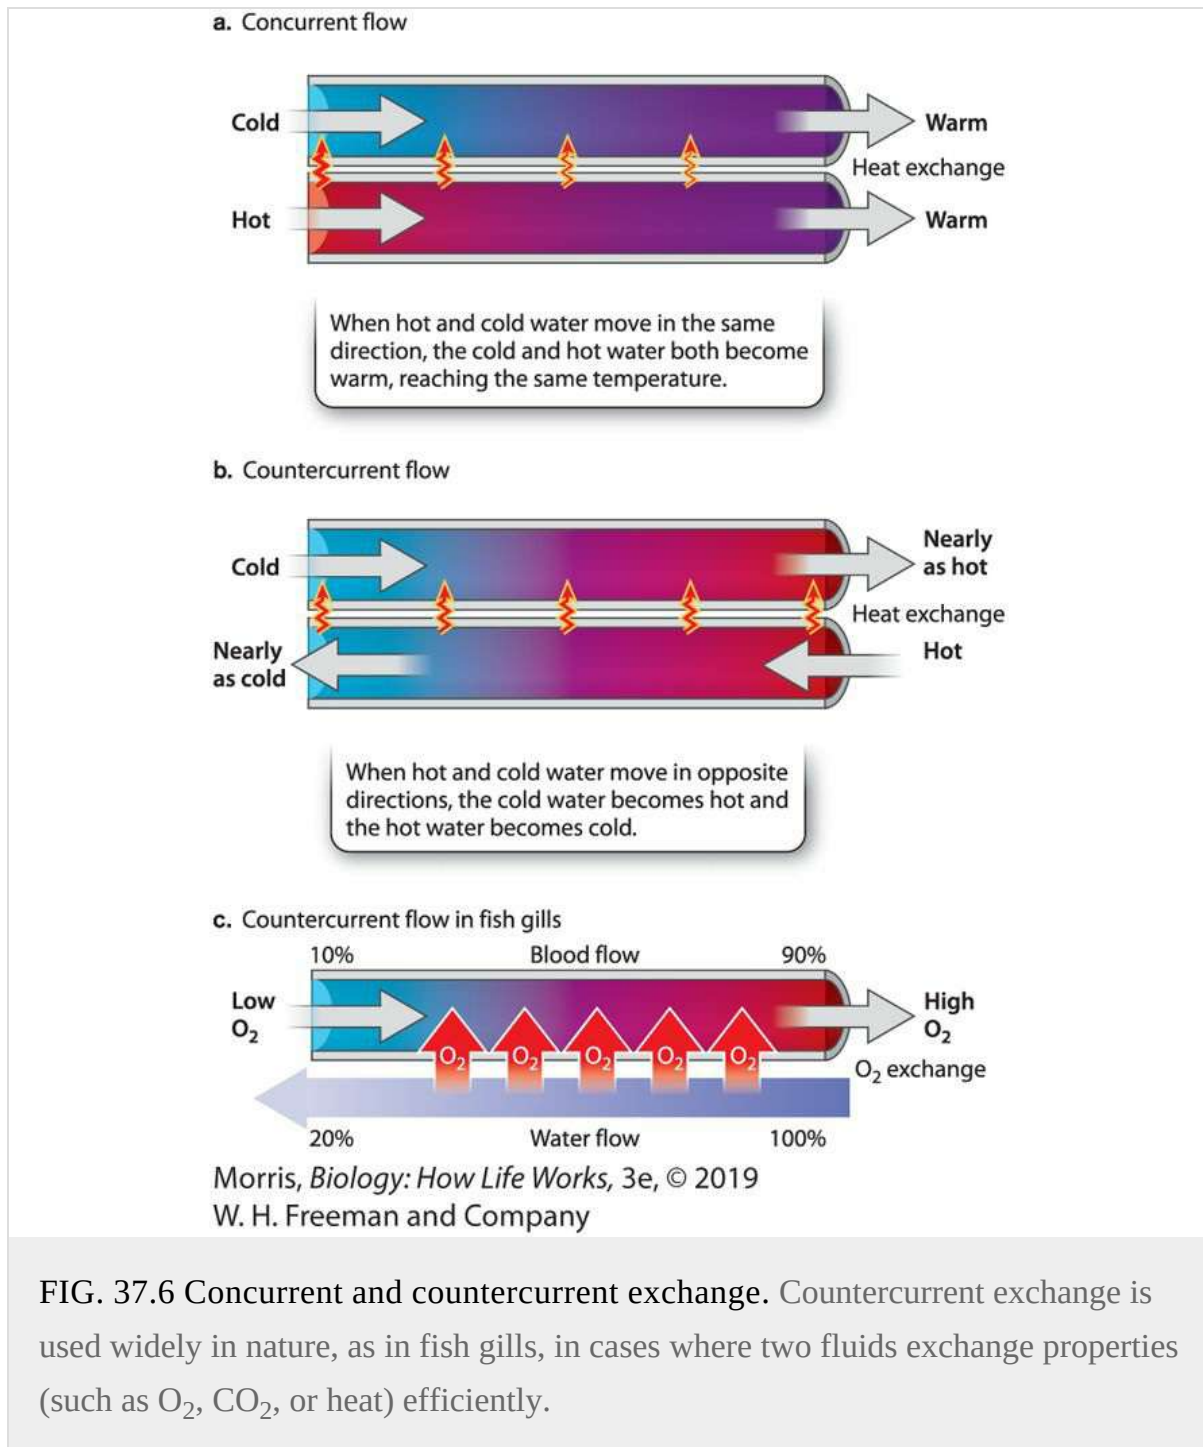

**lamellae** (singular, **lamella**), thin sheetlike structures, are evenly but tightly spaced along the length of each gill filament and extend upward from the filament's surface. A series of blood vessels brings O<sub>2</sub>-poor blood from the heart to the lamellar surfaces. The lamellae are composed of flattened epithelial cells and are extremely thin, so the water passing outside and blood passing inside the lamellae are separated by only about 1 to 2 μm. The lamellae give the gills an enormous surface area for their size. As a consequence, O<sub>2</sub> in the water passing over the gill can readily diffuse into the small blood vessels of the lamellae.

Blood flows through the lamellae in a capillary network. The lamellae are oriented so that blood flowing through the capillaries moves in a direction opposite to the flow of water past the gills ([Fig. 37.5](#)). This type of organization, in which fluids with different properties move in opposite directions, is an efficient way to exchange properties between the two fluids. The property exchanged can be a chemical property, such as O<sub>2</sub> concentration, or a physical property, such as heat. The movement of two fluids with different properties in opposite directions is called countercurrent flow.

Consider for a moment two tubes right next to each other, one carrying hot water and the other carrying cold water ([Fig. 37.6](#)). Heat is transferred between the two tubes: the hot water gets colder and the cold water gets hotter. The efficiency of heat transfer between the two tubes depends on the direction of flow. Suppose the water in the tubes flows in the same direction (concurrent flow; [Fig. 37.6a](#)). Given enough distance, the water will be at an intermediate (warm)

temperature at the end of the tubes, reaching the same average temperature in both tubes.

Now consider what happens when the water in the two tubes flows in opposite directions (countercurrent flow). In this case, the cold water

encounters increasingly hot temperatures and, given enough distance, becomes nearly as hot as the hot water entering the other tube ([Fig 37.6b](#)). Similarly, the hot water encounters increasingly cold temperatures, and becomes nearly as cold as the cold water entering the other tube. With countercurrent flow, the fluids in the two tubes essentially exchange properties (heat, in this example).

This mechanism, known as [countercurrent exchange](#), is used widely in nature. As a result of countercurrent exchange, fish gills can extract nearly all the  $O_2$  in the water that passes over them ([Fig. 37.6c](#)). The  $O_2$  in the oxygen-rich water moves down its concentration gradient into the oxygen-poor blood of the gills along the entire length of the lamellae. At the same time,  $CO_2$  readily diffuses out of the blood vessels and into the water that leaves the gill chamber. A set of blood vessels carries the  $O_2$ -rich blood away from the gills to supply the body.

## Insects breathe air through tracheae.

With the evolution of life on land, animals that breathe air were able to increase their uptake of  $O_2$  and achieve higher rates of metabolism.

Oxygen uptake increased for the following reasons:

1. The  $O_2$  content of air is typically 50 times greater than that of a similar volume of water. Fresh air contains approximately 210 mL  $O_2$  per liter of air (21%), whereas the concentration of  $O_2$  in well-mixed freshwater or salt water rarely exceeds 4 mL  $O_2$  per liter of water (0.4%).
2. Oxygen diffuses nearly 8000 times faster in air than in water. This

fact explains why the O<sub>2</sub> content can be close to zero a few centimeters beneath the surface of a stagnant pond.

3. Water is 800 times denser and 50 times more viscous than air. As a consequence, it requires more energy to pump water past a gas exchange surface than to pump air.

Because of their small size, insects can use a direct pathway of air transport that gets air directly to their tissues (see [Fig. 37.4b](#)). In contrast to terrestrial vertebrates, insects rely on a two-step process of ventilation and diffusion to supply their cells with O<sub>2</sub> and eliminate CO<sub>2</sub>. First, air enters an insect through openings, called [spiracles](#), along either side of its abdomen. The spiracles can be opened or closed to limit water loss and regulate O<sub>2</sub> delivery, much like the stomata of leaves in plants ([Chapter 27](#)). Inside the insect body, air is ventilated through a branching series of tiny air tubes, known as tracheae and tracheoles, directly to the cells. Second, diffusion occurs at the cell: O<sub>2</sub> supplied by the fine airways diffuses into the cells. CO<sub>2</sub> diffuses out and is eliminated through the insect's tracheae.

The mitochondria of the flight muscles and other metabolically active tissues of insects are located within a few micrometers of tracheole airways. Because O<sub>2</sub> and CO<sub>2</sub> diffuse rapidly in air, the tracheal system of insects delivers O<sub>2</sub> to cellular mitochondria at high rates. Active insects also have an air sac system connected to their tracheae. Powered by contracting abdominal muscles, the air sacs act like bellows to pump air through the tracheae, speeding the movement of air to tissues so that gas exchange is faster.

# Most terrestrial vertebrates breathe by tidal ventilation of internal lungs.

Unlike fish gills, the lungs of most land vertebrates inflate and deflate to move fresh air with high levels of  $O_2$  into the lungs and expire stale air with high levels of  $CO_2$  out of the lungs. The low density and viscosity of air enables these animals to breathe by **tidal ventilation** without expending too much energy. In tidal respiration, air is drawn into the lungs during **inhalation** as the lungs inflate and then moved out during **exhalation** as the lungs deflate (**Fig. 37.7a**).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 37.7 Tidal ventilation of the lungs. (a) The movement of the diaphragm causes lung volume to increase and decrease during breathing, drawing in air and then expelling it. (b) The change in lung volume in humans is typically approximately 0.5 L when breathing at rest.

Mammals and reptiles expand their thoracic cavity to draw air inside their lungs on inhalation. The thoracic cavity is located in the front of the animal's trunk and contains the lungs. Expansion of the

thoracic cavity causes the lungs to expand as well, which lowers the air pressure inside the lungs relative to the air pressure outside the lungs. The resulting negative pressure draws air into the lungs. By contrast, amphibians inflate their lungs by positive pressure produced by their mouth cavity. In most animals, exhalation is passively driven by elastic recoil of tissues that were previously stretched during inhalation. Elastic recoil compresses the lungs, causing the air pressure inside the lungs to become higher than the air pressure outside the lungs. The resulting positive pressure forces air out of the lungs.

In mammals, inhalation during normal, relaxed breathing is driven by contraction of the **diaphragm**, a domed sheet of muscle located at the base of the lungs that separates the thoracic and abdominal cavities ([Fig. 37.7a](#)). When the diaphragm contracts, it expands the thoracic cavity, drawing air into the lungs. Exhalation occurs passively by elastic recoil of the lungs and the chest wall surrounding the thoracic cavity. During exercise, other muscles come into play to assist with inhalation and exhalation. For example, **intercostal muscles**, which are attached to adjacent pairs of ribs, assist the diaphragm by elevating the ribs on inhalation and depressing them during exhalation. The action of the intercostal muscles helps to produce larger changes in the volume of the thoracic cavity, increasing the negative pressure that draws air into the lungs during inhalation, and assisting elastic recoil of the lungs and chest wall to pump air out of the lungs during exhalation.

At rest, humans inhale and exhale approximately 0.5 L of air every cycle ([Fig. 37.7b](#)). This amount represents the **tidal volume** of the lungs. With a breathing frequency of 12 breaths per minute, the

ventilation rate (breathing frequency  $\times$  tidal volume) is 6 L per minute. When more  $O_2$  is needed during exercise, both breathing frequency and tidal volume increase to elevate ventilation rate.

The fresh air inhaled during tidal breathing mixes with  $O_2$ -depleted stale air that remains in the airways after exhalation. As a result, the  $pO_2$  in the lungs (approximately 100 mmHg in humans) is lower than the  $pO_2$  of freshly inhaled air (approximately 160 mmHg at sea level). Consequently, the fraction of  $O_2$  that can be extracted is lower than the fraction that can be extracted by the countercurrent flow of fish gills, which can reach 90% or more. Typically, mammalian lungs extract less than 25% of the  $O_2$  in the air, and reptile and amphibian lungs extract even less. Nevertheless, the disadvantages of tidal respiration are offset by the ease of ventilating the lung at high rates and by the high  $O_2$  content of air.

## Mammalian lungs are well adapted for gas exchange.

Despite the limitations of tidal respiration, mammalian lungs are well adapted for breathing air. They have an enormous surface area and a short diffusion distance for gas exchange. Consequently, the lungs of mammals supply  $O_2$  quickly enough to support high metabolic rates.

Except in the case of birds (discussed in the next subsection), the lungs of air-breathing vertebrates are blind-ended sacs located within the thoracic cavity. Air is taken in through the mouth and nasal passages and then passes through the [larynx](#), an organ in the throat made of muscle and cartilage that helps to isolate breathing from

swallowing and within which the **vocal cords** are located. The vocal cords enable speech, song, and sound production. Air then enters the **trachea**, the central airway leading to the lungs (**Fig. 37.8**). The trachea divides into two airways, called the **primary bronchi**, one of which supplies each lung. The trachea and bronchi are supported by rings of cartilage that prevent them from collapsing during respiration, ensuring that airflow meets with minimal resistance. You can feel some of these cartilage rings at the front of your throat below your larynx (the part of the larynx you can feel is your Adam's apple).

The primary bronchi divide first into smaller secondary bronchi, and again into finer **bronchioles**. This branching continues until the

terminal bronchioles have a diameter of less than 1 mm. The very fine respiratory bronchioles end with clusters of tiny thin-walled sacs, the [alveoli](#) (singular, [alveolus](#)), where gas exchange by diffusion takes place. As a result of this branching pattern, each lung consists of several million alveoli, providing a large surface area. Together, the two human lungs include 300 to 500 million alveoli with a combined surface area as large as a tennis court—about 100 m<sup>2</sup>!

Small blood vessels, the [pulmonary capillaries](#), supply the alveolar wall. Each alveolus is lined with thin epithelial cells in intimate contact with the endothelium of these small blood vessels ([Fig. 37.8](#)). As a result, the diffusion distance from the alveolus into the capillary is extremely short (approximately 2 μm), similar to that of gill lamellae and the terminal airways of bird lungs.

Keeping the surfaces of the airways and alveoli moist is critical. Moisture helps move O<sub>2</sub> molecules from the air into solution, thereby helping O<sub>2</sub> diffuse across the alveolar wall. A film of mucus secreted by specialized epithelial cells keeps the airways moist.

This film has surface tension, a cohesive force that holds the molecules of a liquid together, causing the surface to act like an elastic membrane. Surface tension is the reason why it requires greater pressure to inflate a small balloon than a large one. Specialized alveolar epithelial cells produce [surfactant](#), a compound that acts to reduce the surface tension of the fluid film. Surfactant allows the lungs to be inflated easily at low volumes when the alveoli are partially collapsed and small. It also ensures that alveoli of different sizes inflate

with similar ease, enabling more uniform ventilation of the lung.

The mucus lining the lung airways not only keeps them moist, but also traps and removes foreign particles and microorganisms that an animal may breathe in with air. Beating cilia on the surface of other epithelial cells move the mucus and foreign debris out of the lungs and into the throat, where it is swallowed and digested. Smoking even one cigarette can stop the cilia's beating for several hours or even destroy them. This is one reason why smokers cough—they must clear the mucus that builds up.

## The structure of bird lungs allows unidirectional airflow for increased oxygen uptake.

Birds extract  $O_2$  efficiently to supply the considerable energy needed for flight. An efficient  $O_2$  supply is particularly important for migratory birds that fly at high altitude, where the partial pressure of  $O_2$  is relatively low. The lungs of birds are unique in that they are rigid and do not inflate and deflate. As a consequence, birds do not use tidal breathing. Instead, they benefit from unidirectional airflow that enhances gas exchange by maintaining larger concentration gradients for diffusion.

A bird's respiratory system consists of two sets of air sacs: one located posterior to the lungs (behind them) and one located anterior to the lungs (in front of them). Air is pumped through these air sacs continuously in a bellows-like action ([Fig. 37.9](#)). As the posterior air

sacs expand, air is drawn from the bird's mouth into those sacs. Surrounding muscles compress the sacs, pumping air through the bird's rigid lungs. The lungs consist of a series of larger air channels that branch into fine air capillaries having a large surface area. The air capillaries direct the air so that it moves **crosscurrent** (that is, at 90°) to the path of blood flow through the walls of the air capillaries. This crosscurrent flow is not as efficient as the countercurrent flow of fish gills, but it enables birds to extract more O<sub>2</sub> from the air than mammals can.

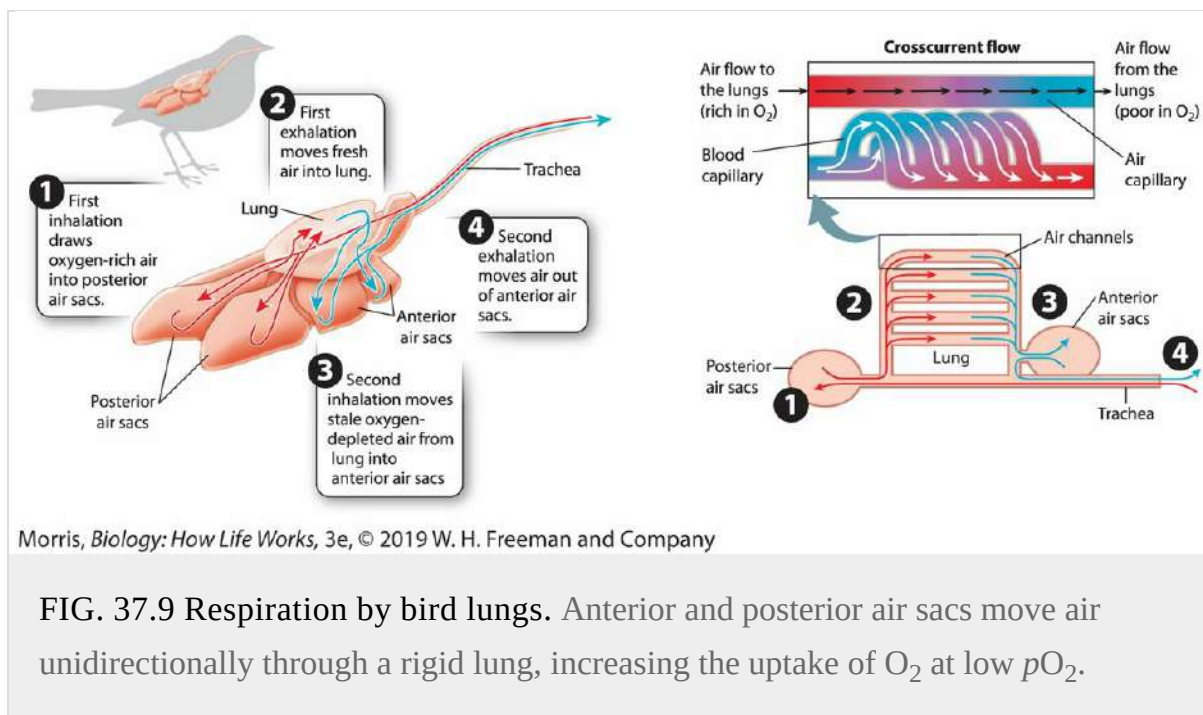

FIG. 37.9 Respiration by bird lungs. Anterior and posterior air sacs move air unidirectionally through a rigid lung, increasing the uptake of O<sub>2</sub> at low  $pO_2$ .

After losing O<sub>2</sub> and gaining CO<sub>2</sub>, the air leaves the bird's lungs and enters the set of anterior air sacs. Fresh air is again inhaled into the posterior air sacs, and the stale air in the anterior air sacs is exhaled out of the bird's trachea and mouth. As a result, birds achieve a continuous supply of fresh air into the lung during both inhalation *and* exhalation. In contrast to other air-breathing vertebrates, therefore, birds move air

through their respiratory system in two cycles of ventilation.

## Voluntary and involuntary mechanisms control breathing.

Because an animal's need for  $O_2$  varies with activity level, animals adjust their respiratory rate to meet their changing demand for  $O_2$ .

Respiration is a unique physiological process in that it is controlled by both the voluntary and involuntary components of the nervous system ([Chapter 34](#)). In sleep and most other circumstances, breathing is controlled unconsciously.

The regulation of blood  $O_2$  levels is a key example of homeostasis, like the maintenance of core body temperature ([Chapter 33](#)) and blood glucose levels ([Chapter 36](#)). Recall that homeostasis often depends on sensors that monitor the levels of the chemical being regulated. In the case of breathing, these sensors are chemoreceptors located within the brainstem and in sensory structures called the [carotid](#) and [aortic bodies](#) that are located in the neck and near the heart, respectively ([Fig. 37.10](#)). Together, they sense  $O_2$ ,  $CO_2$ , and proton ( $H^+$ ) concentrations of the blood. The most important factor in the control of breathing is the amount of  $CO_2$  in the blood. When the concentration of  $CO_2$  in the blood is too high, these chemoreceptors stimulate motor neurons that activate the respiratory muscles to contract more strongly and frequently. Stronger, faster breathing rids the blood of excess  $CO_2$  and increases the supply of  $O_2$  to the body.

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

FIG. 37.10 Homeostatic control of breathing. Breathing becomes stronger or faster when  $\text{CO}_2$  levels increase or  $\text{O}_2$  levels decrease.

Breathing can also be controlled voluntarily. It is a simple matter to choose to hold your breath. Holding the breath makes it possible for humans and marine mammals to dive under water; it is also critical to the production of speech, song, and sound for communication. Sound is produced by voluntarily adjusting the magnitude and rate of airflow over the vocal cords of mammals, the syrinx of songbirds, or the glottal folds of calling amphibians, such as some toads and frogs.

#### Self-Assessment Questions

4. What are two features of the gills of aquatic animals that favor diffusion of  $\text{O}_2$  and  $\text{CO}_2$ ?
5. What are two differences in the physical properties of water and of air that affect gas exchange in aquatic animals?
6. How does the tracheal respiratory system of insects enable high metabolic rates?
7. What generates the pressure changes needed to draw air into the lungs and to expel air out of the lungs?

## 37.3 OXYGEN TRANSPORT BY HEMOGLOBIN

Once O<sub>2</sub> is extracted from the environment and diffuses into the animal, it is transported to respiring cells. Oxygen is transported in the circulation by specialized body fluids: the blood of vertebrates or the hemolymph of invertebrates.

### Blood is composed of fluid and several types of cell.

Although this chapter focuses on the role of blood and hemolymph in O<sub>2</sub> and CO<sub>2</sub> transport, blood serves many other functions. These include heat transport for temperature regulation and nutrient transport to metabolically active tissues ([Chapter 38](#)), hormone transport ([Chapter 36](#)), waste transport to excretory organs ([Chapter 39](#)), and transport of immune cells involved in fighting pathogens ([Chapter 41](#)) as well as wound healing. Blood can be separated into a cellular fraction and a fluid fraction, called blood plasma. Red blood cells that carry [hemoglobin](#) constitute most of the cellular fraction of blood. In both vertebrates and invertebrates, hemoglobin evolved as a specialized iron-containing, or heme, molecule for O<sub>2</sub> transport.

The fraction of total blood volume that is red blood cells in vertebrates is defined as the [hematocrit](#). Whereas a hematocrit of 45% is considered normal for humans ([Fig. 37.11](#)), fishes have hematocrits that range from 20% to 35%, crocodiles have hematocrits of approximately 20%, birds have hematocrits that vary from 35% to 58%, and diving mammals have hematocrits as high as 65%. Blood

with a lower hematocrit flows with less resistance (that is, has a lower viscosity), but carries less oxygen. Humans with low hematocrits are considered to be iron deficient because their blood contains fewer red blood cells and, therefore, too little hemoglobin.

A much smaller fraction (approximately 1%) of cells are white blood cells, which help to defend the body against pathogens ([Chapter 41](#)). The remaining cells are platelets, which respond to damaged blood vessels by helping to form a clot to prevent blood loss.

Red blood cells are the densest component of blood. Therefore, when blood is spun in a centrifuge, the red blood cells form a layer in the bottom of a centrifuge tube, and a thin layer of white blood cells and platelets forms above them. The remaining components of the blood, the blood plasma and solutes, rise to the top of the centrifuge

tube ([Fig. 37.11](#)).

Blood plasma can hold only as much  $O_2$  or  $CO_2$  as can be dissolved in solution. How much  $O_2$  goes into solution at a given partial pressure is a measure of its [solubility](#). Because  $O_2$  is nearly 30 times less soluble than  $CO_2$ , only about 0.2 mL of  $O_2$  can be carried in 100 mL of blood. By binding  $O_2$  and removing it from solution, hemoglobin increases the amount of  $O_2$  in the blood by a hundredfold. Because of its greater solubility,  $CO_2$  is transported in solution within the blood. Rather than remaining dissolved in solution as a gas, most of the  $CO_2$  (about 95%) is converted to carbonic acid, which dissociates to form bicarbonate ions ( $HCO_3^-$ ) and protons ([Chapter 6](#)).

Whereas some invertebrate hemoglobins exist in solution in the hemolymph and others exist within cells carried by the hemolymph, all vertebrate hemoglobins are produced by and reside in red blood cells. Hemoglobin gives the cells and the blood their red appearance.

## Hemoglobin is an ancient molecule with diverse roles related to oxygen binding and transport.

Hemoglobin is an ancient molecule that has been found in organisms from all kingdoms of life. In bacteria, archaeons, and fungi, similar forms of hemoglobin evolved as a terminal electron acceptor in cellular respiration. These hemoglobins may have also served a role in scavenging  $O_2$  to avoid damage due to oxidative stress.

Plant hemoglobins bind and transport  $O_2$  within the cell. In

soybeans, hemoglobin binds  $O_2$  in root nodule cells to keep concentrations low enough to avoid inhibiting nitrogenase, the enzyme used by symbiotic rhizobial bacteria in the root nodules for nitrogen fixation ([Chapter 27](#)).

Invertebrate hemoglobins found in roundworms, annelid worms, and arthropods bind  $O_2$  in the circulatory fluid, as discussed earlier. They share considerable gene and amino acid sequence similarity with vertebrate hemoglobins, indicating that a common ancestor of invertebrate and vertebrate animals evolved a shared form of hemoglobin more than 670 million years ago.

## Hemoglobin reversibly binds oxygen.

Hemoglobin exists in large concentrations within red blood cells. This globular protein consists of four polypeptide units ([Fig. 37.12](#)). Each of these four units surrounds a heme group that contains an iron atom, which reversibly binds one  $O_2$  molecule. After  $O_2$  diffuses into the blood, it diffuses into the red blood cells and binds to the heme groups in hemoglobin. Hemoglobin's binding of  $O_2$  removes  $O_2$  from solution, keeping the  $pO_2$  of the red blood cell below that of the blood plasma. As a result,  $O_2$  continues to diffuse into the cell. The removal of  $O_2$  from the plasma, in turn, keeps the  $pO_2$  of the plasma below that of the lung alveolus, so  $O_2$  continues to diffuse from the lungs into the blood.

HOW DO WE KNOW?

FIG. 37.12

What is the molecular structure of hemoglobin

## and myoglobin?

### BACKGROUND

In the 1950s, the Austrian scientist Max Perutz worked with British structural chemist John Kendrew in the Cavendish Laboratory of the University of Cambridge to determine the molecular structure of globular proteins. Perutz and Kendrew were interested in understanding how the structures of hemoglobin and myoglobin, the two O<sub>2</sub> transport proteins, enabled binding and transport of O<sub>2</sub>.

### EXPERIMENT

Perutz and Kendrew developed and applied the new technique of X-ray crystallography to determine the three-dimensional molecular structures of hemoglobin and myoglobin.

### RESULTS

Perutz and Kendrew showed that an adult hemoglobin molecule consists of four polypeptide subunits: two  $\alpha$  (alpha) and two  $\beta$  (beta) subunits. Each subunit contains a heme group that contains an iron atom. The iron atom is the site of O<sub>2</sub> binding. By contrast, a myoglobin molecule consists of only a single subunit with one heme group. Myoglobin is also more highly folded and compact than hemoglobin. These differences in molecular structure underlie the different O<sub>2</sub>-binding and dissociation properties of the two O<sub>2</sub> transport proteins.

### FOLLOW-UP WORK

Work by Perutz in the 1960s showed how the molecular structure of hemoglobin changes when it binds  $O_2$ . Perutz also supervised Francis Crick as a doctoral student (Crick later worked with James Watson to determine the structure of DNA). Perutz and Kendrew received the 1962 Nobel Prize in Chemistry for their work.

SOURCES Kendrew, J. C., and M. F. Perutz. 1948. "A Comparative X-Ray Study of Foetal and Adult Sheep Haemoglobins." *Proceedings of the Royal Society, London, Series A* 194:375–398; Perutz, M. F. 1964. "The Hemoglobin Molecule." *Scientific American* 211:64–76; Perutz, M. F. 1978. "Hemoglobin Structure and Respiratory Transport." *Scientific American* 239:92–125.

When more  $O_2$  is present in blood plasma, we expect more  $O_2$  to become bound to hemoglobin, and that is what happens. But an interesting wrinkle enables hemoglobin to readily bind  $O_2$  leaving the lung. If we plot blood  $pO_2$  against the percentage of  $O_2$  bound to hemoglobin (the relation defined as "hemoglobin saturation"), we get the curve shown in [Fig. 37.13a](#). As blood  $pO_2$  increases, hemoglobin saturation rises slowly at first, then more steeply, and then more slowly again until it levels out. At 100% saturation, all hemoglobin molecules bind four  $O_2$  molecules. The curve, which is called the hemoglobin's

**oxygen dissociation curve**, has a sigmoidal shape—that is, a shape like an “S”.

FIG. 37.13 (a) Hemoglobin and (b) myoglobin dissociation curves.

The shape of this curve can be explained by changes in the ability of hemoglobin to bind O<sub>2</sub> (a property called its binding affinity) at different O<sub>2</sub> partial pressures. At 25% saturation, each hemoglobin molecule binds, on average, one O<sub>2</sub> molecule. As  $pO_2$  rises, hemoglobin binds O<sub>2</sub> with increasing binding affinity as a result of the interaction of adjacent heme groups. After one heme group binds the first O<sub>2</sub> molecule, hemoglobin undergoes a conformational change that increases the binding affinity of the remaining heme groups for additional O<sub>2</sub>. The increase in binding affinity with additional binding of O<sub>2</sub> is called **cooperative binding**, and it gives the O<sub>2</sub> dissociation curve for hemoglobin its sigmoidal shape.

Cooperative binding has important physiological consequences. In the middle part of the O<sub>2</sub> dissociation curve, small increases in O<sub>2</sub>

concentration lead to large increases in hemoglobin saturation. Therefore, in normal circumstances, hemoglobin in the blood leaving the lung is fully saturated with  $O_2$ ; that is, each hemoglobin molecule is bound to four  $O_2$  molecules.

The shape of the  $O_2$  dissociation curve also helps to explain how  $O_2$  is delivered to respiring cells. When the hemoglobin in red blood cells reaches tissues needing  $O_2$  to supply their mitochondria, the  $O_2$  is released from the hemoglobin. As active cells consume  $O_2$ , they reduce the local  $pO_2$  of the cell and surrounding tissues to 40 mmHg or less. At these lower  $pO_2$  values, the hemoglobin's  $O_2$  dissociation curve has a steep slope ([Fig. 37.13a](#)). The steepness of the slope indicates that for a relatively small decrease in  $pO_2$ , large amounts of  $O_2$  can be released from hemoglobin to diffuse into the cell.

## Myoglobin stores oxygen, enhancing oxygen delivery to muscle mitochondria.

[Myoglobin](#) is a specialized  $O_2$  carrier within the cells of vertebrate muscles. In contrast to hemoglobin, myoglobin is a monomer that contains only a single heme group. Because there are no interacting subunits, the  $O_2$  dissociation curve for myoglobin has a different shape from that of hemoglobin ([Fig. 37.13b](#)). In fact, over the physiological range of  $pO_2$ , myoglobin has a greater affinity for  $O_2$  than hemoglobin does, and it binds  $O_2$  more tightly. As a result, hemoglobin releases  $O_2$  to exercising muscles. As the exercising muscles consume the available  $O_2$ , the intracellular  $pO_2$  drops, and the myoglobin releases its bound

O<sub>2</sub> to the mitochondria.

Red muscle cells that depend mainly on aerobic respiration to produce ATP ([Chapter 35](#)) store large amounts of myoglobin. The myoglobin in these cells can release O<sub>2</sub> quickly at the onset of activity, before the respiratory and circulatory systems have had time to increase the supply of O<sub>2</sub>. Diving marine mammals, such as whales and seals, have large amounts of myoglobin within their muscles. The myoglobin loads up with O<sub>2</sub> when the animals breathe at the surface before beginning a dive. The O<sub>2</sub> bound to the myoglobin is then used to supply ATP during the dive, when the animal cannot breathe. These marine mammals can stay under water for 30 minutes or longer and dive to considerable depths ([Fig. 37.14](#)).

---

## Many factors affect hemoglobin–oxygen binding.

Obtaining enough  $O_2$  can be a challenge. How does a mammalian fetus in its mother's uterus take up  $O_2$  from its mother's blood? How do animals that live at high altitude obtain enough  $O_2$  under conditions of low  $pO_2$ ? In each case, the species adapts by evolving forms of hemoglobin with higher binding affinity.

In mammals, the mother's respiratory and cardiovascular systems must provide the fetus with  $O_2$  and remove  $CO_2$ , as well as supply nutrients and remove wastes. Maternal and fetal blood do not mix, but rather exchange gases across the placenta. Yet the  $O_2$  concentration gradient at this exchange point does not strongly favor the movement of  $O_2$  from the mother's blood to the fetal blood. Fetal mammals solve the problem of extracting  $O_2$  from their mother's hemoglobin by expressing a form of hemoglobin that has a higher affinity for  $O_2$  than does their mother's hemoglobin. The  $O_2$  dissociation curve for fetal hemoglobin is shifted to the left of the curve for maternal hemoglobin ([Fig. 37.15a](#)), allowing the fetal hemoglobin to extract  $O_2$  from the mother's circulation. At birth, when the newborn begins to breathe, its red blood cells rapidly shift to expressing the adult form of hemoglobin, maintaining this form throughout life.

FIG. 37.15 Changes in hemoglobin's  $O_2$  dissociation curve.

Many animals live at high altitude. For example, birds have been observed flying over the highest peaks (taller than 9000 m), even though air at this altitude has less than one-third the  $O_2$  content of air at sea level. Similarly, llamas inhabit the Andes at altitudes up to 5000 m even though the air has about one-half the  $O_2$  content of air at sea level. Consequently, the lung  $pO_2$  of a llama is only about 50 mmHg. How do these animals obtain enough  $O_2$ ? Their hemoglobin has a higher affinity for  $O_2$  and binds  $O_2$  more readily than does the hemoglobin of animals living at sea level. Consequently, their  $O_2$  dissociation curve is shifted to the left, favoring the binding of more  $O_2$  at a given  $pO_2$ .

Shifts in blood and tissue pH cue the body that more oxygen is needed to fuel exercise. The pH falls (that is,  $H^+$  concentration increases) when  $CO_2$  is released from metabolizing cells during exercise, or when an inadequate supply of  $O_2$  leads to the production of lactic acid ([Chapter 7](#)). When pH falls, the affinity of hemoglobin for

$O_2$  decreases, shifting the  $O_2$  dissociation curve to the right ([Fig. 37.15b](#)). This phenomenon is called the Bohr effect after Christian Bohr, the Danish physiologist who first described it in 1904. Because hemoglobin's affinity for  $O_2$  is reduced, more  $O_2$  is released to cells for aerobic ATP synthesis.

Carbon dioxide also reacts with the amine ( $NH_2$ ) groups of hemoglobin, reducing hemoglobin's affinity for  $O_2$ . Thus, when released from respiring tissues,  $CO_2$  promotes increased  $O_2$  delivery both through its direct effect on hemoglobin and through its contribution to a decrease in blood pH by the Bohr effect. Whereas the production of  $CO_2$  promotes  $O_2$  release at the tissues, its elimination at the lung increases hemoglobin's affinity for  $O_2$ , thereby enhancing  $O_2$  uptake.

#### Self-Assessment Questions

8. How does cooperative binding by hemoglobin increase  $O_2$  uptake into blood?
9. Sickle-cell anemia is a genetic disorder of individuals homozygous for a mutation of hemoglobin that causes their red blood cells to be sickle shaped and stiff under conditions of low  $pO_2$ . Why is this disease life threatening?

## 37.4 CIRCULATORY SYSTEMS

The circulatory system transports O<sub>2</sub> carried by hemoglobin in red blood cells to tissues throughout the body ([Fig. 37.16](#)). Generally, smaller animals, such as insects and many mollusks, have [open circulatory systems](#) that contain few blood vessels: most of the circulating fluid, the hemolymph, is contained within the animal's body cavity. The hemolymph bathes the animal's tissues and organs ([Fig. 37.16a](#)). Open circulatory systems have limited control of where the fluid moves. Muscles that are active in locomotion can assist circulation of the hemolymph, and some invertebrates have simple hearts with openings that help pump fluid between different regions of the animal's body cavity.

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

FIG. 37.16 (a) Open and (b) closed invertebrate circulatory systems.

In contrast, the closed circulatory systems of larger animals are made up of a set of internal vessels and a pump—the heart—to transport the blood to different regions of the body ([Fig. 37.16b](#)). Closed circulatory systems have two conflicting requirements: they must produce enough pressure to carry the circulating blood to all the tissues, but, once the blood reaches the smaller vessels that supply the

cells within the tissues, the blood pressure and flow rate must not be too high. High pressure would push fluid through the walls of the smaller vessels, and it would cause the blood to flow so quickly that there would not be enough time to exchange gases.

About 500 million years ago, segmented worms first evolved closed circulatory systems that allow them to expand individual body segments to burrow underground. About 480 million years ago, the first cephalopods (squid and octopus) evolved closed circulatory systems that enabled them to be successful predators in Paleozoic oceans. A closed circulatory system delivers  $O_2$  at high rates to exercising tissues, enabling their mitochondria to provide the energy needed to chase prey. In contrast, open circulatory systems generally operate under low pressure, and their transport capacity is limited. As a result, animals with open circulatory systems are less active. Insects can be very active despite having an open circulatory system because they obtain  $O_2$  by their tracheal system independent of the circulatory system.

Open circulatory systems have limited ability to control the delivery of respiratory gases and metabolites to specific tissues and regions. By contrast, closed circulatory systems can control blood flow to specific regions of the body. For example, wading birds reduce blood flow to their legs when they are in cold water to reduce heat loss, and vertebrates can increase blood flow to their muscles to deliver  $O_2$  and nutrients during exercise. Blood flow is controlled by varying the resistance to flow.

## Circulatory systems have vessels of different sizes.

For a fluid like blood to flow through a set of pipes, pressure ( $P$ ) is required to overcome the resistance to flow ( $R$ ). To pump blood through a set of closed interconnected vessels, a muscular heart is needed to produce sufficient pressure to overcome the flow resistance of the vessels. The pressure developed by a heart when it contracts establishes a rate of blood flow that is governed by  $P/R$ . That is, the rate of blood flow increases with an increase in pressure and decreases with an increase in resistance. The resistance to flow is determined in part by the fluid's viscosity and the vessel's length. More viscous fluid and longer vessels of a given diameter have greater resistance.

However, the main factor governing resistance to flow is the vessel's radius ( $r$ ). Resistance is proportional to  $1/r^4$ , which means that if a vessel's radius is reduced by half, its resistance to flow increases 16 times. The high resistance of narrow vessels presents a challenge. To keep diffusion distances short, gas exchange between cells and blood requires narrow vessels. But how does the circulatory system overcome the dramatic increase in resistance that occurs with narrower diameters?

The organization of animal circulatory systems provides an answer ([Fig. 37.17](#)). Animal circulatory systems are organized to have blood flow over longer distances in a relatively few large-diameter vessels with low resistance to flow ([Fig. 37.17a](#)). **Arteries** are the large, high-pressure vessels that move blood flow away from the heart to the tissues. **Veins** are the large, low-pressure vessels that return blood to

the heart. Arteries branch into blood vessels of progressively smaller diameter called **arterioles**. These arterioles ultimately connect to finely branched networks of very small blood vessels called **capillaries**, which are only one cell in diameter or less. Indeed, the diameter of a capillary is so small that red blood cells pass through one at a time, and must be flexible to squeeze through the capillaries.

Within the capillaries, gases are exchanged by diffusion with the surrounding tissues. The number of smaller-diameter vessels at each branching point in the circulatory system greatly exceeds the number of larger-diameter vessels. The reverse organization is found on the return side of circulation: numerous capillaries drain into vessels of progressively larger diameter called **venules**, and the venules drain into a few larger veins that return blood to the heart.

This organization has two advantages. First, it maintains the same

volume of blood flow at all levels within the circulatory system: the increased resistance to flow in the capillaries is offset by the large increase in the number of capillaries. Second, it enables the blood to flow more slowly in smaller vessels ([Fig. 37.17b](#)), providing time for gases and metabolites to diffuse into and out of the neighboring cells.

## Arteries are muscular vessels that carry blood away from the heart under high pressure.

When animals become active after a period of rest and feeding, blood flow must be increased to their muscles and reduced to their digestive organs ([Fig. 37.18](#)). Animals meet this challenge by changing the radius of vessels. Recall that resistance to flow is strongly affected by the vessel radius. Arterioles supplying regions of the body that need less blood become narrower by contracting the circular smooth muscle fibers in their walls. The narrowing of the blood vessels dramatically increases the resistance to flow, thereby reducing the rate of blood flow. For example, when you put your hands or feet into cold water, the arterioles constrict, reducing the loss of heat from blood flowing to your hands and feet.

Source: Data from C. B. Chapman and J. H. Mitchell, 1965, "The Physiology of Exercise," *Scientific American* 212:88–96.

FIG. 37.18 Changes in blood flow from resting to exercise as measured in humans. Numbers in parentheses indicate percent of total blood flow.

Arterioles supplying regions of the body that need more blood become wider by relaxing the smooth muscles lining their walls. The larger vessels offer less resistance, so more blood can flow through them. As the rate of cellular respiration increases, cells release more  $\text{CO}_2$  as well as other metabolites, such as lactate and hydrogen ions. The increase of these molecules in the bloodstream acts as a signal to the smooth muscle in the arteriole walls to relax. In this way, blood flow increases to the capillaries so as to match  $\text{O}_2$  and nutrient delivery to the metabolic needs of the cells.

In humans, a strong pulse of flow pushes against the arterial walls about every second with each heartbeat that pumps blood through the arteries. This pulse of flow causes a momentary expansion of the arteries. Artery walls can withstand these repeated pressure pulses because they contain multiple elastic layers composed of two proteins: [collagen](#) and [elastin](#). Collagen fibers are strong and resist the

expansion of the arterial wall during pressure pulses. Collagen and elastin fibers together provide for an elastic rebound of the arterial wall once the pulse has passed, returning energy to help smooth out blood flow.

Both collagen and elastin resist overexpansion of the arterial wall. However, if an artery wall deteriorates, the collagen and elastin can become so thin that the artery bulges outward. This outward bulge, called an aneurysm, can lead to a life-threatening rupture.

## Veins are thin-walled vessels that return blood to the heart under low pressure.

Blood collected from local capillary networks returns to the heart through progressively larger veins. These ultimately drain into the two largest veins, the [venae cavae](#) (singular, [vena cava](#)). The venae cavae drain blood from the head and body into the heart. Relatively little pressure is available to push the blood forward in the veins because pressure has been lost to the resistance of the arterioles and capillaries. Consequently, veins have thin walls combined with little smooth muscle or elastic connective tissue. Because of the low pressure, blood tends to accumulate within the veins: as much as 80% of your total blood volume resides in the venous side of your circulation at any one time.

Veins located in the limbs and in the body below the heart have one-way valves that help prevent blood from pooling owing to gravity (see

[Fig. 37.17a](#)). However, the most important mechanism used to return blood to the heart is the voluntary muscle contractions that occur during walking and exercise, which exert pressure on the veins. Above the level of the heart, gravity assists the return of blood to the heart through the veins.

## Compounds and fluid move across capillary walls by diffusion, filtration, and osmosis.

We have seen that  $O_2$  and  $CO_2$  move between capillaries and tissues by diffusion. In addition, blood pressure forces water, certain ions, and other small molecules to move from capillaries into the surrounding interstitial fluid (the extracellular fluid surrounding vessels). Proteins and blood cells remain in the capillaries. In this way, the blood is filtered as the plasma passes through the capillary wall.

Why doesn't the blood plasma lose all its water and ions over time? As water is filtered out of the capillaries, some ions, cells, proteins, and other large compounds remain inside; their concentration increases with the removal of the water ([Fig. 37.19](#)). As a result, water has a tendency to flow back into the capillaries by osmosis ([Chapter 5](#)). At the same time, the resistance to flow imposed by the capillaries decreases blood pressure. When the pressure is no longer high enough to counter osmosis, water moves back into the capillaries.

In vertebrates, excess interstitial fluid is also returned to the bloodstream through the [lymphatic system](#), a network of vessels distributed throughout the body. The fluid that enters the lymphatic system is called [lymph](#). Small lymphatic vessels merge with progressively larger thin-walled vessels, draining the lymph into lymphatic ducts, which empty into the venous system and then the heart. Lymphatic vessels have one-way valves, similar to those in the veins, which assist the return of lymph to the circulatory system. Local muscle contractions also help pump the lymph toward the ducts that return lymph to the circulatory system of vertebrates. In addition to its role in returning plasma to the bloodstream, the lymphatic system has important functions in the immune system ([Chapter 41](#)).

## Hormones and nerves provide

# homeostatic regulation of blood pressure.

An animal that is dehydrated or has lost blood following an injury may experience a decrease in blood pressure. In such cases, the posterior pituitary gland releases antidiuretic hormone (ADH) into the circulation ([Chapter 36](#)). ADH causes arteries to constrict, increasing their resistance to blood flow. The higher resistance increases blood pressure throughout the body.

Blood pressure is continually being adjusted to remain within normal physiological limits, a phenomenon that is an example of homeostasis. If blood pressure drops, animals reduce the supply of blood to the limbs by constricting arterioles that supply the limbs. This response helps maintain blood pressure to the heart, brain, and kidneys. In this case, sympathetic neurons synapsing on the smooth muscles of arterioles in the limbs stimulate these muscles to contract. In contrast, when blood pressure is too high, sympathetic neurons that synapse on the smooth muscles are inhibited. The smooth muscles relax, reducing resistance in the arterioles and increasing blood flow. These two responses are called [vasoconstriction](#) and [vasodilation](#), respectively.

In some circumstances, it may be advantageous to an animal to have blood pressure rise higher than normal levels. Animals faced with a stressful situation exhibit the fight-or-flight response; for example, this response occurs when prey are alerted to the presence of predators. A surge of adrenaline into the bloodstream causes an animal to become alert and aroused. At the same time, the sympathetic nervous system increases the heart and respiratory rates and inhibits digestive

processes. The increase in heart rate increases blood pressure. Arterioles supplying limb muscles dilate to enhance blood flow to exercising muscles, while arterioles supplying organs within the digestive system constrict. The increase in heart and breathing rates increases the rate of O<sub>2</sub> delivery to the exercising muscles to meet their increased demand for ATP. These physiological changes prepare an animal to flee.

In contrast, when an animal has recently eaten a meal, its sympathetic nervous system is inhibited and its parasympathetic nervous system is stimulated. In response, blood flow to the digestive system increases and smooth muscle in the gut becomes more active ([Chapter 38](#)). In this way, regulation of blood pressure is linked to the physiological state of the animal through feedback from the nervous and endocrine systems.

#### Self-Assessment Questions

10. Which change in vessel shape most affects resistance to blood flow?
11. How does the branching of larger arteries into many smaller vessels affect the rate of and resistance to blood flow in the smaller vessels?

## 37.5 STRUCTURE AND FUNCTION OF THE HEART

The pressure required to drive blood through blood vessels is generated by the heart. Animal hearts are pumps made of muscle that rhythmically contracts, producing this pressure. Early hearts were as simple as a muscular thickening of a small region of a blood vessel. Such hearts are still found in insects (see [Fig. 37.16a](#)). More complex hearts have chambers that expand and fill with deoxygenated blood returning from the animal's tissues. After filling, the heart muscle contracts, pumping deoxygenated blood to the lungs or gills and the newly oxygenated blood onward to the animal's tissues. The closed circulatory system of cephalopod mollusks has three hearts: two hearts that pump deoxygenated blood through the gills and another heart that pumps oxygenated blood to the body. In contrast, vertebrates have a single heart with at least two chambers: one for receiving blood and the other for pumping blood to the body during each heartbeat cycle. Hearts also have one-way valves to ensure that blood does not flow backward when the heart contracts.

A theme running through the evolution of vertebrate circulatory systems is the progressive separation of circulation to the gas exchange organ from circulation to the rest of the body. In fishes, deoxygenated blood is first pumped to the gills to gain O<sub>2</sub>; then the freshly oxygenated blood flows to the rest of the body and returns to the heart. This single circulation path limits the rate of blood flow to metabolically active body tissues. By contrast, birds and mammals evolved a separate [pulmonary circulation](#) to the lungs and [systemic](#)

circulation to the rest of the body. This double circulation was made possible by the evolution of a four-chambered heart. This organization has two advantages: it increases the supply of oxygenated blood to active tissues, and it increases the uptake of  $O_2$  at the gas exchange surface.

## Fishes have two-chambered hearts and a single circulatory system.

Fish hearts have two chambers ([Fig. 37.20](#)), an [atrium](#) (plural, [atria](#)) and a [ventricle](#). Deoxygenated blood returning from the fish's tissues enters the atrium, which fills and then contracts to move the blood into a thicker-walled ventricle. The muscular ventricle pumps the blood through a main artery to the gills for uptake of  $O_2$  and elimination of  $CO_2$ . Oxygenated blood collected from the gills travels to the tissues through a large artery called the [aorta](#).

FIG. 37.20 Fish heart and circulatory system. (a) Fishes have a two-chambered heart. (b) Blood flows in a single circuit from the heart, through gills, to the tissues for gas exchange, and back to the heart.

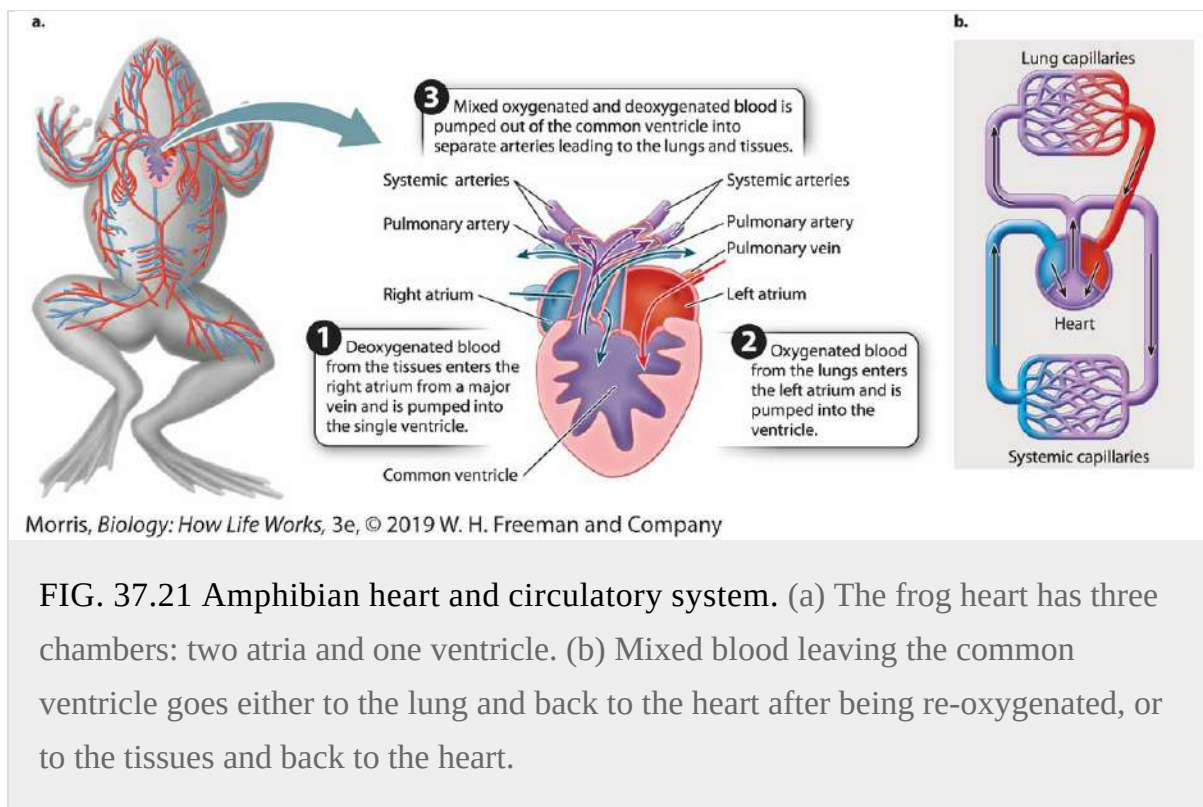

The small gill capillaries impose a large resistance to flow. As a result, much of the blood pressure is lost in moving blood through the gills. This loss of pressure limits the flow of oxygenated blood to body tissues.

## Amphibians and reptiles have three-chambered hearts and partially divided circulations.

As vertebrates moved onto land, the transition from breathing water to breathing air had important consequences for the organization of their circulatory systems. Land vertebrates evolved hearts that separated the circulation of deoxygenated blood pumped to their gas exchange organs from the circulation of oxygenated blood delivered to their body tissues. Gas exchange became more efficient and O<sub>2</sub> delivery increased. Metabolic rates rose, and animals became capable of greater activity.

Reflecting their aquatic and terrestrial lifestyle, amphibians evolved a variety of ways to breathe. Some retain gills, while others use lungs or their skin, or some combination of these, to breathe. Amphibian hearts evolved an additional atrium, becoming divided into two separate atria and a single ventricle ([Fig. 37.21](#)). This arrangement allows oxygenated blood from the gills, lungs, or skin to return to the heart separately from deoxygenated blood returning from metabolically

active tissues. Such a partial separation of the pulmonary and systemic circulations means that freshly oxygenated blood can be pumped under higher pressure to the body than is the case in fishes. However, because amphibians have a single ventricle, oxygenated blood returning to the heart from the gills, skin, or lungs mixes with deoxygenated blood returning from the animal's body before being pumped from the ventricle. Anatomical features of the ventricle limit this mixing, but mixing still hinders the supply of oxygenated blood to an amphibian's body.

Most reptiles also have a three-chambered heart, but their single ventricle has internal ridges to improve the separation of deoxygenated and oxygenated blood. As a result, reptiles are able to deliver more  $O_2$  to their tissues than amphibians can. At the same time, the incompletely divided ventricle provides reptiles with versatile

circulatory responses during exercise and when diving underwater. For example, when they dive, the blood of turtles and sea snakes bypasses their lungs, which they cannot use underwater. Notably, crocodiles and alligators have evolved four-chambered hearts, similar to those of mammals and birds.

## Mammals and birds have four-chambered hearts and fully divided pulmonary and systemic circulations.

Mammals and birds evolved four-chambered hearts with separate atria and separate ventricles ([Fig. 37.22](#)). This arrangement completely separates blood flow to the lungs from blood flow to the tissues. As a result, these animals can pump blood to their lungs under lower pressure, allowing increased uptake of  $O_2$ , and at the same time supply blood gases and nutrients to their tissues at high pressure. Whereas the systemic blood pressure of fishes is only a few mmHg, in a bird or mammal it is 100 mmHg or higher. Moreover, blood flowing to the tissues is fully oxygenated at the outset, so it delivers more  $O_2$  to body tissues at a higher rate. This change in heart structure and circulatory pattern was linked to an increase in the metabolic rates and the evolution of endothermy in birds and mammals ([Chapter 38](#)).

FIG. 37.22 The mammalian heart and circulatory system. (a) Mammals have a fully divided four-chambered heart with two atria and two ventricles. (b) Mammals have separate pulmonary and systemic circulations.

Following the pattern established in amphibians and reptiles, deoxygenated blood enters the right atrium from the venae cavae and, when the atrium contracts, moves through an **atrioventricular (AV) valve** into the right ventricle (Fig. 37.22). When the right ventricle contracts, blood is pumped through the **pulmonary valve** into the pulmonary trunk, which divides into the left and right **pulmonary arteries**, and then to the lungs for oxygenation. The atrioventricular and pulmonary valves ensure that blood flows in one direction into and then out of the right ventricle. The walls of the right ventricle are thinner than those of the left ventricle, and its weaker contractions eject

blood at a lower pressure. As a result, the blood of the pulmonary circulation moves at a slower rate, allowing greater time for gases to diffuse into and out of the lungs.

The oxygenated blood returns from the lungs through the [pulmonary veins](#) and enters the left atrium of the heart. When the left atrium contracts, blood is pumped through a second atrioventricular valve into the left ventricle. The thick muscular walls of the left ventricle eject the blood under high pressure to the body. Oxygenated blood leaving the left ventricle passes through the [aortic valve](#) and then flows to the head and the rest of the body through the large artery called the aorta. The one-way aortic valve ensures that blood leaving the left ventricle does not flow back into the left ventricle as it relaxes.

The contraction of the two atria followed by the contraction of the two ventricles makes up the [cardiac cycle](#) ([Fig. 37.23](#)). The cardiac cycle is divided into two main phases: [diastole](#), which is the relaxation of the ventricles, and [systole](#), which is the contraction of the ventricles. Thus, diastole is the phase in which the atria contract and the ventricles fill with blood, and systole is the phase of the cardiac cycle in which blood is pumped from the ventricles of the heart into the pulmonary and systemic circulations.

## CASE 7 BIOLOGY-INSPIRED DESIGN: USING NATURE TO SOLVE PROBLEMS

### How can we engineer replacement heart valves?

The human heart beats nearly 3 billion times in an average lifetime. This repeated pumping can lead to wear on the heart valves that regulate blood flow through the heart. As a result, damaged valves may need to be replaced or repaired. The aortic valve, which controls blood flow out of the heart, and the mitral (atrioventricular) valve on the left side of the heart are the valves most often in need of surgical replacement or repair. Approximately 2.5% of the U.S. population will

eventually need heart valve replacement surgery (more than 80,000 people per year).

Researchers have developed two types of artificial heart valves, both modeled after their normal counterparts: mechanical valves and biological valves made from a pig's or cow's valve. Both types of valves open and close in response to pressure differences, just like regular valves. Each is associated with different risks and benefits. Mechanical heart valves last longer, often for the remainder of an individual's lifetime. However, because mechanical valves more frequently create blood clots, they carry the risk of stroke or heart attack. Once such a valve is installed, the person must remain on blood thinners the rest of his or her life, which affects the patient's lifestyle. Biological valves from pig or cow valve tissues do not carry this risk, but they deteriorate more quickly, lasting approximately 10 to 20 years. An individual with a biological valve is at risk of needing a second (or third) valve replacement surgery, with the challenges of surgery increasing later in life.

Because of these trade-offs in risk and lifestyle impact, mechanical valves are recommended for individuals younger than 50 years of age and biological valves are recommended for those older than 70 years of age. Nevertheless, in recent years biological valve replacements have become increasingly popular for younger individuals, in part due to their minimal impact on lifestyle. The trade-offs in longevity and health risk continue to stimulate further research with the aim of increasing the lifetime effectiveness of biological replacement valves and better assessing the long-term outcomes of mechanical heart valves

relative to biological valves.

## Cardiac muscle cells are electrically connected to contract in synchrony.

For the heart to function effectively as a pump, the [cardiac muscle](#) cells that make up the walls of the atria and ventricles must contract in a coordinated fashion. Atrial muscle cells contract in synchrony during diastole to fill the ventricles, and ventricular muscle cells contract in synchrony during systole to eject the blood from the heart. For cardiac muscle cells to pump in unison, they must be depolarized in unison by an action potential.

Cardiac muscle cells have contractile properties similar to those of skeletal muscle cells ([Chapter 35](#)), but are distinct in two ways. First, specialized cardiac muscle cells can generate action potentials on their own, independently of the nervous system. Second, cardiac muscle cells are in electrical continuity with one another through gap junctions ([Chapter 10](#)), meaning that they can pass their action potentials to adjacent cells. These two features of cardiac muscle cells ensure that all muscle cells in a region surrounding a heart chamber are activated and contract in unison.

The specialized cardiac muscle cells capable of generating action potentials independently function as a [pacemaker](#) that causes the heart to beat with a basic rhythm. These cells stimulate neighboring cells to contract in synchrony. Pacemaker cells are found in two specialized regions of the heart: the [sinoatrial \(SA\)](#) and [atrioventricular \(AV\) nodes](#) ([Fig. 37.24](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 37.24 Control of heart rate and rhythm. The pacemaker cells of the sinoatrial and atrioventricular nodes keep the heart beating with a basic rhythm. This rhythm can be assessed by recording the electrocardiogram (EKG) of the heart.

Whereas most nerve cells maintain their resting membrane potential until they receive a signal from another cell, the critical feature of pacemaker cells is that their resting membrane potential gradually becomes less negative on its own until it reaches its threshold voltage and the cell fires an action potential. The membrane potential tends to become less negative over time due to slow leakage of sodium ions into the cell and decreased flow of potassium ions out of the cell. When the cell reaches its threshold, voltage-gated calcium ion channels open, causing more rapid depolarization. Like nerve cells, the pacemaker cells repolarize after firing an action potential to reach their resting potential, keeping the heart relaxed between contractions. Also, like nerve cells, pacemaker cells repolarize by opening voltage-gated

potassium channels to allow potassium ions to leave the cell.

The heartbeat is initiated at the sinoatrial node, which is located at the junction of the vena cava and the right atrium ([Fig. 37.24](#)). Because adjacent cardiac muscle cells are in electrical contact, action potentials initiated at the sinoatrial node spread rapidly from one cell to the next. Cell depolarization spreads electrically throughout the right and left atria, causing them to contract in unison. Because there is no electrical contact between the atria and ventricles, the ventricles do not contract. Instead, the depolarization in the atria reaches a second set of pacemaker cells, located in the AV node.

Activation of the AV node transmits the action potential to the ventricles. A modified set of cardiac muscle fibers transmits the action potential from the AV node to the base of the ventricles. From there, the depolarization spreads throughout the ventricle walls, causing the ventricles to contract in unison. Transmission through the conducting fibers causes a delay that ensures the ventricles do not contract until they are fully filled with blood from the atria.

Electrodes placed over the surface of the chest and other body regions can record the electrical currents produced by the depolarization of the heart while it beats. This type of recording is called an electrocardiogram (abbreviated as “EKG” because *kardia* is Greek for “heart,” although “ECG” is also used; [Figure 37.24](#)). Cardiologists use EKGs to diagnose heart problems or to determine which region of the heart has been damaged following a heart attack.

# Heart rate and cardiac output are regulated by the autonomic nervous system.

The volume of blood pumped by the heart over a given interval of time is its **cardiac output (CO)**. This quantity is a key measure of heart function. Cardiac output is determined by calculating the product of the **heart rate (HR)** and the volume of blood pumped during each beat, the **stroke volume (SV)**:  $CO = HR \times SV$ . As this equation indicates, animals can increase their cardiac output by increasing heart rate or stroke volume or both. Whereas humans and other mammals rely most heavily on increases in heart rate to increase cardiac output, fishes rely more on increases in stroke volume. Cardiac output rises or falls in response to the metabolic demand for  $O_2$ , which in turn depends on an animal's state of activity. When an animal sleeps, cardiac output is minimal; when it runs, cardiac output increases to meet the demand for  $O_2$  of its active muscles.

The nervous system controls the heart rate. Stimulation by sympathetic nerves causes the pacemaker cells of the sinoatrial node to depolarize more rapidly and the heart rate to speed up. Stimulation by parasympathetic nerves causes these cells to depolarize more slowly and the heart rate to slow down. Adrenaline released by the adrenal gland into the circulation also increases the heart rate for more prolonged periods of time. This hormone is a key component of the fight-or-flight response of many vertebrate animals.

Stroke volume is adjusted automatically as activity level rises and

falls. During exercise, when an animal's muscles regularly contract, the volume of blood returned to the heart is increased. The influx of additional blood stretches the walls of the atria and ventricles to a greater extent, causing them to contract more forcefully. As a result, more blood is ejected during each heartbeat. The adjustment of stroke volume to changes in activity ensures that heart emptying is matched to heart filling (that is, to venous return). The relationship between the volume of blood filling the heart and stroke volume is described by **[Starling's Law](#)**: a greater volume of blood returned to the heart increases stretching of the muscle, which leads to more forceful ejection of blood and a greater stroke volume.

As we have noted, circulation is linked to several other functions in addition to the transport of respiratory gases, nutrients, and wastes. The circulatory system plays a central role in the temperature regulation of many animals ([Chapters 33](#) and [38](#)). Changes in vasodilation or vasoconstriction are an important factor controlling heat loss or gain between an animal's body and its environment. The circulatory system also provides the route by which hormones ([Chapter 36](#)) and immune cells ([Chapter 41](#)) are distributed throughout the body, enabling the endocrine system to maintain homeostatic control of diverse bodily functions and the immune system to defend the body against pathogens. In doing so, the circulatory system serves as a general pathway by which hormonal and immune communication occurs to regulate, integrate, and protect the functional state of the whole organism.

12. Diagram the path of blood flow through the heart, lungs, and body of a fish and of a mammal or bird.
13. Is the pressure in the atrium or ventricle higher when the atrioventricular valve closes?
14. What are two mechanisms by which the cardiac output of an animal's heart can be adjusted? Which is more important for increasing cardiac output in mammals and which is more important in fishes?

## CORE CONCEPTS SUMMARY

### 37.1 DELIVERY OF OXYGEN AND ELIMINATION OF

**CARBON DIOXIDE:** Respiration and circulation depend on diffusion over short distances and bulk flow over long distances.

Diffusion is effective only over short distances and requires large exchange surface areas with thin barriers. [page 829](#)

Ventilation and circulation provide bulk flow over long distances. [page 830](#)

Oxygen is delivered to tissues in four steps: (1) bulk flow of water or air past the respiratory surface (gills and lungs); (2) diffusion of O<sub>2</sub> across the respiratory surface into the circulatory system; (3) bulk flow through the circulatory system; and (4) diffusion of O<sub>2</sub> into tissues and cells. [page 831](#)

**37.2 RESPIRATORY GAS EXCHANGE:** Respiration provides oxygen and eliminates carbon dioxide in support of cellular metabolism.

Many aquatic animals exchange respiratory gases with water through gills. [page 832](#)

Countercurrent flow of water relative to blood in the gills enhances O<sub>2</sub> extraction from water. [page 832](#)

Terrestrial animals breathe air by means of internal tracheae or lungs. [page 833](#)

Terrestrial vertebrates inflate and deflate their lungs during

bidirectional tidal ventilation driven by changes in pressure. [page 834](#)

Unidirectional flow of air maximizes O<sub>2</sub> uptake by bird lungs. [page 837](#)

Both the voluntary and involuntary nervous systems control breathing. [page 837](#)

**37.3 OXYGEN TRANSPORT BY HEMOGLOBIN:** Red blood cells produce hemoglobin, greatly increasing the amount of oxygen transported by the blood.

Hemoglobin greatly increases the capacity of the blood to transport O<sub>2</sub>. [page 838](#)

Red blood cells contain hemoglobin with iron-containing heme groups that reversibly bind and release O<sub>2</sub>. [page 839](#)

A sigmoidal O<sub>2</sub>-dissociation curve describes the change in the binding affinity of hemoglobin for O<sub>2</sub> with changes in partial pressure. The shape of the curve results from cooperative binding of O<sub>2</sub> by hemoglobin. [page 839](#)

Myoglobin binds and stores O<sub>2</sub> in muscle cells, increasing the delivery of O<sub>2</sub> to muscle mitochondria for activity in general and for diving in marine mammals. [page 840](#)

Fetal hemoglobin expressed by the mammalian fetus has a higher binding affinity for O<sub>2</sub> to allow for O<sub>2</sub> uptake from the mother's blood. [page 841](#)

The affinity of hemoglobin for O<sub>2</sub> is reduced by a decrease in pH and an increase in CO<sub>2</sub> levels. [page 842](#)

**37.4 CIRCULATORY SYSTEMS:** Circulatory systems have vessels of different sizes that facilitate bulk flow and diffusion.

The fluid in an open circulatory system moves through only a few vessels and is mostly contained within the animal's body cavity. [page 842](#)

The fluid in a closed circulatory system travels through a set of internal vessels, moved by a pump, the heart. [page 842](#)

Resistance to blood flow depends most strongly on vessel radius. [page 843](#)

Arteries are thick-walled vessels that contain collagen and elastin fibers, which provide for support against pressure and elastic rebound. [page 844](#)

Capillaries are small-diameter, thin-walled vessels that facilitate diffusion of O<sub>2</sub> and CO<sub>2</sub>. [page 844](#)

Arterioles control blood flow within the body by changing their resistance through contraction and relaxation of the smooth muscle in their walls. [page 844](#)

Veins are thin-walled vessels that return blood to the heart under low pressure. [page 845](#)

Liquids, gases, and other compounds move across capillary walls by diffusion, filtration, and osmosis. In vertebrates, some fluid is

returned to the bloodstream by the lymphatic system. [page 845](#)

**37.5 STRUCTURE AND FUNCTION OF THE HEART:** The evolution of animal hearts reflects selection for a high metabolic rate, achieved by increasing the delivery of oxygen to metabolically active cells.

Fishes have two-chambered hearts and a single circulatory path. [page 847](#)

Amphibians and reptiles have three-chambered hearts and a partially divided circulatory path. [page 847](#)

Birds and mammals have four-chambered hearts and a double circulatory path, consisting of a pulmonary circulation, from the heart to the lungs, and a systemic circulation, from the heart to the rest of the body. This arrangement enhances O<sub>2</sub> uptake and delivery to metabolizing tissues. [page 848](#)

One-way valves control blood flow through the heart. [page 849](#)

The cardiac cycle has discrete ventricular filling (diastole) and ventricular emptying (systole) phases. [page 849](#)

Cardiac muscle cells are electrically connected, allowing them to contract in synchrony as a unified heartbeat. [page 850](#)

Contraction of the heart is controlled by signals from pacemaker cells of the sinoatrial and atrioventricular nodes; these signals are transmitted by electrical conducting fibers to the ventricles. [page 850](#)

The vertebrate autonomic nervous system regulates the heart's cardiac output through changes in heart rate and stroke volume.

## CHAPTER 38 Animal Metabolism, Nutrition, and Digestion

Thomas Kokta/Getty Images

### CORE CONCEPTS

**38.1 PATTERNS OF ANIMAL METABOLISM:** Metabolic rate depends on activity level, body size, and body temperature.

**38.2 NUTRITION AND DIET:** An animal's diet supplies the energy the animal needs for homeostasis and essential nutrients it cannot synthesize on its own.

**38.3 ADAPTATIONS FOR FEEDING:** Animals have evolved different ways to capture food.

**38.4 REGIONAL SPECIALIZATION OF THE GUT:** The digestive tract has regions specialized for digestion, absorption, storage, and elimination.

---

It is literally true that “you are what you eat.” Not only do animals build their bodies and obtain energy from the food they eat, but also their very appearance often reflects what they eat. Consider a cat. We know it's a carnivore—an organism that mainly eats animals—just from looking at it. It has sharp teeth and powerful jaws specialized for tearing meat; strong legs, sharp claws, and keen eyesight for hunting prey; and a short gut because breaking down animal protein is easier than breaking down plant material. Humans are omnivores, adapted for eating both other animals and plants, and this is reflected in our anatomy. Our teeth include sharp canines for tearing meat and flat molars for grinding plant material. Cows are herbivores, animals that eat plants. Cows have evolved a variety of adaptations, including a four-chambered stomach, that allow them to digest cellulose, which is tough but rich in energy.

Animals are heterotrophs, obtaining food from other organisms ([Chapter 6](#)). The energy animals obtain from food is essential for building bodies, moving, surviving, and reproducing. Much of an

animal's activity therefore centers on obtaining food. In turn, the biology of an animal is in large part shaped by the type of food the animal consumes. For example, an animal's metabolism, including the chemical reactions by which it breaks down its food, has evolved in close association with the type of food available to the animal. Likewise, an animal's survival is closely linked to the energy and nutrients contained in that food.

The food that an animal eats also affects its place in an ecosystem. Primary producers, such as plants and some algae, are food for a great diversity of animals. Animals that feed on plants tend to exist in large numbers. Large animals that feed on other, smaller animals exist in smaller numbers and commonly represent fewer species.

This chapter examines how animals obtain and break down the food they eat. We begin at the cellular level, building on the biochemistry of metabolism discussed in [Chapter 7](#). We then examine the dietary needs of animals, followed by the structure and function of animal digestive systems: how an animal eats, digests, and absorbs food to supply its cells with the energy required for its functions. Discussion of the relationship between an animal's diet and its place in an ecosystem is reserved until [Chapter 46](#).

## 38.1 PATTERNS OF ANIMAL METABOLISM

The biochemical pathways that make up animal metabolism are remarkably conserved among diverse groups of organisms. These pathways evolved early in the history of life and have been retained throughout the evolution and diversification of life. In [Chapter 7](#), we examined the pathway of glucose breakdown by cellular respiration, which provides ATP to fuel the work of a cell. Here, we put this and related pathways in an organismal context. We explore how carbohydrates, proteins, and fats are metabolized for building body structures and supplying energy needs, and how metabolic rate varies with an animal's level of activity, internal body temperature, and size.

### Animals rely on anaerobic and aerobic metabolism.

Nearly all animals depend on three main classes of molecules as sources of energy and building blocks for growth and development: carbohydrates, fats, and proteins ([Chapter 2](#)). These molecules are broken down after ingestion, and in the process the energy in their chemical bonds is transferred to biologically useful forms, typically [adenosine triphosphate \(ATP\)](#). While other nucleic acid triphosphates also serve as usable forms of energy, ATP is by far the one most commonly used by animals. The breakdown of carbohydrates, fats, and proteins to produce ATP takes place through a series of chemical reactions. Reactions that break down food sources to fuel the energy needs of a cell are termed [catabolic](#). In contrast,

reactions that result in net energy storage within cells and the organism are called [anabolic](#).

Let's first review the breakdown of the carbohydrate glucose. Glucose can be partially broken down in the absence of oxygen by glycolysis ([Fig. 38.1](#)). Glycolysis occurs in the cytosol of the cell, and the breakdown of each glucose molecule results in the production of 2 molecules of pyruvate, 2 molecules of ATP, and 2 molecules of NADH. In animals, if oxygen is not present, or if it is present only in small amounts, pyruvate is converted by fermentation into lactic acid. The production of ATP by [anaerobic](#) ("absence of oxygen") [metabolism](#) provides rapid but short-term energy to the cell and organism.

FIG. 38.1 Cellular metabolism, which includes anaerobic and aerobic pathways. Animals obtain energy to fuel their activities and development from the breakdown of carbohydrates, fats, and proteins.

In contrast, **aerobic** (“of oxygen”) **metabolism**, which is carried out within the mitochondria of animals, provides a steady supply of ATP for longer-term, sustainable activity. When enough oxygen diffuses into the mitochondria, pyruvate can be further broken down by the **citric acid cycle** rather than converted to lactic acid (Fig. 38.1). In a series of oxidation–reduction reactions, energy-rich NADH and FADH<sub>2</sub> molecules are produced. These molecules then enter the electron transport chain in the inner mitochondrial membrane. The

[electron transport chain](#) couples the transfer of electrons to the pumping of protons across the inner mitochondrial membrane, resulting in a proton electrochemical gradient that drives the synthesis of ATP by oxidative phosphorylation. Because oxygen is reduced to water in the process, oxygen is consumed and water is produced as a by-product. Aerobic metabolism is also called cellular respiration or aerobic respiration.

Overall, aerobic metabolism results in the formation of a total of 32 molecules of ATP when 1 molecule of glucose is broken down, much more than the 2 molecules of ATP from 1 molecule of glucose produced anaerobically. We can define metabolic efficiency as the amount of energy captured in a usable form (at least 234 kcal of useful ATP energy) per amount of energy in the starting molecule (686 kcal in 1 mol of glucose). The metabolic efficiency of aerobic respiration, then, is at least 34% (or  $234/686 \times 100$ ). The remaining 66% of this energy is converted to heat and either lost to the environment or used to warm the animal. Glucose that is not metabolized is stored as glycogen, primarily in the liver and muscles.

Lipids are another important energy source for most animals. Lipids consumed in the diet, such as triacylglycerol, are broken down to glycerol and free fatty acids, which enter glycolysis or the citric acid cycle to yield ATP by oxidative phosphorylation ([Chapter 7](#)). Alternatively, they can be stored as fat (adipose tissue). Storing energy as fat is a particularly efficient mechanism because fat yields more than twice the energy supply per unit weight (9.4 kcal/g) as glycogen (4.2 kcal/g). When needed, stored fats can similarly be broken down into

glycerol and free fatty acids, which yield ATP by the same pathways as lipids from the diet.

Proteins consumed in the diet can also be a useful energy source for animals. Carnivores such as cats get most of their energy from the protein and fat in the meat they eat. Proteins include enzymes and structural elements of cells and tissues, which are needed for building and maintaining the body. Only following prolonged food deprivation, when fat and carbohydrate reserves are depleted, do animals break down protein reserves (mainly from their muscles) to form ATP. Animals rely mainly on fats for long-term energy supply. Well-nourished humans have enough fat reserves to support their metabolic needs for 5 to 6 days before they start to use protein reserves. Because nerve cells depend primarily on glucose to produce ATP, carbohydrates are spared for the brain and nervous system when animals face starvation.

## Metabolic rate varies with activity level.

An animal's overall rate of energy use is termed its **metabolic rate**. Metabolic rate can be measured by the animal's rate of oxygen consumption, or how much oxygen it consumes in a certain amount of time. The rate of oxygen consumption reflects the rate of aerobic production of ATP. (Recall the overall formula for cellular respiration:  $\text{C}_6\text{H}_{12}\text{O}_6 + 6\text{O}_2 \longrightarrow 6\text{H}_2\text{O} + 6\text{CO}_2 + \text{ATP}$ .)

An animal's metabolic rate is affected by many factors, including its activity level. When an animal shifts from rest to activity, its metabolic

rate and oxygen consumption rise to meet the increased demand for ATP. The onset of activity requires immediate energy, which in animals is provided by specialized energy stores in their tissues. In vertebrate muscle cells, for example, phosphocreatine is a ready source of energy. Phosphocreatine is hydrolyzed to provide high-energy phosphates that are used to synthesize ATP directly from ADP at the onset of activity. When the phosphocreatine is used up, the cell begins the relatively rapid production of ATP by glycolysis. Although glycolysis produces relatively few ATP molecules per molecule of glucose, the reactions are extremely fast, providing a rapid short-term supply of energy for animals. Animals rely on glycolysis for short bursts of intensive activity.

With longer activity, the ATP needs of the animal are met by aerobic respiration in mitochondria. The rate of oxygen consumption initially increases as aerobic respiration ramps up, then levels off ([Fig. 38.2](#)). At this point, the animal's need for energy is met entirely by aerobic respiration. The steady production of ATP can continue as long as adequate oxygen reaches the mitochondria, first by transport to the tissue through the cardiovascular system ([Chapter 37](#)) and then by diffusion into mitochondria.

FIG. 38.2 Oxygen consumption during physical activity.

Sprinters rely heavily on anaerobic ATP production for intense short-term bouts of activity. By comparison, longer races are run at progressively slower speeds for increased endurance, as a distance runner relies more heavily on aerobic metabolism to produce ATP. The world record for the 100-m sprint averages a little more than 10 m/s, but for the 1500-m race the average is about 6.6 m/s.

When activity ends, the animal's rate of oxygen consumption declines but does not immediately return to resting levels, as shown in [Fig. 38.2](#). The elevated consumption of oxygen following activity is known as the animal's **recovery metabolism**. An animal continues to expend metabolic energy during this period in an effort to reestablish the resting metabolic state of its cells. As part of recovery metabolism, cells re-synthesize depleted ATP stores and metabolize the end products of fermentation, particularly lactic acid. The difference

between an animal's immediate energy need at the onset of activity and the energy supplied by aerobic metabolism is referred to as the animal's "oxygen debt." This debt is "paid back" following exercise by the animal's recovery metabolism. Recovery metabolism explains the elevated breathing and heart rate that you (and other animals) experience when resting after moderate to intense exercise.

We just saw that metabolic rate increases with activity level. A by-product of metabolism is the generation of heat, which is a necessary consequence of the second law of thermodynamics ([Chapters 1 and 6](#)). Animals have several mechanisms for dissipating excess heat, including sweating, changes in blood flow, and (in dogs, for example) panting.

## Metabolic rate is affected by body size.

In addition to activity level, an animal's size influences its metabolic rate. At rest, larger animals consume more energy and have higher metabolic rates than smaller ones. However, resting metabolic rate does not increase linearly with an animal's mass. Instead, measurements of resting metabolic rate in a wide range of organisms show that metabolic rate increases with mass raised to the  $\frac{3}{4}$  power ([Fig. 38.3](#)). This means that the average rate at which each gram of body tissue consumes energy is *less* in larger organisms compared to smaller ones. Put another way, the larger the organism, the *lower* the metabolic rate *per gram* of body tissue. This scaling pattern of cellular energy metabolism is remarkable because it holds across a diverse size range of unicellular and multicellular organisms, as can be seen in [Fig.](#)

### 38.3.

In addition to comparing resting metabolic rates in different-sized animals, we can examine how metabolic rates vary with activity level in different-sized animals. For example, we can look at how much energy is used when animals move at different speeds. The American comparative physiologist C. Richard Taylor has extensively studied how metabolic rate varies with running speed in different-sized terrestrial animals ([Fig. 38.4](#)). He found that metabolic rate increases linearly with speed, and that larger animals expend less energy per unit mass than smaller ones.

#### HOW DO WE KNOW?

### FIG. 38.4

## How is metabolic rate affected by running speed and body size?

#### BACKGROUND

In the 1970s and 1980s, the American physiologist C. Richard Taylor and his colleagues studied the relationship between metabolic rate and running speed in mammals of different sizes. They were interested in understanding the energetic costs of running in different animals.

#### EXPERIMENT

Taylor and colleagues measured oxygen consumption during running for a wide range of organisms. They trained each animal to run on a treadmill at different speeds and measured oxygen consumption using either a face mask or enclosure. Oxygen consumption over time was used as a measure of metabolic rate.

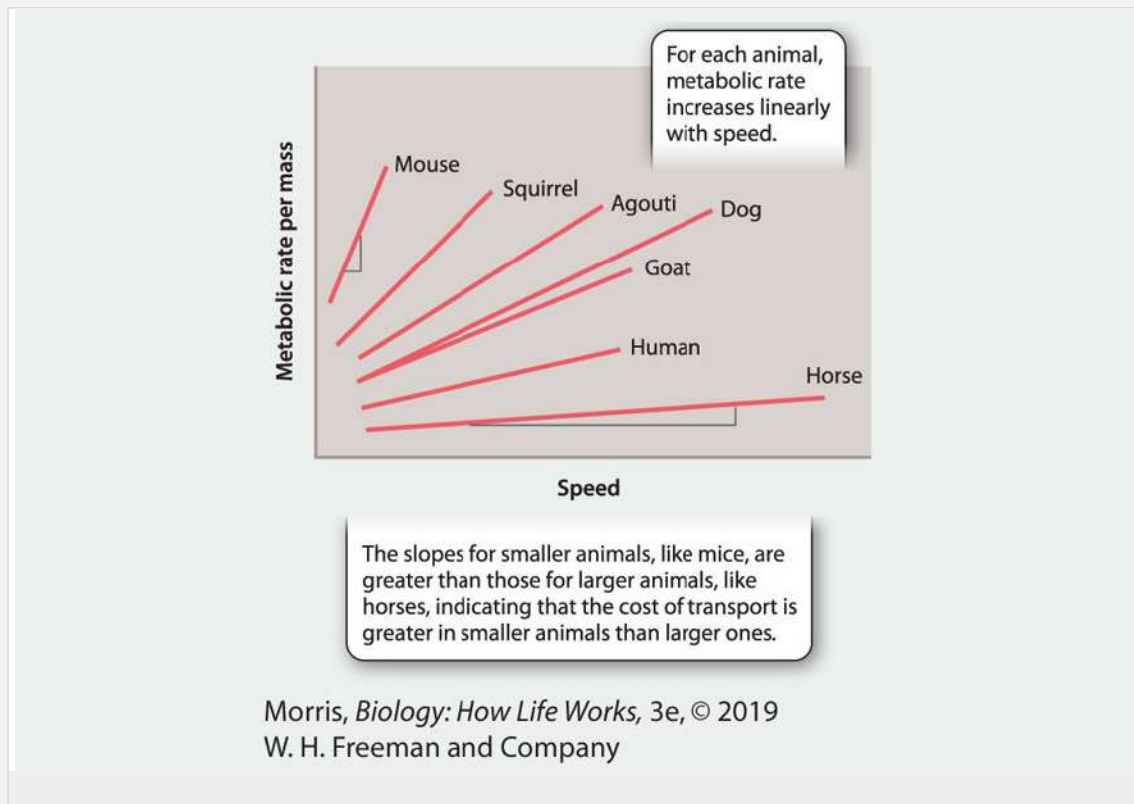

Photo source: Cary Wolinsky/Getty Images.

## RESULTS

The researchers found that there is a linear increase in metabolic rate with speed in different-sized animals. They also found that larger animals expend less energy per unit body mass to move a given distance compared to smaller ones.

## FOLLOW-UP WORK

Similar studies were performed with kangaroos, which move by hopping rather than by running. Interestingly, it was found that it is “cheaper” (that is, it requires less energy) to hop than to run. This finding perhaps explains why kangaroos and other hopping animals survived, while many animals that run on four legs became extinct, in Australia 30,000 to 20,000 years ago with the arrival of early humans. Studies have also compared the energetic costs of running on two legs and running on four legs and have found that the cost is the same.

# Metabolic rate is linked to body temperature.

Metabolic rate is also affected by an animal's internal body temperature. Chemical reaction rates increase as temperature rises, so internal body temperature determines how fast fuel molecules can be mobilized and broken down to supply energy for a cell. Animals can be categorized as either endotherms or ectotherms based on the sources of most of their heat.

Animals that produce most of their own heat as by-products of metabolic reactions, including the breakdown of food, are [endotherms](#). These animals usually, but not always, maintain a constant body temperature that is higher than that of their environment. As we saw in [Chapter 33](#), the maintenance of a constant core body temperature is a form of homeostasis and requires balancing heat production and heat loss. Birds and mammals, including humans, are endotherms.

By contrast, animals that obtain most of their heat from the environment are [ectotherms](#). Ectotherms often regulate their body temperatures by changing their behavior—moving into or out of the sun, for example. Think of a turtle or some other reptile sunning itself on a rock: it is raising its body temperature. The temperatures of these animals usually fluctuate with the outside environment. Most fish, amphibians, reptiles, and invertebrates are ectotherms.

Endotherms are sometimes referred to as “warm-blooded” and ectotherms as “cold-blooded,” but these terms are misleading.

Depending on the environmental conditions, cold-blooded animals can sometimes have core body temperatures that are higher than those of warm-blooded animals. Also keep in mind that these two ways of obtaining heat are not completely distinct, but instead represent extremes of a continuum.

An animal's major source of heat has profound implications for its metabolic rate. Endotherms have a higher metabolic rate than ectotherms. As a result, they are able to be active over a broader range of external temperatures than ectotherms. Both the activity level and metabolic rate of ectotherms increase with increasing body temperature. However, at similar body temperatures, ectotherms have metabolic rates that are approximately 25% those of endotherms of similar body mass. Although ectotherms can achieve activity levels similar to those of endotherms when their body temperatures are similar, ectotherms cannot sustain prolonged activity. Therefore, ectotherms such as lizards or insects demonstrate brief bouts of activity, followed by longer periods of inactivity compared to endotherms.

Endotherms benefit from having an active lifestyle. However, their high metabolic rate requires long periods of foraging to acquire enough food to keep warm and be active. By contrast, although ectotherms cannot sustain activity for long periods, they can survive for much longer periods without food.

As we have discussed, the control of core body temperature, or thermoregulation, is a form of homeostasis and requires the

coordinated activities of the nervous, muscular, endocrine, circulatory, and digestive systems. We summarize how these systems work together in endotherms and ectotherms in [Fig. 38.5](#).

**FIG. 38.5 VISUAL SYNTHESIS: Homeostasis and Thermoregulation**  
Integrating concepts from [Chapters 33–38](#)

### Self-Assessment Questions

1. How can you measure the metabolic rate of an animal?
2. Why is the average world record speed for a 10-m race faster than that for a marathon?
3. Does a dog that is twice as heavy as a cat have twice the resting metabolic rate?
4. What happens in an endotherm and an ectotherm when outside temperature gets cold, and what happens when it gets hot?

## 38.2 NUTRITION AND DIET

Running, jumping, moving, growing, reproducing, and all other activities performed by animals require energy. Autotrophs like plants and certain microbes are able to capture energy from the sun or from inorganic compounds ([Chapters 8](#) and [24](#)), but animals must acquire food as organic compounds obtained from other living organisms, such as plants or other animals. Food does not consist just of carbohydrates, fats, and proteins, however. To enable various cell processes, animals must also obtain in their diet certain minerals and chemical compounds that they cannot synthesize on their own. In this section, we explore what animals need to obtain from their food, and how much they require, in order to sustain their cells and tissues.

### Energy balance is a form of homeostasis.

Like core body temperature ([Fig. 38.5](#)), blood glucose levels ([Chapter 36](#)), and blood pressure ([Chapter 37](#)), the **energy balance** of an organism is often maintained at a constant level. An animal in energy balance takes in over time the same amount of calories of energy from food that it uses over time to meet its metabolic needs. Energy balance can be thought of as a form of homeostasis. Factors determining energy balance include sources of energy, or **energy intake**, and ways in which energy is expended, or **energy use**.

For animals, the source of energy is the diet. In turn, that energy is used to do work—maintain tissues, grow, move about, and the like. The energy required to support basic life processes accounts for the

majority (approximately 70%) of energy use. Interestingly, digestion and absorption of food themselves require energy, and this use is included in the 70% figure. The remaining energy (approximately 30% of energy use) can be used for physical activity, with higher levels of activity using more energy, as we saw.

When energy intake does not equal energy use, there is an energy imbalance. If an animal eats more food than it requires, energy stores such as fat deposits grow over time. The result is that the body shifts its metabolism mostly to anabolic processes that build energy stores. Many animals achieve a net positive energy balance during the late summer and fall when food is plentiful, before it becomes scarce in winter. Other animals maintain a constant energy intake throughout the year by migrating to areas with more abundant food and warmer temperatures, thereby avoiding colder temperatures that require increased energy expenditure to remain active and warm. Still other animals hibernate, or become less active, to conserve their energy use over the winter.

Animals that cannot acquire enough food are in negative energy balance and become undernourished. During prolonged periods of inadequate food supply or starvation, an animal consumes its own internal fuel reserves. Starvation forces animals to deplete their glycogen and fat reserves first. Then, if no food is found, they resort to protein stores, primarily in muscle tissue. The consumption of muscle protein ultimately leads to muscle wasting. Undernourishment and starvation are particularly serious human health problems in many developing countries, especially those ravaged by war and political

instability.

Humans, like most other animals, store excess food calories as fat. We do so because, over much of our evolutionary history, food was less abundant and more unpredictable in its availability than it is today. With the development of agriculture and domestication of livestock, food supplies rapidly increased, and many human populations were able to grow and consume increasing amounts of food. With the rise of mechanized agricultural food production and the availability of highly processed foods developed by the modern food industry, excessive intake of food calories has led to an increasing and now critical public health problem: obesity.

Obesity is now an epidemic in many industrialized nations. In the United States, approximately 36% of the adult population is considered obese. Obesity is a major public health concern because it increases the risk of diabetes, heart disease, and stroke, and contributes to a shorter life-span. For most animals, however, acquiring food and storing its products efficiently in the body allow them to have a fuel reserve to meet their energy requirements. This rationing of stored energy remains an essential part of their metabolic and digestive physiology.

## An animal's diet must supply nutrients that it cannot synthesize.

Through their metabolic pathways, animals are able to obtain energy from the environment as well as to synthesize many of the compounds needed to sustain life. However, many nutrients necessary for life cannot be synthesized by an animal's metabolism and, therefore, must

be acquired in the food that they eat.

Recall that amino acids are the basic units of proteins ([Chapter 4](#)). Twenty different amino acids are typically found in proteins (see [Fig. 4.2](#)). Although all of these amino acids are necessary for life, an **essential amino acid** is defined as one that cannot be synthesized by an organism’s cellular biochemical pathways and instead must be ingested. Most animals can synthesize about half of their amino acids, but which of these each can synthesize varies from species to species.

Humans are unable to synthesize 8 of the 20 amino acids ([Table 38.1](#)). We have to obtain these eight essential amino acids in our diets. Infants require additional amino acids. The most reliable source of all eight essential amino acids is meat. Most plant proteins lack at least one of the eight amino acids essential to humans, and diets heavy in a particular food, such as corn (which lacks lysine), can lead to protein deficiency. Nevertheless, vegetarians can achieve a healthy intake of all essential amino acids by combining plant foods. For example, beans supply the lysine that corn lacks, and corn supplies the methionine that beans lack.

TABLE 38.1 Essential Amino Acids for Humans, Dogs, and Cats

| ESSENTIAL AMINO ACID | HUMAN | DOG | CAT | COMMON SOURCES                         |
|----------------------|-------|-----|-----|----------------------------------------|
| Isoleucine           | ✓     | ✓   | ✓   | Meat, dairy, lentils, wheat            |
| Leucine              | ✓     | ✓   | ✓   | Meat, cottage cheese, lentils, peanuts |
| Lysine               | ✓     | ✓   | ✓   | Meat, beans, lentils, spinach          |

|               |   |   |   |                                 |
|---------------|---|---|---|---------------------------------|
| Methionine    | ✓ | ✓ | ✓ | Meat, dairy, whole grains, corn |
| Phenylalanine | ✓ | ✓ | ✓ | Meat, dairy, peanuts, seeds     |
| Threonine     | ✓ | ✓ | ✓ | Meat, dairy, nuts, seeds        |
| Tryptophan    | ✓ | ✓ | ✓ | Meat, dairy, oats               |
| Valine        | ✓ | ✓ | ✓ | Meat, dairy, grains             |
| Arginine      |   | ✓ | ✓ | Meat, dairy, soy, peanuts       |
| Histidine     |   | ✓ | ✓ | Meat, dairy, soy, eggs          |
| Taurine       |   |   | ✓ | Meat, dairy, eggs               |

**Dietary minerals** are chemical elements other than carbon, hydrogen, oxygen, and nitrogen that are required in cells and must be obtained in the food that an animal eats (shown in red in [Fig. 38.6](#)). They include sodium (Na), chlorine (Cl), magnesium (Mg), phosphorus (P), potassium (K), calcium (Ca), iron (Fe), and zinc (Zn). Magnesium and zinc are sometimes associated with enzymes as cofactors ([Chapter 6](#)); calcium is required for neuron function ([Chapter 34](#)), muscle function ([Chapter 35](#)), and building skeletons ([Chapter 35](#)); and iron in hemoglobin binds oxygen and transports it in the blood ([Chapter 37](#)). Sodium and potassium are essential not only for nerve function, but also for supporting the sodium–potassium pumps characteristic of all cells. Humans typically obtain the minerals sodium and chloride through common table salt and other foods. Many animals seek exposed rock that they lick to obtain minerals and salts.

|          |          |                 |           |           |           |           |           |           |           |           |           |            |            |            |            |            |            |

FIG. 38.6 Commonly recognized minerals required by humans. Dietary minerals, shown in red, are chemical elements other than carbon, hydrogen, oxygen, and nitrogen that are required in the diet.

In addition to amino acids and minerals, animals must ingest essential [vitamins](#), organic molecules that are required in very small amounts in the diet. Vitamins have diverse roles: some bind to and increase the activity of particular enzymes, whereas others act as antioxidants or chemical signals. Different animal species have different vitamin requirements, so a molecule that functions as a vitamin for one may not be a vitamin for another. Thirteen essential vitamins have been identified for humans ([Table 38.2](#)). Knowing which vitamins are required for an animal's health is critical to proper medical and veterinary care. Animals have evolved diets that ensure that their need for vitamins, as well as for essential amino acids and minerals, is met through the combination of foods that they eat.

TABLE 38.2 Essential Vitamins for Humans

| VITAMIN<br>DESIGNATION | NAME | COMMON SOURCES |
|------------------------|------|----------------|
|                        |      |                |

|                         |                  |                                              |
|-------------------------|------------------|----------------------------------------------|
| Vitamin A               | Retinol          | Green and orange vegetables, liver, milk     |
| Vitamin B <sub>1</sub>  | Thiamine         | Pork, grains                                 |
| Vitamin B <sub>2</sub>  | Riboflavin       | Dairy products, eggs, leafy green vegetables |
| Vitamin B <sub>3</sub>  | Niacin           | Meat, dairy products, eggs, vegetables       |
| Vitamin B <sub>5</sub>  | Pantothenic acid | Meat, grains                                 |
| Vitamin B <sub>6</sub>  | Pyridoxine       | Meat, grains                                 |
| Vitamin B <sub>7</sub>  | Biotin           | Meat, eggs                                   |
| Vitamin B <sub>9</sub>  | Folic acid       | Leafy green vegetables, eggs                 |
| Vitamin B <sub>12</sub> | Cobalamin        | Liver, eggs                                  |
| Vitamin C               | Ascorbic acid    | Fruit, vegetables                            |
| Vitamin D               | Calciferol       | Fish, eggs                                   |
| Vitamin E               | Tocopherol       | Fruit, vegetable oils                        |
| Vitamin K               | Phylloquinone    | Leafy green vegetables                       |

In humans as well as in other animals, vitamin deficiency can have serious consequences. Whereas most mammals can synthesize ascorbic acid (vitamin C), primates (including humans) cannot. Vitamin C is necessary for building connective tissue. Humans who do not ingest enough of this vitamin develop scurvy, a disease characterized by bleeding gums, loss of teeth, and slow wound healing. Until it was discovered that green vegetables and fruit supply vitamin C, scurvy was a common disease that could lead to death for sailors who were deprived of fresh produce for long periods of time while at sea.

Deficiencies of vitamins B<sub>1</sub>, B<sub>6</sub>, and B<sub>12</sub> can cause nervous system disorders and various forms of anemia (low levels of red blood cells or

hemoglobin in the blood). Vitamin D is essential for the absorption of calcium in the diet and, therefore, for skeletal growth and health. With adequate exposure to ultraviolet solar radiation, skin cells synthesize enough vitamin D to sustain a growing body. However, people inhabiting northern regions of the world do not get a lot of sunlight. As a result, they produce low levels of vitamin D and require more of it in their diet. Lack of adequate vitamin D can lead to rickets, a disease often seen in malnourished children in which bones do not mineralize properly. The role of vitamin E remains uncertain, but its absence is sometimes linked to anemia.

#### Self-Assessment Questions

5. Muscle, fat, and glycogen are all reservoirs of energy. In which order are they used during a prolonged fast?
6. In the context of nutrition, what does “essential” mean?

## 38.3 ADAPTATIONS FOR FEEDING

Animals have evolved a variety of adaptations to enhance their ability to acquire energy and nutrients from the environment. Animals eat other organisms, whether they are other animals, plants, or fungi. Herbivores are adapted to eat plants; carnivores are adapted to eat animals; and omnivores are adapted to eat both. Animals have evolved a diversity of ways to capture food and mechanisms to break food down before its digestion in the gut.

### Suspension filter feeding is common in many aquatic animals.

The most common form of food capture by animals is [suspension filter feeding](#), in which water with food suspended in it is passed through a sievelike structure ([Fig. 38.7](#)). Suspension filter feeding is possible only in aquatic environments, and it is common in a great diversity of animals found in oceans and freshwater bodies, such as lakes and streams. This form of feeding evolved multiple times independently on many different branches of the tree of life, so these occurrences of filter feeding are examples of convergent evolution ([Chapter 22](#)).

Sources: a. Andrew J. Martinez/SeaPics.com; b. Jean-Marc Bour/Biosphoto.

FIG. 38.7 Suspension filter feeding by (a) a scallop and (b) a baleen whale.

Many worms and bivalve mollusks, such as scallops, clams, and oysters, pump water over their gills to trap food particles suspended in the water ([Fig. 38.7a](#)). Cells of the gills produce mucus that acts as an adhesive to trap food particles, and the cells' beating cilia sweep food trapped in the mucus to the mouth and gut.

Other aquatic organisms move water containing suspended food particles through filters in their oral cavity to separate the food from the water. The food is then conveyed into the gut. Large baleen whales have long comblike blades of baleen (which is made of keratin, the same material that makes up hair and nails) in their mouth to capture small shrimp called krill that are plentiful in ocean waters ([Fig. 38.7b](#)).

## Large aquatic animals apprehend prey by suction feeding and active swimming.

Aquatic animals that do not rely on suspension filter feeding capture their prey in other ways. Many fish feed by suction. A rapid expansion

of the fish's mouth cavity draws water and the desired prey into the mouth ([Fig. 38.8](#)). After the fish closes its mouth, the water is pumped out of the mouth past the gills. Trapped inside the mouth, the prey moves into the pharynx (part of the throat) and is broken up by a second set of jaws in the pharynx before being swallowed. Suction feeding is the most common form of prey capture among fishes, as it allows them to be “sit-and-wait” predators; they can hide in a coral reef or under a rock before rapidly striking to capture prey moving in front of them. A wide variety of fishes use suction feeding, as do aquatic salamanders, and this feeding method has contributed to their evolutionary diversification and success.

*Source: Marevision/Getty Images.*

FIG. 38.8 Suction feeding. A rapid expansion of the fish's mouth draws in water and prey.

Many insects that bite to obtain a blood meal draw the blood of their prey into their digestive system by suction. Young mammals feed by suckling milk from their mother's breast, using their tongue and generating suction as fishes do.

As top predators in marine and freshwater environments, larger fishes like sharks and marine mammals like whales and dolphins actively swim to capture their prey ([Fig. 38.9](#)). Their large size and formidable speed enable them to catch smaller or similar-sized prey. As discussed next, the evolution of jaws and teeth considerably enhanced the ability of these and other vertebrate animals to capture new kinds of food, allowing them to lead a more active and energetically demanding lifestyle.

Source: C & M Fallows/SeaPics.com.

FIG. 38.9 Feeding by active swimming. Large marine predators, like this great white shark, use their size and speed to capture prey.

## Specialized structures allow for capture and mechanical breakdown of food.

Jaws and teeth were an important evolutionary innovation for active

predators. Some of the first vertebrates, the jawed fishes, became dominant in their aquatic environment through the ability to swim and bite forcefully to obtain their food. [Fig. 38.10](#) shows a phylogenetic tree of vertebrates indicating the appearance of jaws. Jawed fishes evolved from jawless ancestors, and jaws can be found in present-day fishes, amphibians, reptiles, and mammals. As you can see from the large number of jawed groups, jaws are key to the evolutionary success of vertebrates. Jaws evolved from cartilage that supported the gills, providing a spectacular example of an organ adapted for one function (gill support) changing over time to become adapted for an entirely different function (predation).

FIG. 38.10 A phylogeny of vertebrates, showing the appearance of jaws. Jaws, which evolved more than 400 million years ago from a group of jawless ancestors, contributed to the success of many groups of animals.

Among vertebrates, mammals evolved a specialized jaw joint, the **temporomandibular joint**, as well as a great diversity of specialized forms of teeth. These teeth have cutting and crushing surfaces, enabling mammals to break down a variety of foods mechanically before swallowing those foods. **Fig. 38.11** illustrates the arrangement of specialized teeth in mammals with different diets. Teeth in the front of the mouth, the **incisors**, are specialized for biting. Other teeth, such as the **canines** of dogs, cats, and other carnivores, are specialized for piercing the body of their prey. Saber-toothed cats, which lived as recently as 10,000 years ago, had remarkably long canines (up to 16 inches [40 cm]!) specialized for killing large prey. **Premolars** and **molars** are teeth in the back of the mouth that are well adapted for crushing and shredding tougher foods, such as meat and fibrous plant material.

FIG. 38.11 Jaws and teeth of carnivorous, herbivorous, and omnivorous mammals. Mammals evolved a diverse arrangement of teeth for diverse diets.

Herbivorous animals, such as cattle, sheep, and horses, have specialized premolars and molars with prominent surface ridges. These teeth can shred tough plant material before it is swallowed and digested. Mammalian herbivores use their front incisors and canines to bite grasses and leaves; they then move the food to the back of the mouth, where it is ground and crushed between their ridged premolars and molars.

Arthropods, such as insects and crustaceans, lack jaws and teeth, yet are also able to capture, manipulate, and break down food. Some of them use paired mouthparts called [mandibles](#), one on each side of the head ([Fig. 38.12](#)). In contrast to the teeth of vertebrates, mandibles are located outside and in front of the mouth. They are used to capture and physically break down food before it enters the mouth and then the gut. Arthropod mandibles have evolved a great diversity of structures and are well adapted to different sources of food ([Chapter 42](#)).

FIG. 38.12 Mandibles. (a) Ants and (b) beetles have jaw-like mandibles that are used to capture, hold, and tear apart food.

#### Self-Assessment Questions

7. What are four ways in which animals capture prey? Provide an example of an animal that uses each one.
8. The jaws of vertebrates and the mandibles of insects have similar functions. Are they an example of analogous or homologous structures?

## 38.4 REGIONAL SPECIALIZATION OF THE GUT

After animals obtain food, they need to break it down. The process of breaking down food into smaller components is called [digestion](#).

Digestion can occur either mechanically or chemically. The food is isolated in a specialized organelle or compartment so that it can be broken down without damaging other organelles or structures of the body.

Organisms on different branches of the tree of life have evolved very different means of isolating and digesting food. Single-celled protists, which obtain food particles by phagocytosis, rely on intracellular digestion: their food is broken down within cells. In these organisms, lysosomes containing hydrolytic enzymes fuse with vacuoles containing food particles, thereby mixing enzymes and food ([Chapter 5](#)). Following the food particles' chemical breakdown, the products of intracellular digestion are available for use by the cell. Most animals, however, employ the process of extracellular digestion, in which food is isolated and broken down outside a cell in a body compartment. Following digestion, the breakdown products are taken up into the bloodstream in a process called [absorption](#).

**Most animal digestive tracts have three main parts: a foregut, midgut, and hindgut.**

In extracellular digestion, food is broken down in a specialized cavity or body compartment. Some animals, such as sea anemones, carry out digestion in an internal cavity. Food flows directly into this cavity through the mouth. Cells lining the cavity secrete digestive enzymes that break down the food. These very same cells then absorb the smaller chemical compounds produced by digestion.

Other animals have evolved more elaborate digestive systems that allow the transport of food by a long tube that runs from one end of an animal to the other. This tube constitutes an animal's **gut** or **digestive tract**. Food is moved in a single direction through the gut, which contains regions specialized for different functions. These functions include digestion (the mechanical and chemical breakdown of food), absorption of released nutrients, storage, and elimination of waste products.

These various functions take place in the three main parts of the digestive tract: the **foregut**, **midgut**, and **hindgut** (**Fig. 38.13**). Most animals' digestive systems have the same basic plan, though some animals have evolved additional specialized structures, as discussed later in this section. The foregut includes the **mouth**, **esophagus**, and **stomach** or **crop**, which serves as an initial storage and digestive chamber. Next is the midgut, which includes the **small intestine**, where the remainder of digestion and most nutrient absorption takes place. Here, specialized organs secrete enzymes and other chemicals that aid in the breakdown of particular macromolecules, such as carbohydrates and fats. Finally, the digested material reaches the hindgut, which includes the **large intestine** and **rectum**. In the

hindgut, water and inorganic molecules are absorbed, leaving the waste products, or feces. The feces are stored in the rectum until being eliminated from the body.

FIG. 38.13 Organization of animal digestive tracts: foregut, midgut, and hindgut.

Food and its breakdown products move through the gastrointestinal tract by **peristalsis**, waves of smooth muscle contraction and relaxation. These waves keep substances moving from one end of the tract to the other, and help prevent backward movement.

## Digestion begins in the mouth.

Most animals jump-start digestion by breaking down food mechanically through biting and chewing, as we saw in [section 38.3](#). Breaking food into smaller pieces increases the surface area that is exposed to taste buds in the tongue and available for the action of enzymes.

After being ingested and mechanically broken down, the food is ready for chemical digestion, which is carried out by enzymes that break the bonds between the subunits of large molecules. These enzymes require the proper chemical environment to function properly. Some enzymes work best at neutral or near-neutral pH, like that found in the mouth or small intestine. Other enzymes work best in acidic environments, like that found in the stomach.

In some animals, such as mammals, chemical digestion begins in the mouth. Food entering the mouth is mixed with salivary secretions that contain [amylase](#), an enzyme that breaks down carbohydrates, and secretions from the tongue that contain [lipase](#), an enzyme that breaks down lipids ([Table 38.3](#)).

TABLE 38.3 Major Sites of Chemical Digestion of Macromolecules

| MACROMOLECULE | SITE OF DIGESTION | ENZYME           |
|---------------|-------------------|------------------|
| Protein       | Stomach           | Pepsin           |
|               | Small intestine   | Trypsin          |
| Carbohydrate  | Mouth             | Salivary amylase |

|       |                 |                             |
|-------|-----------------|-----------------------------|
|       | Small intestine | Pancreatic amylase, lactase |
| Lipid | Mouth           | Lingual (tongue) lipase     |
|       | Stomach         | Gastric (stomach) lipase    |
|       | Small intestine | Pancreatic lipase           |

The muscular tongue of mammals and other land vertebrates manipulates food and transports it within the mouth cavity. The tongue moves the food into position within the mouth for effective cutting and chewing into smaller pieces by the teeth. When food has been chewed and is ready to be swallowed, the tongue moves it to the rear of the mouth cavity.

Swallowing is a complex set of motor reflexes carried out by several muscles and structures in the rear of the mouth and in the **pharynx**, the region of the throat that connects the mouth and nasal cavity (**Fig. 38.14**). Once initiated, swallowing reflexes are involuntary, under the control of the autonomic nervous system. During swallowing, food is pushed through the pharynx, over the **epiglottis** (a flap of tissue that protects food from entering the trachea and lungs), and into the esophagus (a tube that connects the pharynx to the stomach). In the esophagus, peristalsis moves the food toward the stomach.

FIG. 38.14 Swallowing. Swallowing moves food from the mouth to the stomach.

Birds, alligators, crocodiles, and earthworms break down food into smaller pieces farther along their digestive tracts in the **gizzard**, a compartment with thick muscular walls. Birds and earthworms often ingest small rocks or sediment that help grind the food into smaller pieces within the muscular gizzard. Breaking food into smaller pieces aids the chemical digestion that follows.

## Further digestion and storage of nutrients take place in the stomach.

Digestion, begun in the mouth, continues in the stomach. The stomach is one of the main sites of protein and lipid breakdown. The acidic environment of the stomach facilitates digestion. In addition, several digestive enzymes have evolved to act at the stomach's very low pH, in the range of 1–3. Most enzymes, by contrast, are denatured (that is, unfolded and thus made inactive) in acidic environments.

The stomach is maintained at a low pH through the secretion of hydrochloric acid (HCl) by specific cells lining the stomach. A low pH could damage the stomach when no food is present, so the amount of HCl is carefully regulated. The sight, smell, and taste of food send signals to the brain that stimulate a sense of appetite. Signals from the brain to the stomach then stimulate the secretion of HCl and digestive enzymes that break down proteins and lipids.

When food arrives in the stomach, cells lining the stomach secrete a peptide hormone called **gastrin**. Gastrin stimulates the cells lining the stomach to increase their production of HCl still further. If the pH of the stomach becomes too low, gastrin secretion is inhibited, an example of a negative feedback loop ([Chapter 33](#)).

The stomach has several mechanisms to protect itself from the acidic environment and the action of digestive enzymes. Glands in the lining of the stomach secrete mucus to protect the stomach wall. In addition, cells in the stomach secrete some digestive enzymes in an inactive form; otherwise, the cells themselves would be digested. After their secretion, the inactive enzymes are activated by a change in their chemical structure. The primary digestive enzyme produced in the stomach is **pepsin**, an enzyme that breaks down proteins into amino acids ([Table 38.3](#)). Cells lining the stomach release pepsin in an inactive form called pepsinogen that is activated by the low pH of the stomach. The stomach also secretes lipases that break down lipids ([Table 38.3](#)). Like pepsin, gastric lipase works best in an acidic environment.

Animals often eat large amounts of food in a short time, but it takes much longer to digest that food. Therefore, the stomach serves as a storage compartment as well as a digestion compartment. In humans, it typically takes about 4 hours for the stomach to empty, so digestion and absorption of nutrients occur between meals. In other animals, stomach emptying can take much longer. Most carnivorous animals consume large and infrequent meals that are followed by long periods of digestion and nutrient absorption—much longer than the intervals in humans and other animals that eat more regularly. Snakes such as pythons that engulf large prey whole spend several days digesting and absorbing the nutrients from their meal ([Fig. 38.15](#)). To digest their single large meal, their gut undergoes extensive remodeling that produces new energy-demanding secretory and absorptive cell surfaces. As a result, their metabolic rate increases sharply during digestion. These extra cells are not retained between meals because of the high energy cost of maintaining them.

Source: Biosphoto/Ken Griffiths/Photoshot.

FIG. 38.15 Python and prey. Because the prey is eaten whole, the python's metabolic rate is high during digestion, which takes place over several days.

The stomach walls contract to mix the contents of the stomach, aiding their digestion. Waves of muscular contraction move the food toward the base of the stomach. There, the **pyloric sphincter**, a ring of muscle, opens and allows small amounts of digested food to enter the small intestine. Opening and closing of the pyloric sphincter regulates the rate at which the stomach empties, allowing time for the food products released into the small intestine to be further digested and then absorbed.

## Final digestion and nutrient absorption take place in the small intestine.

After the food enters the small intestine, final digestion of protein, carbohydrates, and fats occurs. The nutrients released by digestion are then absorbed by the body. In addition, the acid produced by the stomach is neutralized to create an environment for the intestinal enzymes to act. The small intestine carries out these functions with the help of two other organs, the **pancreas** and **liver** (**Fig. 38.16**). Signals from the small intestine coordinate the actions of these accessory organs.

FIG. 38.16 The small intestine and associated organs. Digestion in the small intestine is aided by secretions from the liver, gallbladder, and pancreas. The small intestine is the main site of nutrient absorption.

The small intestine is named for its small diameter, but it is actually a long (about 20 feet or 6 m in an adult human) and therefore large organ. Because of its length, the small intestine is coiled to fit within the abdominal cavity. The small intestine is made up of three sections ([Fig. 38.16](#), upper right). Food enters from the stomach into the initial section, the **duodenum**. Most of the remaining digestion takes place in the duodenum. Nutrient absorption also begins in the duodenum, but the majority occurs in the next two sections, the **jejunum** and **ileum**.

The small intestine produces some, but not all, of the digestive

enzymes that act within it. For example, its cells produce lactase, an enzyme that breaks down the sugar lactose into glucose and galactose ([Table 38.3](#)). Lactose is found in milk, so lactase is necessary for newborn mammals to digest milk obtained during suckling.

In humans, the gene that encodes lactase has an interesting evolutionary history. Some people cannot drink milk as adults, a condition called lactose intolerance. In these individuals, the gene that encodes lactase is down-regulated and not expressed after weaning. Other people can continue to drink milk as adults. In these individuals, the gene for lactase continues to be expressed after weaning. Researchers have found that lactase persistence in these individuals is the result of mutations that occurred and then were selected for when cattle were domesticated and milk became part of the diet approximately 10,000 to 5,000 years ago.

Some of the digestive enzymes that act in the small intestine are produced by the pancreas, rather than by the small intestine. The pancreas is an organ that lies below the stomach, near the duodenum ([Fig. 38.16](#)). It secretes enzymes and other molecules into ducts that connect to the duodenum, as well as the hormones insulin and glucagon directly into the blood ([Chapter 36](#)). The pancreas produces a variety of digestive enzymes, including lipase, which breaks down fats; amylase, which breaks down carbohydrates; and **trypsin**, which breaks down proteins ([Table 38.3](#)). Like the stomach, which produces pepsin in an inactive form, the pancreas produces trypsin in an inactive form called trypsinogen to avoid digesting itself. Trypsinogen is converted to trypsin by an enzyme produced by intestinal cells.

The pancreas also secretes bicarbonate ions, which neutralize the acid produced by the stomach. The pancreas is stimulated to secrete bicarbonate ions by the hormone [secretin](#) (the first hormone to be identified). Cells lining the duodenum secrete the hormone in response to the acidic pH of the stomach contents entering the small intestine.

The liver participates in digestion by producing [bile](#), which is composed of bile salts, bile acids, and bicarbonate ions. Bile aids in fat digestion by breaking large clusters of fats into smaller lipid droplets, a process called emulsification. Bile produced by the liver is stored in the [gallbladder](#) ([Fig. 38.16](#)). When fats enter the duodenum, cells lining the duodenum release a peptide hormone called [cholecystokinin \(CCK\)](#), which causes the gallbladder to contract, leading to the release of bile into the duodenum. By breaking up the fats into smaller droplets, bile allows lipases to digest the lipids more effectively.

After large macromolecules have been broken down by digestive enzymes, the smaller molecules produced through this process are ready to be absorbed. The small intestine has highly folded inner surfaces, called [villi](#), and the cells constituting the villi themselves have highly folded surfaces, called [microvilli](#) ([Fig. 38.17](#)). Together, these villi and microvilli greatly increase the surface area available for the absorption of nutrients. Cells that line the small intestine are connected by tight junctions ([Fig. 38.17](#); [Chapter 10](#)) that prevent movement of substances between cells, instead directing the products of digestion to be absorbed across the microvilli surfaces. Membrane transporters can then control their movement through the cell and into the bloodstream.

FIG. 38.17 Intestinal villi and microvilli. These structures increase the surface area for absorption of nutrients.

Hydrophilic nutrient molecules, such as glucose and amino acids, need the help of a carrier protein to cross the plasma membrane into cells lining the intestine. These molecules are often co-transported into cells with sodium ions from gut contents. A sodium ion binds to a transmembrane protein on the surface of cells lining the intestine; this protein also binds the nutrient molecule. Absorption of the nutrient molecule into the cell is driven by the movement of the sodium ion down its concentration gradient ([Fig. 38.18](#)). The concentration of sodium ions inside the cell is kept low by the action of the sodium–potassium pump ([Chapter 5](#)). Molecules such as glucose then move

passively down their concentration gradient out of the intestinal cell toward the blood through channels on the basal side of the cell.

The products of fat digestion—fatty acids and glycerol—are lipid soluble, so they readily diffuse across the plasma membrane into a cell without the assistance of a carrier protein. Eventually they are transported to the bloodstream. There, lipids bind molecules that make them water soluble, allowing for their transport in the aqueous (water-based) blood.

## The large intestine absorbs water and

## stores waste.

Peristalsis moves the contents of the small intestine into the large intestine, or [colon](#), of the hindgut at a pace that allows time for nutrient absorption in the small intestine. By the time the gut contents reach the large intestine, the nutrients have been absorbed into the body, but indigestible wastes, water, and inorganic ions remain. Most of the water and inorganic ions are absorbed in the colon (see [Fig. 38.13](#)), resulting in semisolid feces. Feces are stored in the final segment of the colon, the rectum, until they are periodically eliminated through the anus in the case of most mammals. In other vertebrates, including amphibians, reptiles, birds, and a few mammals, waste is eliminated through the cloaca, which is a shared opening for the digestive, urinary, and reproductive tracts.

Excess water absorption within the colon can cause constipation, whereas too little water absorption can cause diarrhea. Constipation and diarrhea can also be caused by toxins released by microorganisms in the food an animal eats. For example, the bacterium *Vibrio cholera* releases toxins that are the cause of cholera.

As we saw in [Case 5 The Human Microbiome](#), digestion is not a solo endeavor. Large populations of bacteria reside in the small and large intestines and help extract nutrients that the animal's body cannot extract itself. The principal gut resident is *Escherichia coli*, the bacterium commonly used for research in laboratories. As they nourish themselves on the host's gut contents, the various bacteria provide nutrients and certain vitamins, such as biotin and vitamin K, that the animal cannot produce itself. Vitamin deficiency can sometimes result

from prolonged antibiotic medication that kills large numbers of gut bacteria. Another by-product of bacterial action in the gut is gases such as methane and hydrogen sulfide. The mutual benefits to the host animal and the bacteria ensure the success of their symbiotic relationship.

## The lining of the digestive tract is composed of distinct layers.

As we have seen, the digestive tract is not a passive tube. Indeed, it secretes enzymes and other chemical compounds for digestion, absorbs nutrients, and actively moves food through the body. How does a series of tubes accomplish all of this? As shown in [Fig. 38.19](#), the digestive tract is made up of several layers of tissue, each with a specialized function. The central space, or [lumen](#), through which the gut contents travel is surrounded by an inner tissue layer, the [mucosa](#), which both secretes enzymes and absorbs nutrients. The cells of the mucosa secrete mucus to protect the gut wall from digestive enzymes and, in the stomach, from hydrochloric acid. Surrounding the mucosa is the [submucosa](#), a layer containing blood vessels, lymph vessels, and nerves.

Outside these layers are two smooth muscle layers ([Fig. 38.19](#)). The inner [circular muscle](#) layer contracts to reduce the size of the lumen. The outer [longitudinal muscle](#) layer contracts to shorten small sections of the gut. Thus, these two muscle layers contract alternately to mix gut contents, producing a traveling wave during peristalsis that moves the contents along the digestive tract from compartment to compartment. Between the two muscle layers are autonomic nerves that control the contractions of the two sets of smooth muscle.

An outer layer of connective tissue called the [serosa](#) covers and

protects the gut ([Fig. 38.19](#)). The gut is supported in the abdominal cavity by a double membrane called the [mesentery](#). Recently, the mesentery was recognized as an organ in its own right. It helps to hold the intestines in place and provides a passageway for blood vessels and nerves to supply the gut.

## Plant-eating animals have specialized digestive tracts adapted to their diets.

As noted earlier, herbivorous (that is, plant-eating) animals evolved specialized digestive tracts that enhance their ability to digest cellulose and other plant compounds. Animals, including herbivores, lack [cellulase](#), the enzyme that breaks down cellulose. Instead, plant-eating animals have specialized compartments in their digestive tract that contain large bacterial populations, which do produce cellulase. As a result, the bacteria are able to digest the cellulose of plants. This association of herbivores and their gut microbes is another example of a symbiotic relationship.

Rather than the single stomach of other mammals, ruminants (cattle, sheep, and goats) have a four-chambered stomach that is highly specialized to enhance the ability of their gut bacteria to digest plants ([Fig. 38.20a](#)). The first two chambers—the [rumen](#) and the [reticulum](#)—harbor large populations of anaerobic bacteria that break down cellulose. To assist breakdown, the rumen contents are frequently regurgitated (in a process called rumination) for further chewing in the mouth. This repeated chewing decreases the size of the plant fibers, increasing the surface area available for bacterial digestion in the rumen. The bacteria break down cellulose by fermentation, and the

host uses some of the products as nutrients. The site of fermentation in the foregut is the source of the name “foregut fermenters” for these mammals.

Bacterial fermentation produces carbon dioxide and methane gas. The amount of methane produced by domesticated ruminants is second only to the amount produced industrially. Since methane is a greenhouse gas that traps heat from the sun, methane production by cattle, sheep, and other animals contributes to atmospheric increases in methane and global climate change ([Chapters 46](#) and [48](#)).

After leaving the reticulum, the mixture of food and bacteria passes into the third chamber of the ruminant's stomach, the [omasum](#), where water is absorbed. It then enters the [abomasum](#), the last of the four chambers, where protein digestion begins as it does in other mammals. The acid and protease secretions kill the bacteria, and the nutrients are absorbed in the small intestine. The bacteria, too, are an important protein source for the ruminant, yielding as much as 100 g of protein each day for a cow. This role is important because plants are a poor source of protein but contain considerable nitrogen that the bacteria use to synthesize their own amino acids. The bacteria lost to digestion are replaced by the continual reproduction of bacteria in the rumen.

In contrast to the foregut fermentation of cows and sheep, other mammalian herbivores, such as horses, rabbits, and koalas, digest the plant material they eat by hindgut fermentation ([Fig. 38.20b](#)). Hindgut fermentation occurs in the colon and in the [cecum](#), a chamber that branches off the large intestine. Because the fermentation products released from the cecum have already passed through the small intestine, the main site of nutrient absorption, hindgut fermentation is less efficient at extracting nutrients than foregut fermentation.

In humans and other animals such as lemurs and squirrels, the cecum is present but small and includes the [appendix](#), a narrow, tubelike structure that extends from the cecum. The appendix is an example of a [vestigial structure](#), a structure that has lost its original function over evolutionary time and is now much reduced in size. Although the appendix has no clear function in nonherbivorous animals, evidence suggests it may play a role in the immune system

([Chapter 41](#)). The appendix can become infected when partially digested material enters or blocks it. Unless the infected appendix is removed, it can burst, releasing gut contents into the abdominal cavity; such a rupture can be life threatening.

Charles Darwin put forth a hypothesis explaining how the appendix might have evolved to take on its current form in humans. He suggested that in the ancestors of modern humans, the cecum harbored bacteria that aided in the digestion of plant material such as cellulose. However, as their diet became less reliant on plant material, the cecum became smaller and lost its function over time, becoming what we see today as the appendix. Other vestigial structures, such as the remnants of hind limbs in whales, small eyes in cave-dwelling animals, and wings in flightless birds, provide an illuminating window into the past and strong evidence for evolution.

#### Self-Assessment Questions

9. The rocks and sediments in the gizzards of birds break apart food mechanically. Which structures in vertebrates have a similar function?
10. What are the main sites of digestion of protein, carbohydrates, and fats, and which enzymes are involved in breaking down each of these?
11. What are the similarities and differences between foregut and hindgut fermentation?
12. Some animals, such as rabbits, whose digestive systems include hindgut fermentation, re-ingest the products of digestion. What

function do you think this serves?

## CORE CONCEPTS SUMMARY

**38.1 PATTERNS OF ANIMAL METABOLISM:** Metabolic rate depends on activity level, body size, and body temperature.

Animals acquire carbohydrates, fats, and protein from their diet for energy to fuel cellular processes and activities. [page 855](#)

Carbohydrates are broken down rapidly in the cytosol by glycolysis to produce a small amount of ATP in the absence of oxygen. [page 856](#)

Carbohydrates and fats produce large amounts of ATP by aerobic respiration through the citric acid cycle and oxidative phosphorylation. [page 856](#)

An animal's metabolic rate is its overall rate of energy use; this rate can be measured by oxygen consumption over time. [page 857](#)

Metabolic rate increases with increased physical activity. [page 857](#)

Larger animals consume more energy and have higher metabolic rates than smaller ones, but the increase in metabolic rate is less than proportional to mass. [page 858](#)

Endothermic animals maintain elevated body temperature by metabolic heat production and have high metabolic rates. [page 858](#)

Ectothermic animals depend on external heat sources to warm their bodies. They have lower metabolic rates compared to endothermic animals. [page 858](#)

**38.2 NUTRITION AND DIET:** An animal's diet supplies the energy

the animal needs for homeostasis and essential nutrients it cannot synthesize on its own.

An animal is in energy balance when the amount of energy that it takes in is equal to the amount it uses to perform its functions and sustain life. [page 862](#)

Animals must ingest essential amino acids, minerals, and vitamins, those that cannot be synthesized in their cells. [page 862](#)

**38.3 ADAPTATIONS FOR FEEDING:** Animals have evolved different ways to capture food.

Aquatic animals take in food by suspension filter feeding, suction feeding, and active swimming. [page 864](#)

Vertebrates have specialized jaws and teeth for biting and mechanically processing food. [page 865](#)

Carnivorous animals have enlarged canines and slicing molars for catching prey and eating meat. [page 866](#)

Herbivorous animals have molars and premolars with surface ridges that enable them to grind plant matter. [page 866](#)

Many insects have paired mandibles for capturing, holding, and tearing prey. [page 866](#)

**38.4 REGIONAL SPECIALIZATION OF THE GUT:** The digestive tract has regions specialized for digestion, absorption, storage, and elimination.

The animal digestive tract is a long tubelike structure with distinct

regions having different functions. [page 867](#)

Peristalsis mixes and moves food through the gut by means of smooth muscle contraction and relaxation. [page 868](#)

Most animals break down their food into small pieces in the mouth, making it easier to digest. [page 868](#)

Initial chemical digestion of carbohydrates and fat begins in the mouth. [page 868](#)

The stomach stores food and initiates protein and fat digestion through secretions of hydrochloric acid and digestive enzymes, including pepsin. [page 868](#)

Proteins, carbohydrates, and lipids are further broken down in the duodenum of the small intestine, assisted by the secretion of digestive enzymes by the pancreas and of fat-emulsifying bile by the liver. [page 870](#)

Nutrient absorption takes place in the small intestine. [page 870](#)

Nutrient absorption in the small intestine is enhanced by an enlarged surface area provided by villi and microvilli. [page 871](#)

The large intestine absorbs water and inorganic molecules before waste products are eliminated as semisolid feces from the rectum through the anus or cloaca. [page 872](#)

Herbivorous animals have specialized digestive chambers (the rumen and cecum) that enable bacterial fermentation to break down plant cellulose. [page 873](#)

## CHAPTER 39 Animal Renal Systems: Water and Waste

Steve Allen/Getty Images

### CORE CONCEPTS

**39.1 WATER AND ELECTROLYTE BALANCE:** All animals regulate the water and electrolyte levels within their cells.

**39.2 EXCRETION OF WASTES:** Excretory organs eliminate nitrogenous wastes and regulate water and electrolyte levels.

**39.3 THE MAMMALIAN KIDNEY:** The mammalian kidney can produce urine that is more concentrated than blood as an adaptation for living on land.

---

In the 1960s, researchers at the University of Florida developed a new sports drink for players on the football team, the Gators. In addition to water and sugar, the drink contained electrolytes, ions such as sodium ( $\text{Na}^+$ ) and potassium ( $\text{K}^+$ ) that give the solution electrical properties. The researchers who came up with the formula for the drink reasoned that it was important to replace both water and electrolytes lost in sweat. The drink they created, called Gatorade, is now well known.

Water and electrolytes are two key substances that allow cells and organisms to maintain their size and shape, as well as to carry out essential functions. Life originated and diversified in a watery environment. Consequently, the chemical functions of cells and organisms crucially depend on the properties of water ([Chapter 2](#)) and the relative amounts of water and electrolytes inside a cell. In general, the internal environment of a cell, including the concentration of electrolytes, is maintained within a narrow window. The active maintenance of a stable internal environment in the face of a changing external environment is known as [homeostasis](#) ([Chapters 5](#) and [33](#)).

Animals must also maintain homeostasis in terms of the molecules produced by metabolic activity. Metabolism generates wastes that, in many cases, can be toxic to the cell. These wastes must somehow be

eliminated. In most organisms, the elimination of wastes is closely tied to the maintenance of water and electrolyte balance.

In this chapter, we explore the physiological and cellular mechanisms that underlie water and electrolyte balance, as well as waste elimination. We examine how animals meet the demands for water and electrolyte balance in different environments. We also consider how water and electrolyte balance is linked to waste elimination and explore the diversity of excretory organs that animals have evolved to regulate these processes. The organization and function of the mammalian excretory organ, the [kidney](#), is discussed in the last section of the chapter.

## 39.1 WATER AND ELECTROLYTE BALANCE

A healthy person can live for several weeks without food, but cannot survive for more than a few days without water. A loss of more than 10% of body water threatens survival. Homeostasis of water and electrolyte concentration is critical to normal physiological function, not just in humans, but in all organisms.

### Osmosis governs the movement of water across cell membranes.

Water, like all molecules, moves by diffusion, or the random motion of molecules ([Chapter 5](#)). When there is a difference in water concentration between two regions, a net movement of water molecules occurs from the region of higher water concentration to the region of lower water concentration. Water often contains dissolved molecules, such as electrolytes, amino acids, and sugars, which are collectively called [solutes](#). Because we typically describe solutions in terms of the concentration of dissolved solutes, it is sometimes easier to think about water moving from a region of lower solute concentration (higher water concentration) to a region of higher solute concentration (lower water concentration). Whether considered in terms of water concentration or solute concentration, the direction of net water movement is the same.

Sometimes a barrier separates two solutions. When that barrier allows water or solutes to diffuse through it freely, it is said to be permeable. When it blocks the diffusion of water or solutes entirely, it

is described as impermeable. When the barrier allows the movement of some molecules but not others, it is [selectively permeable](#).

In organisms, the plasma membrane of a cell serves as a barrier between solutions, as we saw in [Chapter 5](#). The plasma membrane is a lipid bilayer with embedded proteins. It is selectively permeable: water and smaller solutes can diffuse freely through the membrane, but larger solutes, such as proteins, cannot. Water is able to move to a limited extent through the lipid bilayer by diffusion. However, it moves much more readily through channels called [aquaporins](#) by facilitated diffusion.

The process by which water moves from regions of higher water concentration to lower water concentration across a selectively permeable membrane is called [osmosis](#) ([Fig. 39.1](#)). Consider a situation in which there is a difference in solute concentration on the two sides of a selectively permeable membrane that is freely permeable to water but impermeable to the solute ([Fig. 39.1a](#)). Water moves by osmosis from regions of higher *water* concentration (lower *solute* concentration) to regions of lower *water* concentration (higher *solute* concentration) ([Fig. 39.1b](#)).

FIG. 39.1 Osmosis and osmotic pressure.

The tendency of water to move from one solution into another by osmosis is called **osmotic pressure**. It is the pressure needed to *prevent* water from moving by osmosis across a selectively permeable membrane. The higher the solute concentration, the higher the osmotic pressure of that solution (that is, there is a greater tendency for water to move *into* that solution).

Water movement by osmosis can be prevented by hydrostatic pressure that results from gravity or from the stiffness of the container walls. As water diffuses across a selectively permeable membrane into a region with a higher solute concentration (higher osmotic pressure), the hydrostatic pressure of that solution increases. When osmotic pressure equals hydrostatic pressure, the net movement of water stops and equilibrium is reached ([Fig. 39.1c](#)). At equilibrium, water molecules still move across the membrane in both directions by diffusion, but there is no net movement of water molecules.

Whether water moves by osmosis into or out of a cell depends on

the solute concentration inside of the cell relative to the solute concentration outside of the cell. Similarly, whether water moves by osmosis into or out of an organism depends on the solute concentration inside an animal relative to its environment, as well as the permeability to water of the sheets of cells that make up the skin and other surfaces exposed to the environment.

Note that water movement is driven by differences in *total* solute concentration between the two sides of a cell membrane. That is, if a particular electrolyte such as potassium is present in a high concentration inside the cell and in a low concentration outside the cell, but another electrolyte, such as sodium, has exactly the opposite distribution, there will be no net water movement because the total concentrations of the solutes on the two sides of the membrane are the same.

Also note that water moves across selectively permeable membranes in response to concentration differences of *any* solute. That is, the solute can be an electrolyte, such as sodium, or a dissolved molecule, such as glucose, an amino acid, or even waste, as long as the membrane is impermeable to it.

## Osmoregulation is the control of osmotic pressure inside cells and organisms.

Animals on Earth can survive in a wide range of environments by adopting different means of osmoregulation. [Osmoregulation](#) is the

regulation of osmotic pressure. It can be thought of as the regulation of water content, which keeps internal fluids from becoming too concentrated (high osmotic pressure) or too dilute (low osmotic pressure).

Osmoregulation, like energy balance ([Chapter 38](#)), is a form of homeostasis. High osmotic pressure inside a cell can lead to damage, sometimes even causing the cell to burst. Low osmotic pressure can lead to dehydration. Although cells and tissues can tolerate some degree of dehydration, often as high as 50% or more, excessive dehydration impairs a cell's metabolic function. Many chemical reactions depend on the presence of water, such as hydrolysis reactions that break down proteins and nucleic acids into individual subunits.

How do cells control their internal osmotic pressure? We have seen that water follows solutes across selectively permeable cell membranes. To regulate water and solute levels, and hence the osmotic pressure inside cells, the cell controls the solute concentration inside the cell relative to the solute concentration outside the cell. At the level of the cell, then, osmoregulation is achieved by the movement of solutes, particularly electrolytes.

At the level of the organism, osmoregulation is achieved by balancing input and output of water and electrolytes. Let's first consider how animals gain and lose water. Both terrestrial and freshwater animals gain water by drinking water that is less concentrated in solutes (hypotonic) than their body fluids. Animals also gain water through the food they eat. Finally, animals produce water as

a product of cellular respiration ([Chapter 7](#)). This is the primary source of water for some animals that have become adapted to deserts and oceans, where drinkable water is not readily available. Animals lose water in their urine and feces. Terrestrial animals lose water through evaporation from their lungs, and, in the case of humans, by sweating. Freshwater fishes gain water through their gills, whereas most marine fishes lose water through their gills.

Now let's consider how animals gain and lose electrolytes. Animals gain electrolytes in the food they eat. Marine animals gain electrolytes by drinking salt water, which has a higher solute concentration than their body fluids. Marine animals also gain electrolytes as hypertonic water moves across their gills. In contrast, freshwater animals lose electrolytes through diffusion across their gills into the hypotonic watery environment. Humans lose electrolytes as well as water when they sweat. Drinking beverages high in electrolytes is helpful before engaging in demanding physical activities—including sports—because sweating during these activities can result in substantial water and electrolyte loss. Electrolytes are also lost by specialized glands (discussed later in this chapter) and in urine and feces.

Given these inputs and outputs, there are two ways in which animals maintain homeostasis of water and electrolytes: by matching their internal osmotic pressure to that of their external environment or by using energy to maintain an internal osmotic pressure different from that of their external environment.

## Osmoconformers match their internal

## solute concentration to that of the environment.

Some animals keep their internal fluids at the same osmotic pressure as the surrounding environment. These animals are called [osmoconformers](#). Because the solute concentrations inside and outside their bodies are similar, osmoconformers do not spend a lot of energy regulating osmotic pressure. However, they must adapt to the solute concentration of their external environment. Osmoconformers tend to live in environments that have stable solute concentrations, such as seawater, because maintaining stable internal solute concentrations is easier in stable environments.

Although osmoconformers generally match the overall concentration of solutes within their tissues with the overall concentration of solutes in their external environment, they often expend energy to regulate the concentrations of particular ions, such as sodium, potassium, and chloride, and particular molecules, such as amino acids and glucose. For example, whereas the intracellular space of nearly all animals has a relatively high concentration of potassium ions and a low concentration of sodium ions, the extracellular space has concentrations that are just the opposite: it is low in potassium and high in sodium. This means that these cells are actively pumping sodium out and potassium in ([Chapter 5](#)).

Most marine invertebrates, such as sea stars, mussels, lobsters, and scallops, are osmoconformers. These organisms maintain high concentrations of sodium and chloride in their cells to achieve an overall solute concentration close to that of seawater. Consequently,

they have few specializations for osmoregulation beyond the need to regulate specific internal ion concentrations relative to their environment. Some marine vertebrates, such as hagfish and lampreys, are also osmoconformers that maintain high internal concentrations of particular electrolytes.

Other osmoconformers, including sharks, rays, and coelacanths, match seawater's solute concentration by maintaining a high internal concentration of a compound called urea. Urea is a waste product of protein metabolism that many animals excrete, thereby ensuring it does not build up to high concentrations ([section 39.2](#)). By retaining this solute, these marine vertebrates are able to achieve osmotic equilibrium with the surrounding seawater.

## Osmoregulators have internal solute concentrations that differ from that of their environment.

The second way in which animals achieve water and electrolyte homeostasis is by maintaining an internal solute concentration that is different from that of the environment. The animals that rely on this mechanism are called [osmoregulators](#). Osmoregulators expend considerable energy pumping ions across cell membranes to regulate the movement of water into or out of their bodies. Some freshwater and marine fishes that are osmoregulators are estimated to expend 50% of their resting metabolic energy on osmoregulation. However, the ability to regulate osmotic pressure allows osmoregulators to live in diverse environments—in salt water, in fresh water, and on land.

Teleosts (also called bony fishes; they are the largest group of marine vertebrates) are osmoregulators. So are all freshwater and terrestrial animals. Marine bony fishes maintain concentrations of electrolytes much lower than those in the surrounding seawater, whereas freshwater fishes and amphibians maintain concentrations that are higher than those in the surrounding fresh water.

Let's consider how osmoregulators achieve osmotic balance in salt water, in fresh water, and on land. In salt water, marine organisms live in an environment that is hypertonic relative to their internal fluids, such as blood and the cytoplasm of the cell. These organisms maintain internal electrolyte concentrations lower than that of the surrounding salt water. As a consequence, they face the problem of water loss (across their gills, as well as in their urine and feces) and electrolyte gain (across their gills and in seawater that they drink). To manage this balance, they need to take in as much water as possible and eliminate excess electrolytes. They obtain water primarily through the food they eat and cellular respiration. They avoid water loss by producing concentrated urine (discussed in [section 39.2](#)).

Bony fishes have evolved specialized gills that allow them both to excrete excess electrolytes and to breathe. The thin gill filaments, with their extensive surface area, are useful sites for electrolyte transport out of the body in addition to being well adapted for gas exchange ([Fig. 39.2](#)). Specialized chloride cells in the gills pump chloride ions into the surrounding seawater. By pumping these negatively charged ions out of the body, the chloride cells create an electrical gradient that is balanced by positively charged sodium ions moving out of the body as

well ([Fig. 39.2a](#)).

In fresh water, the environment is hypotonic relative to an organism's internal fluids. In this case, the problem is just the opposite of that faced by marine organisms: water gain and salt loss. To deal with this challenge, freshwater organisms tend to minimize their water intake and maximize water elimination. For example, in contrast to marine fishes, they do not drink water. In addition, freshwater fishes produce very dilute urine (discussed in [section 39.2](#)).

To maintain electrolyte concentrations higher than that of the surrounding water, freshwater fishes have gill chloride cells with reversed polarity relative to marine bony fishes. Their chloride cells pump chloride ions (with sodium ions following) into the body to counter their ongoing loss from the gills into the surrounding fresh water ([Fig. 39.2b](#)).

Nearly all amphibians also live in freshwater environments, so they face challenges similar to those experienced by freshwater fishes. To maintain homeostasis, amphibians take up electrolytes across their skin and produce dilute urine.

On land, the challenge is water loss. Terrestrial animals lose water in their urine and feces, through evaporation from their lungs, and, in humans, by sweating. To counter these losses, they drink water that is hypotonic relative to their body fluids. They also acquire water by eating food and by producing water during cellular respiration. Finally, terrestrial animals produce concentrated urine to minimize their water loss.

Many marine birds have evolved specialized nasal salt glands to rid themselves of the high salt content obtained through their diet ([Fig. 39.3](#)). These salt glands actively pump ions from the blood into the cells that make up the gland; the birds then excrete salt from their bodies through this gland and the nasal cavity. Their salt glands allow the birds to gain net water intake by drinking seawater. In contrast, humans and many other animals not adapted to marine life are incapable of deriving useful net water gain by drinking seawater because they cannot eliminate salt in high enough concentrations. The high concentration of magnesium sulfate in seawater results in diarrhea if too much seawater is consumed, exacerbating the net loss of water in the feces.

An extreme example of the ability of an animal to regulate water and electrolyte levels is provided by the life cycle of salmon. Mature salmon swim in the salt water of the open ocean but return upriver to spawn in fresh water. During the course of their return, they swim from high-salt ocean water through water of intermediate saltiness into freshwater rivers and streams that have little salt. After spawning, the young feed and grow in fresh water for up to 3 years, eventually returning to the open ocean, where they live until they become reproductively mature and return to their home river system to spawn again.

These changes in aquatic habitat demand that salmon make dramatic

adjustments in the way they handle water and solutes. When in the ocean, salmon must avoid loss of water and uptake of electrolytes. The challenge is reversed when mature salmon migrate upriver to spawn and as young salmon continue to grow in freshwater streams and rivers: they must avoid gaining too much water and losing critical electrolytes across their gills. In salmon, radical changes in osmoregulation are required over the course of an animal's lifetime to enable it to reproduce in freshwater streams and return to the sea for further growth and maturation. Next, we explore how gills and kidneys meet these challenges.

#### Self-Assessment Questions

1. Given a selectively permeable membrane that is permeable to water but not to a particular solute, and given that there are different solute concentrations on the two sides of the membrane, draw a diagram showing the direction of water movement. Label the side with the higher osmotic pressure.
2. What happens when a cell is placed in a hypotonic solution (one with a solute concentration lower than that of the cell)? What happens when a cell is placed in a hypertonic solution (one with a solute concentration higher than that of a cell)?
3. A solution of water and dissolved ions is separated by a selectively permeable membrane that allows the passage of water but not small ions. The concentration of sodium is higher on one side of the membrane than on the other side. However, there is no net movement of water across the membrane. How is this possible?

4. How do animals gain and lose water and electrolytes?
5. Name two animals that are osmoconformers and two animals that are osmoregulators. What is the difference between the two types of animals?

## 39.2 EXCRETION OF WASTES

In most organisms, the regulation of water and solute levels is closely tied to waste excretion. Excretion is the elimination of waste products and toxic compounds from the body. Some of these wastes are generated as by-products of metabolism, particularly protein and nucleic acid breakdown. Others were originally ingested, like the undigested remains of food.

Most animals have evolved specialized excretory organs, such as the vertebrate kidney, to isolate, store, and eliminate toxic compounds and metabolic waste products. Because these compounds are eliminated as solutes that have been dissolved and transported within the blood or other body fluids, their elimination from the body is intimately tied to water and electrolyte balance. The excretory organs of most animals therefore have two functions: they maintain water and electrolyte balance and they eliminate waste products.

Both the gastrointestinal tract ([Chapter 38](#)) and excretory organs like the vertebrate kidneys eliminate wastes from the body. However, the gastrointestinal tract is continuous with the outside world, so its role in the elimination of wastes is quite different from that of excretory organs that separate toxic compounds from essential nutrients, electrolytes, and cells circulating in the blood.

**The excretion of nitrogenous wastes is linked to an animal's habitat and evolutionary history.**

When proteins and nucleic acids are broken down, one of the by-products is ammonia ( $\text{NH}_3$ ). Ammonia contains nitrogen and is toxic to organisms, so it is a form of **nitrogenous waste** (**Fig. 39.4**). By far, most ammonia is produced from the breakdown of proteins. Ammonia can disturb the pH balance of cells and damage neurons. At high levels, it is lethal to organisms. It is either eliminated from the body or converted into a less toxic form.

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

FIG. 39.4 Nitrogenous waste. Animals excrete nitrogenous waste in three major forms—ammonia, urea, and uric acid—that vary in their toxicity and cost to produce.

Some organisms, such as fishes, are able to excrete ammonia directly into the surrounding water, primarily through their gills. As a result, ammonia does not accumulate to toxic levels in their bodies. This process is not energetically expensive, but it requires high volumes of water in the surrounding environment to dilute the highly toxic ammonia.

When animals moved from water to land, they faced the challenge of how to eliminate waste. No longer could they rely on simple diffusion of ammonia into the surrounding water. Instead, they evolved biochemical pathways to convert ammonia to less toxic forms. One of these forms is urea ([Fig. 39.4](#)). Because urea is less toxic than ammonia, it can be stored in a fairly concentrated form before being excreted. Mammals (including humans), many amphibians, sharks, and some bony fishes excrete nitrogenous waste in the form of urea. In mammals, urea is produced in the liver and carried by the blood to the kidneys, from which it is eliminated. Urea is less toxic than ammonia but requires energy to produce and water to eliminate.

Ammonia can also be converted into uric acid ([Fig. 39.4](#)). Uric acid is the least toxic of the three forms of nitrogenous waste, so animals can store it at a higher concentration than urea. Birds and many reptiles, arthropods (including insects), and land snails excrete nitrogenous waste in the form of uric acid. These groups evolved the

ability to convert ammonia to uric acid independently of one another as an adaptation to living on land, providing a good example of convergent evolution ([Chapter 22](#)). Uric acid precipitates from solution and forms a semisolid paste (familiar as bird droppings). Because this uric acid is not dissolved in water, it does not exert osmotic pressure and is eliminated with minimal water loss. By limiting water loss, many reptiles and insects are able to live in extremely hot and dry environments. However, uric acid is energetically expensive to produce.

Many amphibians, including frogs, excrete ammonia early in their development, when they live in water, then excrete urea when they move onto land after metamorphosis. Alligators and turtles also adjust what they excrete: ammonia when in the water and uric acid when on land.

Ammonia, urea, and uric acid are the three major forms of nitrogenous wastes, but they are not the only forms. Animals excrete nitrogen as trimethylamine oxide, creatine, creatinine, and even amino acids. The form of nitrogenous waste that an animal excretes is ultimately linked to its environment and evolutionary history.

## Excretory organs work by filtration, reabsorption and secretion.

Organisms eliminate waste and other compounds from the blood through two mechanisms: filtration and secretion. [Filtration](#) is the process by which the blood is passed into an extracellular space, with some substances being allowed to pass through the blood vessel wall

into the space but others being retained in the blood. [Secretion](#) is the active transport of molecules from the blood into the extracellular space. Filtration is energetically inexpensive and can be used to remove novel compounds, but it also removes compounds that the body needs, such as water, electrolytes, and essential nutrients. Secretion is specific but energetically expensive.

Initially, filtration is used to isolate most wastes, but [reabsorption](#) is required to retain filtered compounds that the body needs. Reabsorption is the process by which essential molecules are transported back into the blood. Reabsorption and secretion together help to balance water and electrolyte levels, producing dilute or concentrated urine as required by the animal.

The first step of excretion is to isolate the waste into an extracellular space. In the case of unicellular organisms such as *Paramecium* and simple multicellular organisms such as sponges and cnidarians (jellyfish and sea anemones), wastes are isolated in a cellular compartment called a [contractile vacuole](#) ([Fig. 39.5](#)). Fusion of the contractile vacuole with the cell membrane eliminates the waste contents by exocytosis from the cell ([Chapter 5](#)).

Source: Michael Abbey/Science Source.

FIG. 39.5 Contractile vacuole of a paramecium when (a) full and (b) after emptying.

Animals with pressurized circulatory systems (annelid worms, mollusks, and vertebrates) isolate wastes from the blood by filtration ([Fig. 39.6](#)). Circulatory pressure pushes fluid containing the wastes through specialized filters into an extracellular space. The filtered fluid, called the filtrate, contains waste products along with water, electrolytes, and other solutes. The filtrate drains into [excretory tubules](#) that connect to the outside. The excretory filter, like a cell's plasma membrane, is selectively permeable. It allows smaller ions and solutes to pass into the tubule along with water, but retains larger solutes such as proteins and cells.

FIG. 39.6 Filtration, reabsorption, and secretion. These three processes eliminate wastes and provide osmoregulation in animals with pressurized circulatory systems.

Filtration is followed by reabsorption of key ions and solutes from the filtrate into the blood ([Fig. 39.6](#)). Cells lining the excretory tubule take up substances that are needed by the animal, such as electrolytes, amino acids, vitamins, and simple sugars, and return them to the bloodstream. Reabsorption can be an active process, requiring active transporters for some molecules, or it can be a passive process involving diffusion for other molecules. Water is reabsorbed into the cells by osmosis, driven by the osmotic pressure established by the active transport of solutes into the cell.

The final step in waste removal is the secretion of additional toxic

compounds and excess ions ([Fig. 39.6](#)). Secretion is an active process, carried out by protein transporters in the plasma membranes of cells lining the tubules. Using the energy of ATP, these transporters pump molecules and ions from the blood into the excretory tubules. Secretion eliminates substances that were not filtered from the blood, and it helps to fine-tune electrolyte levels in the blood.

In summary, filtration, reabsorption, and secretion are the three steps that almost all animal excretory systems perform to eliminate toxic wastes, retain essential nutrients, and regulate water and electrolyte levels.

## Animals have diverse excretory organs.

As we have seen, the processes of filtration, reabsorption, and secretion serve two important and complementary functions: they isolate wastes that are then removed from the body, and they allow the organism to adjust the amounts of water and electrolytes required to meet its osmoregulatory needs. These two functions are carried out by diverse excretory organs adapted to the needs of specific organisms.

Consider waste excretion in flatworms, small flattened animals that glide along the streambed floor. Flatworms have no pressurized circulatory system, so waste is excreted without being filtered: the fluid from the body cavity is isolated in excretory organs called [protonephridia](#) ([Fig. 39.7](#)). Cells with beating cilia move the fluid down the lumen of a tubule to an excretory pore. Freshwater flatworms, such as *Planaria*, have an extensive network of tubules that

eliminate excess fluid along with waste products. As the fluid passes down the tubule, cells lining the tubule modify the fluid's contents through reabsorption and secretion. As is typical of freshwater animals, the urine leaving a freshwater flatworm is less concentrated (that is, more dilute) than its internal body fluids to balance the water the animal ingests as it feeds.

Segmented annelid worms such as earthworms do have a

pressurized circulatory system. In this case, the blood is filtered through small capillaries into a pair of excretory organs called **metanephridia** within each body segment (**Fig. 39.8**). The filtrate enters a metanephridium at a funnel-shaped opening surrounded by cilia. The cilia direct the filtrate into a series of tubes in the next body segment and then out of the animal through an excretory pore. Blood vessels and cells surrounding the tubules reabsorb and secrete additional compounds as urine is formed. Like freshwater flatworms, earthworms reabsorb electrolytes and eliminate dilute urine containing dissolved nitrogenous wastes.

FIG. 39.8 Excretory organ of an earthworm.

In insects and other terrestrial arthropods, body fluid called hemolymph passes from the main body cavity into a series of tubes called **Malpighian tubules** that empty into the hindgut (**Fig. 39.9**). The cells lining the tubules actively secrete uric acid and excess electrolytes into the lumen of the tubules while retaining key solutes. Muscle fibers in the walls of the tubules help push the fluid to the hindgut. In the hindgut, the fluid becomes increasingly acidic as uric acid builds up, causing uric acid to precipitate from solution when it enters the rectum.

Because uric acid is removed from the fluid, it does not influence the movement of water. Water is therefore free to diffuse back into the tissues as electrolytes are reabsorbed from the rectum. The uric acid and remaining dried digestive wastes are then eliminated. Malpighian tubules are one of the most successful adaptations for excreting nitrogenous wastes with minimal water loss. They enable insects to live in diverse terrestrial environments, including some extremely arid areas.

## Vertebrates filter blood under pressure

## through paired kidneys.

The excretory organs of vertebrates are the kidneys. Like all excretory organs, they both eliminate wastes and play an important role in maintaining water and electrolyte balance. Moreover, vertebrate kidneys reflect the evolutionary transition of vertebrates from water to land, where there is a need to minimize water loss. Mammals and birds, for example, can excrete urine that is more concentrated in solute than their blood and tissues.

The kidneys lie posterior to the abdominal cavity. The kidneys of humans and other mammals are bean-shaped, whereas the kidneys of birds and other vertebrate animals are elongated and segmented ([Fig. 39.10](#)). Vertebrate kidneys receive blood from the heart through paired renal arteries (“renal” means “relating to the kidneys”) that branch from the abdominal aorta.

FIG. 39.10 Location and shape of kidneys in different vertebrates.

Vertebrates filter their blood through specialized capillaries that have openings in their walls. These porous capillaries form a tufted loop called a **glomerulus** (Fig. 39.11). There are thousands to millions of glomeruli in each kidney. Driven by circulatory pressure, nitrogenous wastes, electrolytes, other small solutes, and water move through small holes in the capillary walls into an extracellular space surrounded by a capsule (called Bowman's capsule after the surgeon William Bowman, who identified it in 1842). The filtrate then moves through a series of **renal tubules**, which further process the filtrate by reabsorption and secretion. Finally, the filtrate enters the **collecting ducts** as urine. The collecting ducts converge on a larger tube called the **ureter**, which brings urine from the kidneys to a hollow organ called the **bladder** for storage and elimination from the body.

FIG. 39.11 Vertebrate kidney and nephron.

The glomerulus, capsule, renal tubules, and collecting ducts make up a **nephron**, the functional unit of the kidney. Nephrons perform the three basic steps of excretion and osmoregulation: filtration of blood passing through the glomerulus, reabsorption of key electrolytes and solutes from the renal tubule and return of these substances to the bloodstream, and secretion of additional wastes and electrolytes by cells lining the renal tubules.

In saltwater and freshwater fishes, the kidneys run along the length of the body, and the nephrons are arranged segmentally. Because fishes excrete nitrogenous waste in the form of ammonia through their gills, the kidney is primarily an organ of water and electrolyte balance rather than one of waste elimination. Recall that saltwater and freshwater fishes face different challenges in achieving water balance. Saltwater fishes must eliminate excess electrolytes that enter through their gills and in the seawater that they drink, whereas freshwater fishes must

eliminate excess water that enters through their gills. In saltwater fishes, the walls of the renal tubules are readily permeable to water: water diffuses out of the tubule by osmosis, and the urine that remains is relatively concentrated (high concentration of electrolytes and low concentration of water). By contrast, the walls of the renal tubules in freshwater fishes are relatively impermeable to water, but readily allow reabsorption of electrolytes, sugars, and amino acids. Because water is retained in the tubules, freshwater fishes excrete very dilute urine, thereby eliminating the excess water that continually enters their bodies through their gills.

The kidneys of amphibians are similar to those of freshwater fishes. Amphibians take in excess water across their gills and skin as they breathe. Amphibian kidneys therefore produce extremely dilute urine, enabling them to maintain an electrolyte concentration in their body that exceeds that of their freshwater environment.

Reptiles are found in a variety of habitats, from oceans to deserts, and are well adapted to their environments. Marine iguanas, for example, ingest salt water with their food, so they rely on specialized salt glands to eliminate excess electrolytes from their body. Terrestrial reptiles living in desert regions with limited water availability face the challenge of minimizing water loss. Because reptiles excrete nitrogenous waste in the form of uric acid, they are able to reabsorb most of the water from the urine.

Mammals also live on land, but they excrete most of their nitrogenous waste in the form of urea dissolved in water. Their kidneys

are well adapted for excreting waste and balancing their water and electrolyte levels, as we discuss in the next section.

#### Self-Assessment Questions

6. What are three forms of nitrogenous waste? How is each an adaptation for the environment in which an animal lives?
7. Why do mammals convert ammonia to urea rather than simply excreting it, as fishes do?
8. What are the three steps in which animals excrete wastes?

## 39.3 THE MAMMALIAN KIDNEY

Mammals excrete urea dissolved in solution, but they must be able to do so without losing too much water, an adaptation to living on land. To minimize the loss of water, they remove water from the waste-containing fluid by osmosis as it moves through the kidney. In this way, the urine is concentrated without the kidney ever actively transporting water itself.

The cells of the kidneys are surrounded by a solution called interstitial fluid. Mammals concentrate their urine by generating concentrated (hypertonic) interstitial fluid deep in the kidney, through which the collecting ducts pass. Then, as the filtrate passes through the collecting ducts, water moves out of collecting ducts and into the interstitial fluid by osmosis, leaving concentrated urine in the collecting ducts.

This process, which is quite efficient, allows animals to thrive in diverse environments. For example, the giant kangaroo rat shown in [Fig. 39.12](#) is a desert mammal; it reabsorbs so much water that it does not need to drink. It can obtain enough water from seeds and cellular respiration. The giant kangaroo rat is thought to produce the most concentrated urine of all mammals. Marine mammals, such as whales, dolphins, and seals, also have an exceptional ability to concentrate their urine. They can remain at sea for long periods of time, but cannot drink seawater for net water uptake. They, too, rely on water produced by cellular respiration in combination with water in the food they eat to

remain hydrated.

Source: Tom McHugh /Science Source.

FIG. 39.12 A giant kangaroo rat (*Dipodomys ingens*). Giant kangaroo rats do not drink water. Instead, they obtain water through cellular respiration and from the seeds they eat, which contain small amounts of water.

In this section, we examine the mammalian kidney in more detail. The kidneys of birds share many features with those of mammals. These features arose independently in birds and mammals. Thus they are the result of convergent evolution, presumably occurring as adaptations for efficient processing of wastes in endothermic vertebrates with high metabolic rates ([Chapter 38](#)).

## The mammalian kidney has an outer cortex and inner medulla.

The paired kidneys of mammals are organized into two layers: an outer layer called the [cortex](#) and a deeper layer, surrounded by the cortex, called the [medulla](#) ([Fig. 39.13](#)). Large numbers of nephrons are organized into wedge-shaped pyramids. Each nephron's glomerulus is located within the renal cortex or outer layer of the medulla and feeds into a renal tubule that starts in the renal cortex, then dips into the

medulla at the base of the pyramid, and finally loops back up to the cortex. The renal tubules drain into the collecting ducts. Those ducts also descend into the pyramid's base, emptying into the renal pelvis and draining through the ureter into the bladder.

## Glomerular filtration isolates wastes carried by the blood along with water and small solutes.

Blood is filtered as it passes through the tuft of capillaries forming the glomerulus. Blood enters the glomerulus by an afferent (“toward”) arteriole and leaves by an efferent (“away”) arteriole ([Fig. 39.14](#)). The tuft of capillaries is encased in a membranous sac called [Bowman’s capsule](#), and the space enclosed by the capsule is called Bowman’s space. The capillary wall and Bowman’s capsule together act as the filter: water, wastes, and solutes from the blood pass through the capillary wall and capsule into Bowman’s space.

FIG. 39.14 The mammalian glomerulus and Bowman's capsule. Three layers create the filter: endothelial cells, basal lamina, and podocytes.

To filter the blood, the capillaries of the glomerulus have a different structure from that of capillaries elsewhere in the body. The cells that line the capillaries, known as endothelial cells, have pores called fenestrae (a term that means “windows”) that allow fluid to pass through. The filtration barrier of the glomerulus is made up of three layers ([Fig. 39.14](#)): the endothelial cells, a basal lamina, and a layer of cells with footlike projections called **podocytes**, which loosely interlock to create slits in the cell layer. Together, these three layers create a filter that allows small molecules to pass through but blocks the passage of large proteins and cells, so that they remain in the blood. As a result, wastes such as urea, as well as water and solutes such as electrolytes, glucose, and amino acids, all end up in the filtrate. After passing into Bowman's space, the filtrate enters the renal tubule.

# The proximal convoluted tubule reabsorbs solutes by active transport.

The renal tubule of the mammalian kidney is divided into three sections: the **proximal convoluted tubule**, the **loop of Henle**, and the **distal convoluted tubule** (Fig. 39.15). Although the renal tubule is one long tube, these three sections are specialized for different functions because they are permeable to different substances.

FIG. 39.15 The organization of the mammalian renal tubules and collecting

duct.

The filtrate initially moves into the first portion of the renal tubule, the proximal convoluted tubule ([Fig. 39.15](#)). Here, electrolytes and other nutrients that the animal requires are reabsorbed into the blood. To maximize absorption, the proximal convoluted tubule has thick walls composed of epithelial cells with fingerlike projections called [microvilli](#) on their surfaces, similar to those found in the small intestine ([Chapter 38](#)). The microvilli form a brush border along the inside (lumen) of the tubule, greatly increasing the surface area available for solute and water reabsorption. The epithelial cells also possess numerous mitochondria that produce the ATP needed to actively reabsorb solutes from the filtrate into the bloodstream.

The proximal tubule reabsorbs all the glucose and amino acids filtered by the glomerulus, as well as most sodium and chloride ions. Because the proximal tubule is permeable to water, water diffuses by osmosis in the same direction as the electrolytes and solutes. By the time the filtrate leaves the proximal convoluted tubule, approximately 75% of the water, along with most of the electrolytes and solutes, has been reabsorbed into the bloodstream. What is left is primarily water, urea, and electrolytes.

**The loop of Henle acts as a countercurrent multiplier to create a concentration gradient from the cortex to the medulla.**

The proximal convoluted tubule connects to the loop of Henle, the second portion of the renal tubule ([Fig. 39.15](#)). Although many nephrons contain short loops of Henle that are confined to the renal cortex, others descend all the way into the medulla before looping back up to the cortex. These longer loops of Henle play an important role: they create a concentration gradient in the interstitial fluid from the cortex to the medulla, so that the interstitial fluid of the cortex is less concentrated in solutes and the interstitial fluid of the medulla is more concentrated in solutes. This concentration gradient allows water passing through the downstream collecting duct to be reabsorbed by osmosis, producing concentrated urine.

How is the gradient generated? The key to understanding how the loop of Henle creates a concentration gradient is to recognize that the two limbs of the loop of Henle run in parallel but opposite directions, and that they differ in their permeability to water and ability to actively transport electrolytes out of the tubule. Although the filtrate enters the descending limb before looping around to the ascending limb, it is easier to consider the ascending limb first.

The thick portion of the ascending limb of the loop of Henle is impermeable to water but not electrolytes ([Fig. 39.16](#)). As the filtrate moves up the thick ascending limb of the loop of Henle, electrolytes are actively transported out of it into the surrounding interstitial fluid. As a result, the interstitial fluid becomes more concentrated, and the filtrate passing through the ascending limb becomes less concentrated.

FIG. 39.16 The mammalian nephron. The loop of Henle creates a concentration gradient, with higher concentration in the medulla and lower concentration in the cortex.

In contrast to the ascending limb, the descending limb is permeable to water. Water moves passively out of the descending limb, driven by osmosis due to the electrolytes pumped into the interstitial fluid by the ascending limb. As water moves out of the descending limb, the filtrate becomes increasingly more concentrated, matching the concentration in the surrounding interstitial space. We have already seen that, as electrolytes are pumped out of the thick ascending limb, the filtrate becomes less concentrated. Thus, the filtrate enters and leaves the loop of Henle at approximately the same concentration. Although the filtrate concentration is unchanged, the trip around the loop creates a concentration gradient in the interstitial fluid surrounding the loop of

Henle. Notably, fluid in the inner medulla is much more concentrated than fluid in the outer cortex.

The gradient results from the combination of active transport of electrolytes in the ascending limb, osmosis of water in the descending limb, and the movement of the filtrate through the loop of Henle. The filtrate is most concentrated at the base of the loop, and the concentration of solutes inside and outside the loop is roughly the same, leaving the medulla more concentrated than the cortex.

In [Chapter 37](#), we saw how the movement of water and blood in opposite directions in fish gills provides an efficient way to extract oxygen from the water and move it into the blood. This mechanism, called countercurrent exchange, is an efficient mechanism by which two fluids can exchange properties such as amount of oxygen. In the loop of Henle, active transport of electrolytes creates a concentration gradient, which is then multiplied because the descending and ascending limbs move in parallel but opposite directions. This system is known as a [countercurrent multiplier](#). While countercurrent exchangers maintain a concentration gradient, countercurrent multipliers generate them.

Typically, a high concentration of solutes in the interstitial fluid would be quickly lost as water flows out of blood vessels by osmosis. To avoid dissipating the concentration gradient, the blood vessels in the kidneys are organized in a unique pattern. The blood vessels, collectively called the [vasa recta](#), have descending and ascending vessels arranged in a countercurrent organization, similar to the loops

of Henle ([Fig. 39.17](#)). The blood within these vessels flows down into the medulla in one arm and back up through the cortex in the other. This arrangement maintains the concentration gradient. Blood flowing from the cortex to the base of the kidney encounters increasingly concentrated interstitial fluid, allowing water to diffuse passively out of the blood. The ascending vessels, which pass nearby, reabsorb the water. In effect, water passes straight from one arm of the vasa recta to the other, so the interstitial fluid and the bloodstream have no net gain or loss of water.

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

FIG. 39.17 Vasa recta. The blood in the vasa recta moves in a countercurrent fashion, just like the filtrate in the loop of Henle, to maintain the concentration gradient from the cortex to the medulla.

The generation of a concentration gradient by a countercurrent multiplier in the loop of Henle is a key step in producing urine that is more concentrated than the blood. It was first proposed by the Swiss chemist Werner Kuhn in the 1950s. Although his hypothesis was initially met with skepticism, experimental work confirmed its predictions ([Fig. 39.18](#)).

#### HOW DO WE KNOW?

### FIG. 39.18

## How does the mammalian kidney produce concentrated urine?

#### BACKGROUND

The mammalian kidney can produce urine that is more concentrated than the blood. How it concentrates urine was one of the most perplexing problems in renal physiology.

#### HYPOTHESIS

One hypothesis is that the kidney actively transports water out of the collecting ducts as the filtrate leaves the kidney. Another hypothesis, first suggested by the Swiss chemist Werner Kuhn in the early 1950s, is that the loop of Henle creates a concentration gradient in the interstitial fluid surrounding the collecting ducts from the cortex to the medulla by a countercurrent multiplier mechanism. According to this model, the solute concentration of the interstitial fluid is low in the cortex and high in the medulla, so water leaves the collecting ducts passively as the filtrate moves from the cortex to the medulla.

#### PREDICTION

Kuhn's hypothesis predicts that the solute concentrations of fluid taken at the same level from the medulla, loop of Henle, and collecting ducts

should be similar to one another, and higher than that of the blood. If, instead, water is simply pumped out of the collecting ducts, then the fluid in the collecting ducts should be more concentrated than the fluid in the loop of Henle.

#### EXPERIMENT

American physiologists Carl W. Gottschalk and Margaret Mylle tested Kuhn's hypothesis. They used innovative micropuncture techniques in hamsters to measure the solute concentration of fluid taken from the loop of Henle and the collecting ducts at the same level. They then compared the concentrations to that of blood plasma (the liquid portion of blood).

| SOLUTE CONCENTRATION (MILLIOSMOLES PER KILOGRAM OF WATER) |               |                 |        |
|-----------------------------------------------------------|---------------|-----------------|--------|
| HAMSTER NUMBER                                            | LOOP OF HENLE | COLLECTING DUCT | PLASMA |
| 1                                                         | 1391          | 1402            | 308    |
| 2                                                         | 725           | 720             | 336    |
| 3                                                         | 1270          | 1206            | 325    |
| 4                                                         | 453           | 453             |        |

#### RESULTS

Their results, shown in the table, are consistent with the predictions of Kuhn's hypothesis. That is, the solute concentrations of the fluid in the loop of Henle and the fluid in the collecting ducts are similar to each other and higher than that of the blood plasma.

#### CONCLUSION

These results are consistent with a model in which concentrated urine is produced by first generating a concentration gradient between the cortex and the medulla, and then allowing water to move out of the collecting ducts into the interstitial fluid by osmosis.

#### FOLLOW-UP WORK

Similar measurements in other areas of the kidney and in other mammals

and birds further supported the model.

## The distal convoluted tubule secretes additional wastes.

The distal convoluted tubule is located in the cortex. The filtrate entering the tube is dilute, having lost nearly all of its electrolytes in the ascending limb of the loop of Henle, as we have seen. Urea is the principal solute in the filtrate at this point.

The distal convoluted tubule is one of the main sites of secretion. Additional wastes not filtered by the glomerulus are actively secreted into the distal convoluted tubule from the bloodstream. In addition, the distal convoluted tubule participates in the regulation of key electrolytes, such as potassium, sodium, and calcium ions. Potassium ions are secreted from the blood into the tubule, whereas the few sodium and calcium ions left in the tubule are reabsorbed into the blood in response to hormones. Finally, the distal convoluted tubule helps to regulate blood pH: bicarbonate ( $\text{HCO}_3^-$ ) and protons ( $\text{H}^+$ ) are secreted into the tubule or reabsorbed out of it, as needed to maintain pH homeostasis.

As a result, the filtrate leaving the distal convoluted tubule and entering the collecting ducts is dilute and contains mainly urea and

other wastes.

## The final concentration of urine is determined in the collecting ducts and is under hormonal control.

The final segment of the nephron is the collecting duct. This is where the concentration gradient from cortex to medulla established by the loop of Henle becomes important: it allows the collecting ducts to retain or lose water as needed depending on the water levels of the organism. By this means, the kidney maintains water homeostasis.

The dilute filtrate enters the collecting ducts. These ducts pass from the cortex to the medulla and drain into the renal pelvis at the base of the kidney. In response to the concentration gradient from the cortex to the medulla, water moves out of the collecting ducts into the interstitial fluid by osmosis as long as the collecting ducts are permeable to water.

The permeability of the collecting ducts to water can be adjusted to make the urine either more dilute or more concentrated. The water permeability of the collecting ducts is controlled by [antidiuretic hormone \(ADH\)](#), also called [vasopressin](#). This peptide hormone is secreted by the posterior pituitary gland and is released when the body is dehydrated ([Chapter 36](#)). It acts to make the collecting ducts more permeable to water, so less water is lost in the urine.

The secretion of ADH is controlled by the hypothalamus. Receptors in the hypothalamus monitor the concentration of solutes in the blood. When a person is dehydrated, solute concentration is high, and the

hypothalamus sends a signal to secrete ADH. In the presence of ADH, aquaporins are inserted into cell membranes ([Fig. 39.19a](#)). Water in the collecting duct diffuses into the interstitial fluid through the aquaporins, and the urine becomes more concentrated. When a person is dehydrated, the urine leaving the collecting ducts can become as concentrated as the interstitial fluid at the base of the kidney.

FIG. 39.19 Hormonal control of urine concentration by ADH. (a) In the presence of ADH, the collecting duct is more permeable to water than (b) in the absence of ADH.

When a person is well hydrated, no ADH is released. The collecting ducts are then impermeable to water, and no water is reabsorbed ([Fig. 39.19b](#)). The result is dilute urine. Some diuretic substances (*diuretic* is from a Greek word meaning “to flow through”), such as alcohol,

promote the dilution of urine by interfering with ADH production, thereby making the collecting ducts impermeable to water. When dilute urine is produced, there is net water loss. Consequently, diuretic drinks often cause dehydration.

The regulation of water and solute reabsorption by the kidney is remarkably precise. The kidneys of a human filter 180 L of blood each day (125 mL/min). The total blood volume of a human is about 5 L (of which 3 L is plasma), which means that the blood is filtered about 60 times per day. Humans produce, on average, 0.5 L of urine per day. Thus, under normal conditions, the kidneys reabsorb 99.9% of the water entering the renal tubules. In addition, the kidneys reabsorb all the glucose and amino acids that are filtered out of the blood, together with 99.9% of the electrolytes in the blood.

The exceptional ability of the kidneys to filter and reabsorb electrolytes, solutes, and water also explains why kidney damage can have such serious consequences. People with kidney disease must have their blood filtered by dialysis treatment as frequently as three times per week, with each treatment lasting several hours. Otherwise, toxic wastes will build up to dangerous levels in their bodies. Kidney disease remains a substantial health problem around the world, costing more than \$34 billion in the United States alone.

## The kidneys help regulate blood pressure and blood volume.

In another example of homeostasis, the body maintains blood pressure at relatively constant levels. Because the kidneys receive a large

fraction of the blood leaving the heart, they are well suited for monitoring changes in blood pressure and helping to maintain blood pressure homeostasis. Low blood pressure can lead to dizziness and fainting, and high blood pressure contributes to heart disease, stroke, and kidney failure. The kidneys help to regulate blood pressure by secreting hormones that cause blood vessels to constrict and that result in the reabsorption of more electrolytes and water into the blood, increasing blood volume.

Specialized cells of the efferent arteriole leaving the glomerulus of each nephron are well positioned to sense and respond to changes in the blood pressure. These cells form the [juxtaglomerular apparatus](#) ([Fig. 39.20](#)). In response to a drop in blood pressure, they secrete the hormone renin. Renin converts angiotensinogen, which is produced in the liver and circulates in the blood, into angiotensin I. Angiotensin I, in turn, is converted by an enzyme present in the lungs and elsewhere to its active form, [angiotensin II](#). Angiotensin II acts on the smooth muscles of arterioles throughout the body, causing them to constrict; this action increases blood pressure and directs more blood back to the heart.

FIG. 39.20 Control of blood volume and blood pressure by the kidney. Cells of the efferent arteriole of the glomerulus sense blood pressure and start a hormone cascade when blood pressure gets too low.

Angiotensin II also stimulates the release of the hormone **aldosterone** from the adrenal glands (Fig. 39.20). Aldosterone stimulates the distal convoluted tubules and collecting ducts to increase the reabsorption of electrolytes and water back into the blood. As blood

volume increases, blood pressure increases, too.

Clearly, the kidneys play many roles in the body. In addition to eliminating wastes and other toxic compounds, they maintain homeostasis in several ways, including through the maintenance of water and electrolyte balance and the regulation of blood volume and blood pressure.

## CASE 7 BIOLOGY-INSPIRED DESIGN: USING NATURE TO SOLVE PROBLEMS

### How does dialysis work?

As we have seen, the kidney serves many critical functions. It removes wastes from the bloodstream as well as maintains water and solute balance. These functions are so important that we cannot live without them. When kidney function drops to less than 10% to 15% of the normal level, wastes accumulate in the blood and disrupt the functioning of other organs, including the brain. In addition, water and solute homeostasis is not achieved, leading to high or low blood pressure, for example. The inability of the kidney to filter wastes and maintain water and solute balance is called renal failure, and it can be either a short-term (acute) or long-term (chronic) condition.

Chronic renal failure is currently treated in one of two ways: transplantation or dialysis. Transplantation is the surgical implantation of a healthy kidney in place of one that is damaged by disease. Donor kidneys can come from living or recently deceased donors, but their

supply is limited. Transplantation also requires a proper immunological match between the donor and the recipient, so that the recipient's body will not reject the transplanted kidney ([Chapter 41](#)).

Many people with chronic renal failure depend on dialysis, or more specifically hemodialysis—a term that reflects the procedure's function of filtering (*dialysis*) of the blood (*hemo*). A dialysis machine is essentially a bioengineered apparatus that mimics the function of the kidney. Blood from a patient is passed through a filter, not unlike the natural filter of the glomerulus. The filter retains blood cells and large molecules that are returned to the patient. The filtrate is adjusted so that proper levels of water and solutes are also returned to the patient, while wastes such as urea are removed, similar to the function of the proximal convoluted tubules, distal convoluted tubules, and collecting ducts.

Dialysis is effective at replacing many of the functions of the kidney. Unfortunately, it requires treatment three times per week, and each treatment lasts several hours. In an effort to increase the convenience of therapy for patients with chronic renal failure, scientists and engineers are researching other kinds of treatments. For example, scientists at Vanderbilt University are working on what they call a bio-artificial kidney. This kidney is implanted in the body, so the individual does not require frequent and lengthy dialysis treatments. It also avoids the need for a supply of donor kidneys.

The researchers looked to nature in the design of the bio-artificial kidney. The filter does not rely on small circular holes as dialysis

machines do, but instead on slit pores. These pores are similar to those of the glomerulus and other effective filters found in the natural world, such as the baleen of whales that separate food (krill) from water. Because it relies on slit pores, the bio-artificial kidney can use the pressure of the heart to push fluid through the filter in the first stage of filtering the blood.

Engineering a way to achieve proper water and solute balance is difficult, so the researchers incorporated living renal tubule cells into the device instead. Challenges remain, but an implantable artificial kidney would provide a much-needed alternative to current treatments of chronic renal failure.

#### Self-Assessment Questions

9. Draw a mammalian nephron, label and describe the primary function of each part, and show the direction of water and electrolytes in each part.
10. The filtrate is dilute at the start and the end of the loop of Henle. What, then, is the function of the loop of Henle?
11. What is the role of ADH in the regulation of urine concentration?
12. How do the kidneys help to regulate blood volume and blood pressure?

## CORE CONCEPTS SUMMARY

**39.1 WATER AND ELECTROLYTE BALANCE:** All animals regulate the water and electrolyte levels within their cells.

Cell membranes act as selectively permeable membranes, allowing the passage of water but restricting or controlling the movement of many solutes. [page 878](#)

Water moves across selectively permeable membranes by osmosis from a region of lower solute concentration to a region of higher solute concentration. [page 878](#)

Osmotic pressure is a measure of the tendency for water to move by osmosis across a selectively permeable membrane into a solution with higher solute concentration. [page 878](#)

Osmoregulation is the regulation of osmotic pressure inside cells or organisms. [page 879](#)

Osmoconformers maintain an internal solute concentration similar to that of the environment, whereas osmoregulators have an internal solute concentration different from that of the environment. [page 879](#)

Osmoregulators that live in high-salt environments excrete excess electrolytes and minimize water loss. [page 880](#)

Osmoregulators that live in low-salt or freshwater environments excrete excess water and minimize electrolyte loss. [page 880](#)

Osmoregulators that live on land minimize water loss. [page 881](#)

**39.2 EXCRETION OF WASTES:** Excretory organs eliminate nitrogenous wastes and regulate water and electrolyte levels.

Osmoregulation and excretion are closely coordinated processes controlled by the excretory organs of animals. [page 881](#)

Ammonia, urea, and uric acid are three major forms of nitrogenous waste that animals excrete, depending on their evolutionary history and habitat. [page 882](#)

Ammonia is toxic but readily diffuses into water; urea is less toxic and can be stored before it is eliminated; uric acid is a semisolid and can be eliminated with minimal water loss as an adaptation for living on land. [page 882](#)

All animal excretory systems first isolate or filter fluid into an extracellular space. Key electrolytes, solutes, and water are then reabsorbed from the filtrate. Additional wastes are subsequently secreted into the remaining filtrate before it is eliminated from the body. [page 883](#)

Examples of excretory organs are the protonephridia of flatworms, the metanephridia of segmented annelid worms, the Malpighian tubules of insects, and the kidneys of vertebrates. [page 884](#)

The urine produced by the kidneys and other excretory organs is stored in a bladder until it is eliminated from the body. [page 886](#)

The functional unit of the vertebrate kidney is the nephron, which consists of a glomerulus, capsule, renal tubules, and collecting duct. [page 886](#)

**39.3 THE MAMMALIAN KIDNEY:** The mammalian kidney can produce urine that is more concentrated than blood as an adaptation for living on land.

The kidney has an outer cortex and an inner medulla. [page 887](#)

The renal tubules have specialized regions, including the proximal convoluted tubule, the loop of Henle, and the distal convoluted tubule. [page 888](#)

The loop of Henle of some nephrons extends into the medulla before looping back to the cortex, creating a concentration gradient from the cortex to the medulla by a countercurrent multiplier mechanism. [page 889](#)

The final concentration of urine is under the control of the hormone ADH, which regulates the water permeability of the walls of the collecting ducts as they pass from the cortex to the medulla through the concentration gradient generated by the loops of Henle. [page 892](#)

The kidneys help to regulate blood pressure by secreting the hormone renin, leading to the production of angiotensin II, which constricts blood vessels, and aldosterone, which increases reabsorption of electrolytes and water by the kidneys. [page 893](#)

## CHAPTER 40 Animal Reproduction and Development

Spl Science Source

---

### CORE CONCEPTS

#### **40.1 THE EVOLUTIONARY HISTORY OF REPRODUCTION:**

Reproduction is a basic feature of living organisms and occurs both

asexually and sexually.

## **40.2 MOVEMENT ONTO LAND AND REPRODUCTIVE**

**ADAPTATIONS:** The movement of vertebrates from water to land involved changes in reproduction, including internal fertilization and the amniotic egg.

## **40.3 HUMAN REPRODUCTIVE ANATOMY AND PHYSIOLOGY:**

The male reproductive system is adapted for the production and delivery of sperm, and the female reproductive system is adapted for the production of eggs and, in some cases, support of the developing fetus.

**40.4 GAMETE FORMATION TO BIRTH IN HUMANS:** Human reproduction involves the formation of gametes, fertilization, and growth and development.

---

Children are sometimes gently introduced to the subject of human reproduction by reference to “the birds and the bees.” Since birds and bees reproduce, it is assumed that they can substitute for humans in discussions about reproduction. But how relevant is bird and bee reproduction to human reproduction? It might come as a surprise that most male birds don’t have penises, and that male bees don’t even have fathers. Perhaps, then, the lesson of “the birds and the bees” is not so much in what it teaches us about human reproduction, but, as we explore in this chapter, in showing us that reproductive strategies among organisms are spectacularly diverse.

Reproduction is a striking and conspicuous feature of the natural world. Flowers burst into bloom each spring to attract pollinators; male fireflies light up brilliantly on warm summer nights as they signal to

females in the grass below; birds sing and display ornate plumage to attract mates. Most living organisms have the ability to reproduce—that is, to make new organisms like themselves. This remarkable ability is not unique to living organisms: after all, computer viruses and self-replicating molecules are capable of reproduction but are not themselves living. Nevertheless, reproduction is a key attribute of life. All living things came about by reproduction, and most are capable in turn of reproduction. Of course, this statement does not address the question of how life originated in the first place, a topic considered in Case 1 Life's Origins.

This chapter focuses on reproduction and development. We begin by considering reproduction broadly among diverse organisms. We then turn our attention to animal, and specifically vertebrate, reproduction and the surprise that even among vertebrates there is quite an array of reproductive strategies. In the last two sections, we focus on human reproduction, starting with reproductive anatomy and physiology, and then following reproduction from gamete formation to fertilization, pregnancy, and birth.

# 40.1 THE EVOLUTIONARY HISTORY OF REPRODUCTION

While the ability to reproduce is shared across all domains of life, the particular way in which organisms reproduce varies among species, from the familiar to what might strike us as truly bizarre. To take just one of many examples: soon after it is born, a male anglerfish finds a female anglerfish, bites her skin, and fuses with her. His body atrophies, leaving the male reproductive organs physically attached to the female and allowing the female's eggs to be fertilized when she is ready. To begin to make sense of this and other reproductive strategies, we start by considering how different forms of reproduction evolved, which organisms use them, and what their adaptive significance is.

## Asexual reproduction produces clones.

Organisms have two potential ways to reproduce. One is the production of genetically identical cells or individuals called [clones](#). This form of reproduction, which is called [asexual reproduction](#), occurs in a wide variety of organisms ([Fig. 40.1](#)).

Sources: a. CNRI/Science Source; b. SPL/Science Source; c. WaterFrame/Alamy; d. Mike Lane/Alamy.

FIG. 40.1 Asexually reproducing organisms. (a) Bacteria divide by binary fission. (b) The yeast *Saccharomyces cerevisiae* reproduces by budding. (c) Corals are propagated by fragmentation. (d) Komodo dragons can reproduce by parthenogenesis.

For example, bacteria ([Fig. 40.1a](#)) and archaeons reproduce by binary fission, a form of cell division in which the genome replicates and then the cell divides in two ([Chapter 11](#)). The result is two cells that are either identical to the parent cell or nearly identical, differing only because of chance mutations.

Prokaryotes can nevertheless increase genetic variation by horizontal gene transfer, as described in [Chapter 24](#). For example, they can transfer DNA from one individual to another, usually of the same species, and much more rarely to an individual of another species, during conjugation. They can also obtain DNA directly from the

environment and by viral infection, incorporating genes that might have evolved in even distantly related species. These processes allow prokaryotes to acquire novel genetic sequences that can increase or decrease fitness.

Eukaryotic cells, in contrast, divide by mitotic cell division ([Chapter 11](#)), a process that evolved early and was present in the common ancestor of all living eukaryotes. Mitotic cell division is a mechanism of growth and development in all eukaryotes, and is the basis of asexual reproduction in many eukaryotes.

One form of asexual reproduction observed in fungi, plants, and some animals is **budding**. In this process, a bud, or protrusion, forms on an organism and eventually breaks off to form a new organism that is smaller than its parent. The budding yeast, *Saccharomyces cerevisiae*, which is used to make bread and beer, is so named because of its ability to produce new individuals by budding ([Fig. 41.1b](#)). Budding can also occur in animals: for example, the water-dwelling hydra can grow and subsequently break off part of itself to form a new, free-living individual. Whether it occurs in unicellular or multicellular organisms, budding involves an unequal division between a mother and daughter cell or organism. Budding is the result of mitosis, so, like binary fission, it results in an offspring that is genetically identical to the parent.

Another form of asexual reproduction is **fragmentation**. In this type of reproduction, a single individual splits into pieces, and each piece develops into a new individual by mitotic cell division. Certain molds,

algae, worms, sea stars, and corals can reproduce by fragmentation. Fragmentation occurs naturally, but humans can use this mode of reproduction to propagate corals in the restoration of coral reefs ([Fig. 40.1c](#)). Once again, the new individual is a clone of the parent.

A final form of asexual reproduction is [parthenogenesis](#), which literally means “virgin birth.” In parthenogenesis, females produce eggs that are not fertilized by males, but rather divide by mitosis and develop into new individuals. Parthenogenesis explains why male bees don’t have fathers. It occurs in invertebrates, including some insects and crustaceans, as well as in vertebrates, including some fishes and reptiles ([Fig. 40.1d](#)). The details of parthenogenesis differ depending on the organism. In most sexually reproducing animals, egg cells are usually the product of meiosis and are haploid, having one set of chromosomes. In some parthenogenic organisms, this haploid egg cell divides repeatedly by mitosis to become a haploid adult; in others, the DNA content doubles during development so the adult is diploid, having two sets of chromosomes; and in still others, the egg cell is not the product of meiosis (it is diploid) and divides by mitosis to become a diploid adult. In all cases, parthenogenesis involves a single maternal parent.

## Sexual reproduction involves the formation and fusion of gametes.

The second way that organisms reproduce is by combining complete sets of genetic information from two individuals to make a new genetically unique individual. This form of reproduction is called [sexual reproduction](#).

parent cell. So, in a diploid species with  $2n$  chromosomes, the result of meiosis is four cells with  $n$  chromosomes. The resulting haploid cells are called **gametes** or **spores**. Human individuals, for example, have 23 pairs of chromosomes ( $2n = 46$  chromosomes) and human gametes have half this number ( $n = 23$  chromosomes).

Many species produce two types of gametes that differ in shape and size. The smaller, male gametes are called **spermatozoa** or **sperm**, and the larger, female gametes are called **ova** or **eggs**. For other organisms, including green algae, diatoms, slime molds, and most fungi, the two types of gametes are the same size. In spite of their similar size and appearance, they come in two (or more) distinct mating types and cannot reproduce sexually with individuals of the same type.

Fertilization takes place by the fusion of two gametes, one from each parent ([Fig. 40.2](#)). The result is a single cell called a **zygote**. If each gamete has  $n$  chromosomes, the resulting zygote has  $2n$  chromosomes. For diploid multicellular organisms, fertilization is the direct basis for reproduction. The zygote divides by mitosis and develops into an **embryo**, an early stage of multicellular development.

Meiotic cell division and fertilization have important genetic consequences. During meiotic cell division, pairs of homologous chromosomes undergo recombination, which shuffles the combination of alleles between chromosomes. In addition, meiotic cell division randomly sorts homologous chromosomes into different gametes. As a result, the products of meiotic cell division, the haploid gametes, are each genetically unique and represent a mixture of the parental genetic

makeup. Then, during fertilization, two of these unique haploid gametes fuse, creating a new genetic combination and a unique diploid individual.

## Many species reproduce both sexually and asexually.

Most organisms that reproduce asexually are also capable of reproducing sexually. For example, hydras reproduce asexually by budding, but are also able to reproduce sexually. Even budding yeast are capable of sexual reproduction. Likewise, most aphids, fishes, and reptiles capable of parthenogenesis can reproduce sexually.

What determines when an organism reproduces sexually and when it reproduces asexually? This question has been examined in the freshwater crustacean *Daphnia*. *Daphnia* reproduces asexually by parthenogenesis in the spring, when food is plentiful, perhaps because asexual reproduction is a rapid form of reproduction that allows the organism to take advantage of abundant resources ([Fig. 40.3](#)). Later in the season, conditions are less favorable because of increased crowding, decreased food, and cooler temperatures. At this time, *Daphnia* reproduces sexually, mating to produce a zygote that starts to form an embryo. At an early stage, however, development is arrested and metabolism slows dramatically. The embryo forms a thick-walled structure, called a cyst. In that form, it is able to resist freezing and drying, allowing it to survive the winter.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 40.3 Sexual and asexual reproduction in *Daphnia*. *Daphnia* can reproduce sexually or asexually, depending on environmental conditions.

This link between environmental conditions and mode of reproduction has been observed in many other species, from algae to slime molds. The life cycle of *Daphnia* hints that asexual reproduction and sexual reproduction have both costs and benefits, a subject we address next.

## Exclusive asexuality is often an evolutionary dead end.

Asexual reproduction has some advantages compared to sexual

reproduction. It does not require taking time and energy to find and attract a mate. Certain birds, for example, go to elaborate lengths to attract mates. Male birds of paradise invest significant energy in growing colorful plumage, and male bowerbirds take time to build elaborate homes for potential mates ([Fig. 40.4](#)). For other organisms, finding a mate can be difficult because of very low population density. This is the case for anglerfish, and may help to explain their unusual reproductive strategy, described earlier.

Source: Tim Laman Photography.

FIG. 40.4 Time and energy costs of sexual reproduction. (a) A male bird of paradise has colorful plumage to attract a mate. (b) A bowerbird builds an elaborate hut to entice a female.

In addition, asexual reproduction is rapid, allowing organisms to increase their numbers quickly. Consider rates of population growth for organisms that reproduce asexually and those that reproduce sexually. In asexual organisms, all offspring can produce more offspring, so population growth can be exponential if conditions are favorable. By contrast, in sexually reproducing organisms, it takes two individuals to produce new offspring. The consequence of this difference is that an asexual group can have a much greater rate of population growth than a

sexually reproducing one. The British evolutionary biologist John Maynard Smith called this effect the **twofold cost of sex** ([Fig. 40.5](#)), and it is one of the key disadvantages of sexual reproduction.

FIG. 40.5 The twofold cost of sex. Population size increases more rapidly in asexually reproducing organisms compared to sexually reproducing organisms.

In spite of the advantages of asexual reproduction, a survey of the natural world reveals a striking pattern: most organisms reproduce sexually at least part of the time. Even prokaryotes, as we have seen, have mechanisms for genetic exchange between individuals. The observation that the vast majority of organisms reproduce sexually at some point suggests that sexual reproduction offers advantages over asexual reproduction. Asexual reproduction is quick, but it produces

offspring that are genetically identical to one another and to the parent. The only source of genetic variation with this means of reproduction is chance mutations. By contrast, one of the defining features of sexual reproduction is the production of offspring that are genetically different from one another and from their parents.

Many hypotheses have been developed to explain the advantages of producing genetically distinct offspring in spite of the costs of sexual reproduction. One proposes that sexually reproducing species adapt faster than asexually reproducing ones because rare beneficial mutations that arise in different organisms can be brought together, increasing the overall fitness of the population. Another set of hypotheses proposes that sexual reproduction allows a population to purge itself of harmful mutations more quickly than could a population of asexual individuals.

A third hypothesis proposes that sexual reproduction is a mechanism of parasite defense. In host–parasite interactions, the host evolves defenses against the parasite, and the parasite evolves new ways to infect the host. Thus, each partner evolves rapidly simply to maintain its ecological position. Called the Red Queen hypothesis, this idea takes its name from Lewis Carroll’s *Through the Looking-Glass*, in which the Red Queen tells Alice that she needs to keep running to stay in the same place. Such rapid evolution requires lots of genetic variation on which natural selection can act, and sexual reproduction increases genetic variation among individuals faster than asexual reproduction does.

These different hypotheses for the prevalence of sexual reproduction are not mutually exclusive. It may be that several mechanisms work together, or that different ones are important for different organisms.

It is instructive to consider groups of eukaryotes that have lost the ability to reproduce sexually, and those that have lost the ability to reproduce asexually. While some organisms, such as the New Mexico whiptail lizard (*Cnemidophorus neomexicanus*), reproduce only asexually, these species are not very old in evolutionary terms. In other words, there are very few, if any, *ancient* asexual groups. It appears that asexual reproduction on its own rarely allows a species to persist for very long in evolutionary terms.

A possible exception to this rule may be bdelloid rotifers, a group of microscopic freshwater invertebrates that are thought to have reproduced asexually for at least 35 to 40 million years ([Fig. 40.6](#)). If bdelloid rotifers really have persisted for tens of millions of years without sexual reproduction, we would predict that they have evolved some process other than sexual reproduction for increasing their genetic variation. In fact, evidence suggests that these organisms are able to take up DNA from their environment, similar to what bacteria do through transformation ([Chapter 24](#)). The bdelloid rotifers seem to be fantastic “collectors” of DNA from other organisms, including bacteria, plants, and fungi. However, comparison of DNA sequences among bdelloids has recently demonstrated that different individuals can share genes that are identical or almost identical in sequence, which is not possible without at least occasional sexual reproduction. More research is needed to fully understand reproduction in this group.

#### HOW DO WE KNOW?

### FIG. 40.6

## Do bdelloid rotifers only reproduce asexually?

#### BACKGROUND

Many groups of animals reproduce asexually, but most of these organisms reproduce sexually at least some of the time. The bdelloid rotifer, one of several species of microscopic aquatic animals called rotifers, may be an exception.

#### OBSERVATION

All bdelloid rotifers found to date are females. No males or hermaphrodites (organisms with both male and female reproductive organs) have ever been observed. Meiosis in bdelloid rotifers has never been documented.

#### HYPOTHESIS

Bdelloid rotifers are asexual and reproduce solely by parthenogenesis, in which unfertilized eggs develop into adult females.

#### PREDICTION

American biologists Mark Welch and Matthew Meselson reasoned that in the absence of meiosis, the two copies (alleles) of a gene do not recombine, and mutations that accumulate are not reshuffled between alleles. As a result, two alleles of a gene in an asexually reproducing organism should show a much higher degree of sequence difference compared with two alleles of a gene in a sexually reproducing organism.

#### RESULTS

The researchers sequenced the two copies of the *hsp82* gene in a sexually reproducing rotifer species ([Fig. 40.6a](#)) and the two copies of the *hsp82* gene in an asexually reproducing rotifer species ([Fig. 40.6b](#)). As you can see, the two copies are very similar in [Fig. 40.6a](#) but very different in [Fig.](#)

40.6b.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

## CONCLUSION

The actual results are consistent with the predicted results and suggest that bdelloid rotifers are exclusively asexual.

## FOLLOW-UP WORK

In the absence of sexual reproduction, bdelloid rotifers might have evolved other mechanisms to increase genetic variation. In subsequent work, Meselson and his colleagues found genes in the bdelloid rotifer genome that originated in other organisms, such as bacteria, fungi, and plants. This observation suggests that these organisms might increase genetic variation by horizontal gene transfer, and it helps to explain how bdelloid rotifers might have persisted for extended evolutionary times without reproducing sexually.

SOURCES Welch, M. D., and M. S. Meselson. 2000. "Evidence for the Evolution of Bdelloid Rotifers Without Sexual Reproduction or Genetic Exchange." *Science* 288:1211–1215. Gladyshev, E. A., M. S. Meselson, and I. R. Arkhipova. 2008. "Massive Horizontal Gene Transfer in Bdelloid Rotifers." *Science* 320:1210–1213.

In contrast to organisms that lose the ability to reproduce sexually, mammals are unusual in the opposite way: they have lost the ability to reproduce asexually. Parthenogenesis, as we have seen, occurs in some vertebrates, but does not occur in mammals. Although parthenogenesis may seem odd from our point of view, scientists have wondered just the opposite: why can't female mammals reproduce without a father? Asked another way, why do mammalian embryos need both a maternal genome and a paternal genome? Wouldn't two maternal genomes from a single parent do the trick?

Evidently not. Scientists have known for some time that mammalian maternal and paternal genomes are not quite the same. Certain genes, called imprinted genes, are expressed differently depending on their parent of origin ([Chapter 18](#)). Imprinting ensures that mammals develop from embryos with one maternal and one paternal genome. When researchers manipulated key imprinted genes in a maternal genome, they were able to breed a parthenogenetic mouse, which had two copies of a maternal genome from a single parent. We can hypothesize that early mammals gained fitness advantages in the evolution of imprinted genes, but lost the ability to reproduce parthenogenetically.

#### Self-Assessment Questions

1. Sexual reproduction results in offspring that are genetically different from one another and from their parents. What are four mechanisms that produce this genetic variation?
2. How are asexual and sexual reproduction similar? How are they

different?

3. What are the costs and benefits of asexual and of sexual reproduction?
4. How can you explain the observation that there are very few, if any, ancient asexual organisms?

## 40.2 MOVEMENT ONTO LAND AND REPRODUCTIVE ADAPTATIONS

We have considered the two modes of reproduction observed across all living organisms. In this section, we narrow our focus to vertebrates: fishes, amphibians, reptiles, birds, and mammals. Interestingly, even among vertebrates, there are many different reproductive strategies. Understanding these strategies not only gives us a picture of how these organisms reproduce, but also sheds light on how they live and behave.

How vertebrates reproduce is also intimately connected to the transition of vertebrates from water to land 400 to 375 million years ago. Moving from an aquatic environment to a terrestrial one involved many adaptations, among them changes in the way that reproduction took place, so it is helpful to consider reproductive strategies in an evolutionary context.

### Fertilization can take place externally or internally.

To survive, eggs and sperm require a wet environment. Aquatic organisms such as fishes and amphibians can release eggs and sperm directly into the water by [external fertilization](#). External fertilization, as you might imagine, is a chance affair: somehow, sperm must meet egg in a large environment. Given this reality, animals that release gametes externally have developed strategies to increase the probability of fertilization. Some species release large numbers of

gametes. Many female fishes, including salmon and perch, lay eggs on or near a substrate, such as a rock, and males release their sperm onto the eggs to increase the probability of fertilization. Externally fertilizing animals may also come close together physically to improve chances that the sperm will fertilize the eggs. Male frogs grasp females, releasing sperm as the female lays her eggs ([Fig. 40.7](#)).

*Source: National Geographic Creative/Alamy.*

FIG. 40.7 External fertilization. Tree frogs reproduce by external fertilization: the male frog holds on to the female and fertilizes her eggs as she lays them.

A challenge for land-dwelling organisms is keeping gametes from drying out. [Internal fertilization](#), in which fertilization takes place inside the body of the female, is an adaptation for living on land. Reptiles, birds, and mammals all use internal fertilization. However,

this mode of fertilization is not exclusive to land dwellers. Marine mammals such as whales and dolphins use internal fertilization, as did the land-dwelling ancestors from which they evolved. Even some fishes, such as guppies, reproduce by internal fertilization.

## *r*-strategists and *K*-strategists differ in number of offspring and parental care.

While the terms “external” and “internal” fertilization focus our attention on where fertilization takes place, the two modes of reproduction are associated with a host of other behavioral and reproductive differences. One key difference is the number of offspring produced.

External fertilization is generally associated with the release of large numbers of gametes and the production of large numbers of offspring. An individual offspring has a low probability of survival in part because the offspring typically receive little, if any, parental care. External fertilization, in other words, is a game of numbers. By comparison, when both fertilization and embryonic development take place inside the female, there is much more control over fertilization and subsequent development of the embryo. As a result, animals that use internal fertilization typically produce far fewer offspring and invest considerable time and energy into raising those offspring.

These two strategies represent two ends of a continuum of reproductive strategies that was first described by the American ecologists Robert H. MacArthur and E. O. Wilson in 1967. Organisms that produce large numbers of offspring without a lot of parental

investment are called ***r*-strategists**, and those that produce few offspring but put in a lot of parental investment are called ***K*-strategists** (**Fig. 40.8**; **Chapter 44**). Fishes are *r*-strategists; humans are *K*-strategists.

According to this model, the environment places selective pressures on organisms to drive them in one or the other direction. In general, *r*-strategists evolve in unstable, changing, and unpredictable environments. In such an environment, there is an advantage to reproducing quickly and producing many offspring when conditions are favorable. By contrast, *K*-strategists often evolve in stable, unchanging, and predictable environments, where there tends to be more crowding and larger populations. In the face of intense competition for limited resources, traits such as increased parental care and few offspring are favored.

These two strategies represent the extremes of a spectrum, and there are notable exceptions. An octopus, for example, can lay up to 150,000 eggs, typical of *r*-strategists, but the female guards and takes care of

them for a month or more, typical of *K*-strategists. Nevertheless, the two strategies highlight different reproductive patterns across animals and suggest important links between number of offspring, parental care, and the environment.

## Animals either lay eggs or give birth to live young.

When we speak of parental care, it is natural to think of parents tending the young. However, parental care actually begins much earlier in development, in the provisioning of nutrients for the developing embryo. The eggs of animals that are externally fertilized have a substance called [yolk](#) that provides all the nutrients that the developing embryo needs until it hatches. The embryo obtains water and oxygen directly from the aquatic environment and metabolic wastes easily diffuse out.

The anatomy of the egg was transformed as vertebrates moved onto land. No longer could the developing embryo depend simply on diffusion of key substances into and out of a watery environment. A key innovation is the [amnion](#), a membrane surrounding a fluid-filled cavity that allows the embryo to develop in a watery environment and prevents it from drying out. Reptiles, birds, and mammals are known as amniotes because of the presence of this key membrane in their developing embryos ([Fig. 40.9](#)). A second membrane, called the [allantois](#), encloses a space where metabolic wastes collect. Finally, a third membrane, called the [chorion](#), surrounds the entire embryo along with its yolk and allantoic sac. The embryo is further protected in many species by a hard shell just outside the chorion. Together, the chorion

and shell limit water loss, and the chorion, shell, and allantois allow gas exchange with the environment. The yolk sac, amnion, allantois, and chorion are all [extraembryonic membranes](#), sheets of cells that extend out from the developing embryo ([Fig. 40.10](#)).

FIG. 40.9 The evolution of the amnion. The amnion is a membrane enclosing a fluid-filled cavity surrounding the developing embryo. It evolved during the transition of animals from water to land.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

Photo source: Thanunkorn Klypaksi/iStockphoto.

FIG. 40.10 The amniotic egg. The amniotic egg includes four extraembryonic membranes: the yolk sac, amnion, allantois, and chorion.

Animals that are internally fertilized can either lay eggs or give birth to live young. Animals that lay eggs are oviparous (**oviparity** means “egg birth”). Oviparity is used by most insects, fishes, amphibians, and reptiles, as well as by all birds. Even some mammals—the monotremes, which include the spiny anteater and platypus—lay eggs. For oviparous animals, very little, if any, embryonic development occurs inside the mother, and all the nutrients for the developing embryo come from the yolk.

Other animals give birth to live young. These animals differ in where the embryo gets its nourishment. In some animals, embryos develop inside eggs that are retained inside the mother until they hatch. These embryos receive nutritional support from the yolk, not from the mother. Such animals are ovoviviparous (**ovoviviparity** means “egg live birth”). Some sharks and snakes are ovoviviparous.

In other animals, the embryo develops inside the mother and receives all its nourishment from her. These animals are viviparous (**viviparity** means “live birth”). Most mammals and some sharks and snakes are viviparous. In fact, viviparity has evolved many times independently. In placental mammals, such as humans, the chorion and allantois fuse to form the **placenta**, an organ that allows nutrients to be obtained directly from the mother.

#### Self-Assessment Questions

5. What are three adaptations that allow reproduction to take place on land?
6. Do all mammals give birth to live young? Are mammals the only vertebrates that give birth to live young?

## 40.3 HUMAN REPRODUCTIVE ANATOMY AND PHYSIOLOGY

In this and the next section, we continue to narrow our focus so as to consider reproduction in more detail. In this section, we discuss human reproduction and development. Many features of human reproduction are seen in other mammals: humans are amniotes, reproduce sexually, use internal fertilization, and are viviparous. Other aspects are unique. Our focus on human reproduction allows us to provide a detailed treatment of the topic in one species and gives us a chance to explore ways we intervene in the process to promote, prevent, and follow pregnancy.

### The male reproductive system is specialized for the production and delivery of sperm.

Let's start by considering the human male reproductive system. Male gametes, called spermatozoa or sperm, are produced in the two male **gonads**, or **testes** (singular, testis; [Fig. 40.11](#)). Over the course of his life, a man is capable of making hundreds of billions of sperm. In fact, a single ejaculate typically contains several hundred million sperm. If it takes just one sperm to fertilize an egg, why do males make so many? A likely explanation involves sperm competition. In species such as humans, where females can mate with more than one male, a male's reproductive success is at least partially correlated with the number of

sperm: the more sperm, the better the chance of fertilizing the egg. A second explanation points out that the female reproductive tract is hostile to sperm; many sperm are needed to ensure that at least one makes it to the egg. Of the several hundred million sperm released by a male during a single ejaculation, only several hundred sperm make it to the egg.

FIG. 40.11 The male reproductive system. Haploid sperm are produced in the testes, then travel through the epididymis, vas deferens, ejaculatory duct, and urethra.

Sperm are haploid cells with a unique shape and properties adapted for their function of delivering genetic material to the egg ([Fig. 40.12](#)). They have a small head containing minimal cytoplasm and a very densely packed nucleus. The head is surrounded by a specialized organelle, the [acrosome](#), which contains enzymes that enable the sperm to traverse the outer coating of the egg. Sperm have a long tail,

or **flagellum**, which moves the cell by a whipping motion powered by the sperm's mitochondria.

Photo source: Roland Birke/Getty Images.

FIG. 40.12 Sperm. Sperm are specialized cells with minimal cytoplasm, a densely packed nucleus, an acrosome with digestive enzymes, and a flagellum.

The testes are located outside the abdominal cavity in a sac called the **scrotum** (see [Fig. 40.11](#)). This location is critical for the production of sperm, which require cooler temperatures than are found in the

abdominal cavity of humans. However, the testes of some mammals, such as elephants, whales, and bats, are located inside the abdominal cavity, indicating that there are species-specific differences in sperm temperature requirements.

Sperm are produced within the testes in a series of tubes called the **seminiferous** (“seed-bearing”) **tubules** (**Fig. 40.13**). This is where diploid cells undergo meiosis to produce haploid sperm. When sperm are first produced, they are not fully mature: they are unable to move on their own and incapable of fertilizing an egg. Sperm mature as they move through the male reproductive system.

From the seminiferous tubules, sperm travel to the [epididymis](#), where they become motile ([Fig. 40.13](#)). This is also where sperm are stored prior to ejaculation. From there, sperm enter the [vas deferens](#), a long, muscular tube that follows a circuitous path, starting off in the scrotum of each testis, passing into the abdominal cavity, running along the bladder, and then connecting with an [ejaculatory duct](#) (see [Fig. 40.11](#)). The two ejaculatory ducts merge at the [urethra](#), just below the bladder. The urethra is used by both the urinary and reproductive systems in males.

Along this path, there are several exocrine glands that produce components of [semen](#), the fluid that nourishes and sustains sperm as they travel first in the male reproductive tract and then in the female reproductive tract. Two [seminal vesicles](#), located at the junction of the vas deferens and the prostate gland, secrete a protein- and sugar-rich fluid that makes up most of the semen and provides energy for sperm motility (see [Fig. 40.11](#)). The [prostate gland](#), located just beneath the bladder, produces a thin, slightly alkaline fluid that helps maintain sperm motility and counteracts the acidity of the female reproductive tract. Finally, the [bulbourethral glands](#), found below the prostate gland, produce a clear fluid that lubricates the urethra for passage of sperm.

The urethra is enclosed in the [penis](#), the male copulatory organ (see [Fig. 40.11](#)). When a male is sexually aroused, the penis becomes erect as a result of changes in blood flow: the arteries become dilated and the veins constricted. During ejaculation, semen is expelled from the penis.

The male reproductive system is well adapted for the production, storage, and delivery of sperm. Therefore, male contraceptive methods focus on blocking sperm. For example, a condom is a sheath of rubber or latex that covers the penis and prevents sperm from entering the female during sexual intercourse.

The human penis is a relatively simple organ, consisting of a shaft and a head called the **glans penis**. In other animals, the penis can be quite elaborate, with spikes, hooks, and grooves whose functions are to stimulate the female, grip the female, and in some cases even remove sperm from a previous copulation. In marsupial mammals such as kangaroos and koalas, males have forked penises. In snakes and lizards, males have two penises, called hemipenes. In insects, the external genitalia are often distinct enough to be used in species identification. By contrast, most species of birds do not have a penis.

## The female reproductive system produces eggs and supports the developing embryo.

The female reproductive system, like the male reproductive system, produces gametes, but is also specialized to support the developing embryo. Developing female gametes, called **oocytes**, which mature into ova upon fertilization, are produced in the two female gonads, called **ovaries** (**Fig. 40.14**). Oocytes are released monthly in response to hormones in the process of menstruation, discussed in the next section.

**FIG. 40.14 The female reproductive system.** Oocytes are produced in the ovaries and then travel through the oviducts to the uterus, where they implant if they are fertilized. If not fertilized, the oocytes are shed during menstruation.

The oocyte is a remarkable and unique cell ([Fig. 40.15](#)). Whereas sperm are small and motile, the oocyte is the largest cell by volume in the human body and is visible to the naked eye; it is about the size of the period at the end of this sentence. Its large size reflects the presence of large amounts of cytoplasm containing molecules that direct the early cell divisions following fertilization. Whereas a male produces millions of sperm, a female usually produces just one oocyte each month, as she will nourish and support the developing embryo if the oocyte is fertilized.

Source: Claude Cartier Science Source.

FIG. 40.15 A female gamete. Oocytes are produced in the ovaries, mature into ova (eggs), and are by volume the largest cells in the human body.

Following its release from the ovary, the oocyte travels through the **oviduct**, also called a **fallopian tube** (see [Fig. 40.14](#)). There are two fallopian tubes, one for each ovary. The fallopian tubes have featherlike projections on their ends that help channel the egg into the tube, and not into the abdominal cavity.

The oocyte travels from the fallopian tube to the **uterus**, or womb (see [Fig. 40.14](#)). The uterus is a hollow organ with thick, muscular walls that is adapted to support the developing embryo if fertilization occurs and to deliver the baby during birth. In humans, the uterus is usually a single pear-shaped structure, but it can sometimes have two horns, which can interfere with pregnancy. Other mammals differ in the shape of the uterus, ranging from pear-shaped (humans and other primates), to two horns (pigs, horses), to more completely divided but still connected at the base (cats, dogs), to several completely separate

structures (rodents, rabbits).

The end of the uterus is the **cervix**, or neck of the uterus (see [Fig. 40.14](#)). Under the influence of hormones, the cervix produces different kinds of mucus capable of either blocking or guiding sperm through the cervix.

The uterus is continuous with the **vagina**, or birth canal (see [Fig. 40.14](#)). The vagina is a tubular channel connecting the uterus to the exterior of the body. It is highly elastic, allowing it to stretch during sexual intercourse and birth.

The external genitalia of the female are collectively called the **vulva** ([Fig. 40.16](#)). The vulva includes two folds of skin, the **labia majora** and **labia minora**. The labia minora meet at the **clitoris**, the female homolog of the glans penis.

## Hormones regulate the human reproductive system.

The male testes and female ovaries are not only the site of gamete production, but also part of the endocrine system ([Chapter 36](#)). That is, they respond to hormones and in turn secrete hormones. These hormones play key roles during embryonic development and puberty and regulate reproduction in the adult. Hormonal control of reproduction is critically important, as, for example, it allows an egg to be released only when the uterus is prepared to accept it.

The master regulator of the endocrine system is the hypothalamus, located in the brain ([Chapter 36](#)). The hypothalamus secretes hormones that act on the pituitary gland, which in turn releases hormones that act on target organs ([Fig. 40.17](#)). In the case of the reproductive system, the hypothalamus releases [gonadotropin-releasing hormone \(GnRH\)](#), which stimulates the anterior pituitary gland to secrete [luteinizing hormone \(LH\)](#) and [follicle-stimulating hormone \(FSH\)](#). These hormones act on the male and female gonads. In males, the hormones are secreted almost continually; in females, they are secreted cyclically. In response to the hormones, the testes secrete the hormone [testosterone](#) and the ovaries secrete the hormones [estrogen](#) and [progesterone](#).

FIG. 40.17 Hormonal control of the reproductive system.

In males, LH acts on **Leydig cells**, cells in the testes that secrete testosterone. Testosterone is a steroid hormone derived from cholesterol that plays key roles in male growth, development, and reproduction. During the development of the embryo, testosterone directs development of the male reproductive organs. At puberty,

hormones initiate the onset of sexual maturity. Levels of testosterone increase at this time, leading to the development of male [secondary sexual characteristics](#), traits that characterize and differentiate the two sexes but that do not relate directly to reproduction. For males, these traits include a deep voice; facial, body, and pubic hair; and increased muscle mass. Testosterone and FSH also act on another group of cells in the testes, called [Sertoli cells](#), to stimulate sperm production.

In females, an increase in the level of estrogen at puberty leads to the development of female secondary sexual characteristics, such as enlargement of the breasts, growth of body and pubic hair, and changes in the distribution of muscle and fat. Also at puberty, females begin a monthly cycle, the [menstrual cycle](#), in which an oocyte matures and is released from the ovary under the influence of hormones ([Fig. 40.18](#)). The menstrual cycle consists of cyclical changes in the ovaries and uterus, coordinated by hormones, that time the release of an oocyte from the ovary with the growth of the uterine lining so that the uterus can support the developing embryo if fertilization occurs.

FIG. 40.18 The menstrual cycle. Note the cyclical and coordinated changes in the anterior pituitary hormones, ovary, ovarian hormones, and uterine lining. These changes are regulated by hormonal feedback loops.

The menstrual cycle has two phases: the **follicular phase** and the

**luteal phase**. In the follicular phase, an oocyte develops and is eventually released from the ovary. The oocyte is surrounded by a supporting shell of cells called a **follicle**. At the start of each menstrual cycle, FSH stimulates specific follicle cells, called granulosa cells, to secrete a form of estrogen called estradiol. In response to estradiol, oocytes in several follicles begin to mature each month, but usually only one becomes fully mature. Estradiol also acts on the lining of the uterus, causing it to thicken. Finally, estradiol acts on the hypothalamus and anterior pituitary gland, where it reduces the secretion of GnRH, FSH, and LH by negative feedback ([Fig. 40.18](#)).

At the end of the follicular phase, this negative feedback of estradiol changes to positive feedback ([Fig. 40.18](#)). The mechanism for this change is not well understood, but may be due in part to high levels of estradiol. Positive feedback of estradiol on the hypothalamus and anterior pituitary causes a rapid increase in the level of LH produced by the anterior pituitary gland. This LH surge causes ovulation, the release of the oocyte from the follicle in the ovary.

Ovulation marks the end of the follicular phase and the beginning of the luteal phase. The follicle, now devoid of the oocyte, is converted to a structure known as the **corpus luteum** (literally “yellow body,” so named because of its appearance). The corpus luteum is a temporary endocrine structure that secretes the hormones progesterone and estradiol. Progesterone maintains the thickened and vascularized uterine lining, and estradiol inhibits the secretion of GnRH, FSH, and LH ([Fig. 40.18](#)).

The oocyte, meanwhile, is swept into the fallopian tube and travels to the uterus. If it is fertilized, the developing embryo implants into the uterine lining. In this case, the corpus luteum continues to secrete progesterone; the corpus luteum is maintained first by LH and then by the hormone [human chorionic gonadotropin \(hCG\)](#), which is released by the developing embryo. Eventually, the placenta takes over estrogen and progesterone production to maintain the uterine lining and stimulate growth of the uterus. High levels of estrogen and progesterone during pregnancy also block ovulation because they suppress the release of GnRH, FSH, and LH.

If the oocyte is not fertilized, the corpus luteum degenerates, estrogen and progesterone levels drop, and the uterine lining is shed. The monthly shedding of the uterine lining is known as [menstruation](#). Menstrual cycles usually start occurring around age 12 in the United States and continue until approximately age 45 to 55. The cessation of menstrual cycles, called [menopause](#), results from decreasing production of estradiol and progesterone by the ovaries.

As we have seen, the brain, anterior pituitary gland, ovaries, uterus, and placenta pass hormonal messages back and forth to ensure that behavior, gamete release, the thickening of the uterine lining, and embryonic development are coordinated ([Fig. 40.18](#)). If hormone levels are low or absent, as occurs normally before puberty or as the result of malnutrition or some diseases, ovulation does not occur. Similarly, too much hormone at the wrong time can interfere with fertility, a factor that serves as the basis for oral contraceptive pills (“the pill”). Oral contraceptive pills contain various combinations of

synthetic estrogens, progesterones, or both. Estrogens and/or progesterones in the pill suppress GnRH, FSH, and LH, thereby blocking oocyte development and ovulation.

Humans and chimpanzees both have menstrual cycles. Other placental mammals have an **estrus cycle**, which is characterized by phases in which females are sexually receptive. In these mammals, the uterine lining is reabsorbed instead of shed if fertilization does not occur.

#### Self-Assessment Questions

7. What is the pathway of sperm from its site of production to the urethra?
8. What effect would cutting the vas deferens on both sides and tying off the ends have on male fertility?
9. Describe the pathway of an oocyte (and the egg it develops into) from its site of production to the uterus.
10. What are the relationships among changes in levels of anterior pituitary and ovarian hormones, oocyte development, and changes in the uterine lining during a menstrual cycle?
11. A monthly course of an oral contraceptive pill usually consists of three weeks of hormone pills followed by one week of placebo (a sugar pill with no hormone). Why do you think placebos are sometimes used?

## 40.4 GAMETE FORMATION TO BIRTH IN HUMANS

With an understanding of male and female reproductive anatomy and endocrinology, we are ready to follow human reproduction and development from the formation of sperm and eggs, to fertilization, to subsequent development of the embryo and fetus, and finally to birth. Along the way, we consider how these processes vary in different organisms. Our understanding of these processes is in large part informed by studies in model organisms, including the sea urchin (*Strongylocentrotus purpuratus*), roundworm (*Caenorhabditis elegans*), fruit fly (*Drosophila melanogaster*), African clawed frog (*Xenopus laevis*), and house mouse (*Mus musculus*). These organisms have particular reproductive and developmental features that make them suitable for laboratory study.

### Male and female gametogenesis have both shared and distinct features.

The formation of gametes is called **gametogenesis**. Gametogenesis follows the same steps in males and in females, but there are striking differences in its timing (**Fig. 40.19**).

FIG. 40.19 Spermatogenesis in the male and oogenesis in the female.

**Spermatogenesis** is the formation of sperm. It occurs in the seminiferous tubules of the testes beginning at puberty and continuing throughout life. The process starts with spermatogonia, diploid stem cells that divide by mitosis to ensure a continuous population of precursor cells. During puberty and throughout adulthood, these cells differentiate into diploid **primary spermatocytes**, which undergo the first meiotic division to produce two **secondary spermatocytes** and the second meiotic division to produce four haploid spermatids joined by cytoplasmic bridges. The spermatids subsequently separate from each other to become distinct haploid cells. The maturation process, in which spermatids become spermatozoa or sperm, begins in the testes and continues in the epididymis, where they acquire motility. Spermatogenesis takes about 2 to 3 months.

**Oogenesis** is the formation of ova or eggs. The diploid precursor cells are called oogonia. These cells form during embryonic development and divide by mitosis. Some oogonia differentiate into diploid **primary oocytes** during fetal development. These enter the first meiotic division but their differentiation is arrested immediately in prophase I, the first stage of meiosis. All these steps take place before the female is even born. At birth, a female has approximately 1 to 2 million primary oocytes, all arrested in prophase I of meiosis. They do not resume the first meiotic division until a menstrual cycle begins. Therefore, remarkably, all of oocytes remain arrested for at least 12 years (from birth to the age of menarche) and some for as long as 50 years (to the age of menopause).

In the first phase of the menstrual cycle, approximately 10 to 20 follicles, each containing an oocyte, begin to mature in response to rising FSH levels. One of these follicles becomes dominant, allowing the primary oocyte to complete the first meiotic division. This division is asymmetric, leading to the formation of a large **secondary oocyte** and a much smaller **polar body**. Most of the cytoplasm is partitioned into the secondary oocyte. The secondary oocyte is released from the ovary and immediately enters the second meiotic division, but again arrests, this time in metaphase II. The secondary oocyte remains arrested in metaphase II until fertilization takes place. Upon fertilization, the second meiotic division continues, producing an ootid and another polar body, again allowing most of the cytoplasm to end up in the developing egg. The ootid quickly develops into a mature ovum, or egg.

# Fertilization occurs when a sperm fuses with an oocyte.

During fertilization, two gametes fuse, restoring the diploid chromosome content ([Fig. 40.20](#)). In humans, male and female gametes are usually brought together by sexual intercourse. Sexual arousal leads to a host of physiological changes, including erection of the penis, erection of the clitoris, and lubrication of the vagina. The erect penis is inserted into the vagina until orgasm occurs. Orgasm is characterized by feelings of pleasure and contractions of the pelvic muscles. In males, it is usually accompanied by ejaculation, in which semen, containing sperm, is delivered into the vagina.

FIG. 40.20 Fertilization. Many sperm cluster around an oocyte, but usually just one fuses with it to form a zygote.

Sperm travel through the cervix and into the uterus and fallopian tubes. Fertilization usually occurs in one of the fallopian tubes. Many details about how sperm travel through the female reproductive tract are poorly understood. Sperm are motile, but from studies of the time it takes sperm to reach the fallopian tubes, it appears that the female reproductive tract plays an active role in moving sperm to the oocyte, such as through muscular contractions.

In the female reproductive tract, sperm undergo [capacitation](#), a key developmental step that is unique to mammals. Capacitation is a series of physiological changes that allow the sperm to fertilize the egg. These changes include alterations in the fluidity of the plasma membrane, loss of some surface membrane proteins, and changes in the charge across the membrane, called the membrane potential ([Chapter 34](#)). As a result, sperm motility increases.

In many species, the oocyte releases soluble molecules, creating a concentration gradient that guides the sperm to the oocyte. On reaching the oocyte, the sperm passes through two layers—an outer layer of follicle cells called the corona radiata and an inner matrix of glycoproteins called the zona pellucida—before fusing with the plasma membrane of the oocyte ([Fig. 40.20](#)). In sea urchins, by contrast, a single vitelline membrane surrounds the egg. To facilitate its passage through these various outer layers, the head of the sperm releases enzymes from the acrosome. In addition, surface proteins on the gametes ensure that gametes interact only with other gametes from the same species. For organisms with external fertilization, such as sea urchins, these proteins are especially important.

After passing through the layers surrounding the oocyte, the plasma membranes of the sperm and oocyte fuse ([Fig. 40.20](#)). The oocyte then completes meiosis II and undergoes changes that prevent **polyspermy**, or fertilization by more than one sperm. The mechanisms for preventing polyspermy have been extensively studied in sea urchins and are classified according to how quickly they act. The first line of defense, or fast block to polyspermy, is caused by changes in the membrane potential of the egg: the membrane potential is usually negative but quickly becomes positive on fertilization. The fast block is quick but temporary and does not occur in mammals.

A second, more stable defense is slow block to polyspermy. In this process, vesicles in the egg fuse with the plasma membrane and release their contents, leading to modifications of the structure of the zona pellucida in mammals and the vitelline membrane in sea urchins that make this zone impassable to sperm.

Although sexual intercourse is one way in which gametes are brought together, there are now other methods to achieve fertilization and pregnancy in humans. The various techniques, which are collectively called assisted reproductive technologies, are typically used to treat infertility. For example, **in vitro fertilization (IVF)** is a process in which eggs and sperm are brought together in a petri dish, where fertilization and cell divisions occur. The developing embryos are then inserted into the uterus. The first IVF or “test tube” baby was born in 1978, and since then several million babies have been conceived in this way. Assisted reproductive technologies such as IVF have opened the door to pre-implantation genetic diagnosis, in which

oocytes or embryos are screened for genetic diseases before implantation. This technique raises ethical concerns, as it can be used to determine and select the gender of the embryo and other traits not associated with disease.

## The first trimester includes cleavage, gastrulation, and organogenesis.

How does a single, diploid cell (the zygote) become a complex, multicellular organism? Development depends on a precisely orchestrated set of cell divisions, movements, and specializations coordinated by both maternal and zygotic genetic instructions ([Chapter 19](#)). In this section, we focus on three key processes in early embryonic development: cleavage, gastrulation, and organogenesis.

After fertilization, the single-celled zygote divides by mitosis in a process called [cleavage](#) ([Fig. 40.21](#)). In cleavage, the single large egg divides into many smaller cells. In most organisms, these mitotic divisions are rapid, occur at the same time, and do not increase the overall size of the embryo. Furthermore, they occur in the absence of expression of the zygote's genes. Instead, molecules in the egg's cytoplasm direct these early cell divisions. These molecules include mRNA and proteins encoded by maternal genes ([Chapter 18](#)) and stored in the egg.

FIG. 40.21 Cleavage divisions.

Cleavage in mammals is unique in several respects. Notably, it is slow compared with cleavage in other organisms. The early divisions do not occur at the same time, so it is not unusual to find an odd number of cells in the developing embryo. Finally, transcription of zygotic genes begins very early, as early as the first mitotic division, or two-cell stage.

The pattern of cleavage is different for different organisms. For example, the presence of yolk inhibits cell division ([Fig. 40.22](#)). In animals with lots of yolk, such as insects, fishes, and birds, cell division does not extend through the entire egg ([Fig. 40.22a](#)). In animals with very little or no yolk, such as mammals and sea urchins, cell division extends completely through the egg ([Fig. 40.22b](#)). A developing embryo that lacks sufficient yolk depends on another source of nutrition; that source is the placenta in humans and other placental mammals.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Photo sources: a. © 2002 Steve Baskauf;  
 b. DIOMEDIA/Carolina Biological.

FIG. 40.22 Cleavage patterns. (a) Partial cleavage, shown in this zebrafish embryo. (b) Full cleavage, shown in this sea urchin embryo.

Cleavage results in a solid ball of cells called a **morula** (see [Fig. 40.21](#)). Further cell divisions result in a fluid-filled ball of cells called a **blastula** (or a blastocyst in humans and other mammals). It is around this time, approximately 5 days after fertilization, that the developing embryo implants into the uterine lining, which is thickened and highly vascularized under the influence of progesterone from the corpus

luteum.

Implantation marks the beginning of [pregnancy](#), the carrying of one or more embryos in the uterus. In humans, pregnancy lasts approximately 38 weeks from fertilization. Because the time of fertilization is often not known, human pregnancy is typically measured not from implantation but as 40 weeks from the first day of the last menstrual period. Pregnancy is divided into three periods called [trimesters](#), each lasting about 3 months. The divisions between the three trimesters are arbitrary, but they provide a convenient way to follow the major changes that occur during pregnancy.

The first trimester is characterized by spectacular changes in the developing embryo under the influence of genes and developmental pathways that are largely conserved across vertebrates ([Chapter 19](#)). During this time, the embryo develops all its major organs and begins to be recognizably human. Toward the end of the first trimester, a human embryo is known as a [fetus](#).

In mammals, such as humans, the blastocyst has an inner cell mass and an outer layer of cells ([Fig. 40.23a](#)). The inner cell mass becomes the embryo itself, and the outer cell layer forms part of the placenta. The placenta is composed of both maternal and embryonic cells and is the site of gas exchange, nutrient uptake, and waste excretion between maternal and fetal blood. The placenta also secretes the hormones estrogen and progesterone, which maintain the uterine lining during pregnancy. Meanwhile, the inner cell mass differentiates into a two-layered (bilaminar) structure consisting of the epiblast and the

hypoblast ([Fig. 40.23b](#)).

**a. Blastocyst**

The inner cell mass differentiates into two layers of cells — the epiblast and hypoblast.

**b. Bilaminar embryo**

**c. Gastrulation**

The epiblast cells migrate inward, displace the hypoblast cells, and differentiate into all three germ layers — ectoderm, mesoderm, and endoderm.

**d. Trilaminar embryo**

Germ layers: Ectoderm Mesoderm Endoderm

- Cells in the outer layer of skin
- Pigment cells
- Nerve cells in the brain

- Cells in the inner layer of skin
- Muscle cells
- Bone cells
- Red blood cells

- Cells lining the inside of the digestive tract
- Cells lining the inside of the lung
- Liver cells
- Pancreas cells

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 40.23 Early human embryonic development.

**Gastrulation** is the second key process in embryonic development. It is a highly coordinated set of cell movements that leads to a fundamental reorganization of the embryo. In humans, cells of the epiblast divide and migrate inward ([Fig. 40.23c](#)). These migrating epiblast cells form three layers or sheets of cells called **germ layers**: the outer **ectoderm**, intermediate **mesoderm**, and inner **endoderm** ([Fig. 40.23d](#)). All adult tissues and organs are made from one or more of these three germ layers. At this stage, the embryo is known as a trilaminar (three-layered) embryo to reflect the presence of the three germ layers.

As with cleavage, the details of gastrulation vary in different organisms. One notable difference is the fate of the opening through which cells migrate during gastrulation. In protostomes (“mouth first”), such as worms, mollusks, and arthropods, it becomes the mouth. In deuterostomes (“mouth second”), such as vertebrates and sea urchins, it becomes the anus, with the mouth forming later ([Chapter 42](#)).

**Organogenesis**, the third key developmental process, is the transformation of the three germ layers into all the organ systems of the body. The ectoderm becomes the outer layer of the skin and nervous system; the mesoderm makes up the circulatory system, muscle, and bone; and the endoderm becomes the lining of the digestive tract and lungs ([Fig. 40.23d](#)). Because all of the basic structures and organ systems develop during the first trimester of pregnancy, it is during this time that the developing embryo is particularly vulnerable to toxins,

drugs, and infections.

It is also during the first trimester that the embryo begins to develop male or female characteristics. In humans, sex is determined by the presence or absence of the Y chromosome. The Y chromosome contains a gene, *SRY*, that encodes a protein called testis-determining factor (TDF). TDF acts on the developing gonad to cause it to differentiate into a testis. In the absence of TDF in females, the immature gonad becomes an ovary. Once sex is determined, sexual differentiation follows under the influence of hormones produced by the gonads. In humans, then, sex determination is genetic, as is the case in other mammals and in birds. For other organisms, such as some reptiles and fishes, sex determination depends instead on environmental cues such as temperature and crowding.

## The second and third trimesters are characterized by fetal growth.

During the second trimester, from around 13 to 27 weeks, the fetus continues to develop and grow. This is the time when the mother first detects fetal movements. Because of improvements in medical care, babies born in the last few weeks of the second trimester are often able to survive.

The third trimester, from 28 to 40 weeks, is characterized by rapid growth, with the fetus doubling in size during the last 2 months. Weight gain is critical, as birth weight is a major factor in infant mortality. The fetus often moves less frequently during this trimester as it becomes increasingly compressed by limited space.

# Childbirth is initiated by hormonal changes.

Childbirth marks the end of pregnancy. Although we tend to think of childbirth as the delivery of the baby, it actually consists of three events: changes in the cervix to allow passage of the baby, descent and delivery of the baby, and delivery of the placenta. These three events result from strong muscular contractions of the uterus stimulated by the hormone oxytocin, which is released by the posterior pituitary gland. The action of oxytocin is a good example of positive feedback: exposure to oxytocin causes uterine contractions, stimulating more oxytocin release, which in turn leads to further contractions, and so on.

During pregnancy, the cervix is a tube about 4 cm long closed with a mucus plug. To allow passage of the infant, the cervix shortens and widens. These changes are not enough to accommodate passage of the baby during delivery. Humans have a narrow pelvis relative to that of other primates as an adaptation for bipedalism. To ease its passage through the pelvis, the baby goes through a series of movements ([Fig. 40.24](#)). Babies are usually born head first with the face pointing down (toward the mother's back) when passing through the birth canal. Other positions make vaginal birth more difficult, and sometimes impossible.

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

FIG. 40.24 Childbirth. Childbirth involves changes to the cervix, delivery of the

baby, and delivery of the placenta.

The third and final stage of childbirth is the delivery of the placenta, which usually occurs approximately 15 to 30 minutes after the baby is born.

Although birth normally occurs vaginally, in some cases, such as when the baby is too large or positioned feet first, it is necessary to remove the baby by making an incision in the abdomen and uterus in a surgical procedure known as a caesarean section. Interventions such as caesarean sections, the use of antibiotics, and prenatal and postnatal care have greatly reduced the maternal and fetal mortality associated with childbirth.

Whichever way the baby is delivered, when the umbilical cord is cut and the baby takes its first breath, it begins its life independent of the mother—anatomically independent, that is. Otherwise, human newborns are completely dependent on others. Humans are unusual among animals in having an extended period of immaturity while their brains and bodies grow and develop. This long period of immaturity means that parents usually put considerable effort into raising and caring for their offspring, and it allows for extended periods of learning, the development of strong social bonds, and the transmission of culture to the next generation.

Human development from fertilization to the end of pregnancy is summarized in [Fig. 40.25](#).

### Self-Assessment Questions

12. When are primary oocytes and spermatocytes produced, and how many gametes result from one diploid cell in females and males?
13. How are male and female gametogenesis similar? How are they different?
14. What are three key steps in the development of a single-celled zygote into a multicellular individual?
15. A multicellular organism starts off as a single cell, which divides by mitosis to produce many cells. Therefore, for the most part, all the cells in a multicellular organism are genetically identical—they are clones—yet in time different groups of cells look different and function quite differently from one another. How

can this be?

## CORE CONCEPTS SUMMARY

### **40.1 THE EVOLUTIONARY HISTORY OF REPRODUCTION:**

Reproduction is a basic feature of living organisms and occurs both asexually and sexually.

Asexual reproduction involves a single parent. Offspring are produced by binary fission or mitotic cell division and are clones of the parent. [page 897](#)

Examples of asexual reproduction include budding, fragmentation, and parthenogenesis. [page 898](#)

Sexual reproduction involves two parents: two haploid gametes, produced by meiotic cell division, fuse to make a diploid zygote. [page 899](#)

Many organisms reproduce both sexually and asexually. For some organisms, environmental conditions favor one mode or the other. [page 899](#)

Asexually reproducing populations grow rapidly but are genetically uniform clones. [page 900](#)

Sexual reproduction produces genetically unique offspring, a feature that is thought to explain why most eukaryotes reproduce sexually at least some of the time. [page 901](#)

### **40.2 MOVEMENT ONTO LAND AND REPRODUCTIVE**

**ADAPTATIONS:** The movement of vertebrates from water to land involved changes in reproduction, including internal fertilization and the amniotic egg.

Fertilization can occur outside or inside the body of the female. External fertilization is possible only in an aquatic environment. Internal fertilization is an adaptation to terrestrial life. [page 903](#)

External fertilization is usually associated with the production of many offspring, little or no parental care, and high mortality. These are characteristics of *r*-strategists. [page 903](#)

Internal fertilization is often associated with the production of fewer offspring, increased parental care, and low mortality. These are characteristics of *K*-strategists. [page 903](#)

A watertight sac, called the amnion, is an adaptation for reproduction on land. [page 904](#)

Oviparous animals lay eggs. Ovoviviparous and viviparous animals give birth to live young, but ovoviviparous animals retain eggs until they hatch and commonly get nutritional support from the yolk, whereas viviparous animals get nutritional support from the mother. [page 904](#)

### **40.3 HUMAN REPRODUCTIVE ANATOMY AND**

**PHYSIOLOGY:** The male reproductive system is adapted for the production and delivery of sperm, and the female reproductive system is adapted for the production of eggs and, in some cases, support of the developing fetus.

Male gametes, called sperm, develop in the seminiferous tubules of the testes. [page 905](#)

Sperm travel from the seminiferous tubules to the epididymis to the

vas deferens to the ejaculatory duct and finally to the urethra before being released during ejaculation. [page 905](#)

Semen is a mixture of sperm and fluid from the prostate gland, seminal vesicles, and bulbourethral glands. [page 906](#)

Developing female gametes, called oocytes, are produced in the ovaries. Mature oocytes are called eggs, or ova. [page 907](#)

An oocyte is released from the ovary, travels through the fallopian tube, and implants in the uterus if it is fertilized. [page 908](#)

The reproductive system responds to and produces hormones. The hypothalamus releases GnRH, which stimulates the anterior pituitary gland to release FSH and LH. These hormones, in turn, stimulate the ovaries to release estrogen and progesterone or the testes to secrete testosterone. [page 908](#)

In males, LH stimulates Leydig cells to secrete testosterone, and FSH and testosterone act on Sertoli cells to support sperm production. [page 909](#)

In females, monthly menstrual cycles are driven by the interplay of hypothalamic, anterior pituitary, and ovarian hormones, leading to ovulation, which is the maturation and release of an oocyte from the ovary, and to changes to the uterine lining. [page 909](#)

**40.4 GAMETE FORMATION TO BIRTH IN HUMANS:** Human reproduction involves the formation of gametes, fertilization, and growth and development.

Gametogenesis is called spermatogenesis in males and oogenesis in

females. [page 911](#)

In males, spermatogonia differentiate into primary spermatocytes that undergo meiosis to make immature haploid spermatids and mature spermatozoa or sperm. [page 911](#)

Spermatogenesis begins at puberty and continues throughout life. [page 911](#)

In females, oogonia undergo differentiation into primary oocytes during fetal development. The primary oocytes begin meiosis but arrest in prophase I. During a menstrual cycle, these oocytes are released from arrest, finish meiosis I, but then arrest in metaphase II. They remain arrested in metaphase II until they are fertilized. [page 911](#)

Fertilization is the fusion of the oocyte and sperm plasma membranes. It usually occurs in the fallopian tube and results in the formation of a diploid zygote. [page 912](#)

Cleavage is the division of the zygote by mitotic cell division into smaller cells. At the blastocyst stage, the developing embryo implants in the uterus. [page 914](#)

Human pregnancy lasts approximately 38 weeks from fertilization until birth and is divided into three trimesters. [page 914](#)

Gastrulation results in the formation of the three germ layers: ectoderm, mesoderm, and endoderm. [page 916](#)

Organogenesis is the formation of organs. [page 916](#)

Childbirth, regulated by the posterior pituitary hormone oxytocin, involves changes in the cervix, delivery of the baby, and delivery of the placenta. [page 917](#)

## CHAPTER 41 Animal Immune Systems

SPL/Science Source

### CORE CONCEPTS

**41.1 AN OVERVIEW OF THE IMMUNE SYSTEM:** The immune system protects organisms from pathogens.

**41.2 INNATE IMMUNITY:** The innate immune system acts generally against a diversity of pathogens.

**41.3 B CELLS AND ANTI-BODIES:** The adaptive immune system includes B cells that produce antibodies against specific pathogens that reside outside cells in tissues.

**41.4 T CELLS AND CELL-MEDIATED IMMUNITY:** The adaptive immune system also includes helper and cytotoxic T cells that attack infected, diseased, and foreign cells.

**41.5 THREE PATHOGENS:** A virus, bacterium, and eukaryote illustrate how some pathogens have evolved mechanisms that enable them to evade the immune system.

---

All organisms have mechanisms that protect them against harmful pathogens. Pathogens evolve strategies to evade these mechanisms, and organisms in turn evolve new responses. In animals, the result of this evolutionary back and forth is an elaborate and sophisticated immune system. The immune system is remarkable in its ability, in most cases, to protect organisms from harmful pathogens. Consider how well your body is able to defend itself, without taking antibiotics, from the common cold and from bacterial infections that enter through cuts and scrapes. In fact, because our immune system is so effective, we don't even notice most of the pathogens we encounter every day. A key feature of the vertebrate immune system is that it has evolved both defenses that act against a broad range of pathogens and defenses that target specific pathogens.

We begin with an overview of the immune system and then discuss

general defenses that protect against a diverse array of pathogens. We then turn to a powerful part of the immune system that is tailored to attack specific pathogens and that has the ability to learn and remember, attributes we usually associate with the nervous system. Finally, we consider three infections that illustrate how pathogens have evolved ways to evade these defenses.

# 41.1 AN OVERVIEW OF THE IMMUNE SYSTEM

The immune system differs in important ways from the other systems we have considered up to this point. Most organ systems are made up of discrete tissues or organs. Consider the cardiovascular system, which includes the heart and associated blood vessels. Or think of the gastrointestinal system, which is made up of a series of organs, such as the esophagus, stomach, and intestine, each with a specialized function for digesting food and absorbing nutrients.

By contrast, the immune system consists of organs, cells, proteins, and even biochemical reactions that are spread throughout the body. Its presence everywhere in the body makes sense, in that the immune system must be able to interact with pathogens wherever they might be found. Some organs are dedicated to the immune system, such as the thymus in many vertebrates, but otherwise the immune system is a diffuse system of cells, molecules, and processes. In fact, the phrase “immune system” was not even used until the late 1960s. It was introduced to draw attention to the fact that the immune system is truly a *system* made up of many different components. These components work by different mechanisms, but all share a common function: to protect an organism from pathogens.

## Pathogens cause disease.

**Pathogens** are organisms and other agents that cause disease. For a bacterium, pathogens include viruses that infect bacteria, as we have seen ([Chapter 18](#)). These viruses are called bacteriophages (literally

“bacteria eaters”). They can cause the bacterial cell to lyse, or burst, when viral progeny are produced inside the bacterium. In response, bacteria protect themselves with broadly effective mechanisms such as the cell wall or mechanisms such as CRISPR directed at specific pathogens. CRISPR allows bacteria to “remember” past viral infections and mount a response when subsequent infections by the same virus occur ([Chapter 12](#)).

For a fungus, pathogens include bacteria and viruses. In turn, fungi have evolved molecules that kill or inhibit the growth of bacteria. We have isolated many of these substances and learned how to use them as antibiotics. Penicillin is a famous example. It was discovered in 1928 by Alexander Fleming, who noticed that a fungus in the genus *Penicillium* interfered with the growth of bacteria in a petri dish.

For an animal, pathogens include viruses, bacteria, fungi, single-celled eukaryotes commonly called protists, and worms ([Fig. 41.1](#)). These organisms cause disease in diverse ways. In some cases, they infect a particular type of cell. For example, human immunodeficiency virus (HIV) destroys a specific type of cell involved in the immune system itself, making the body susceptible to other pathogens that it would usually be able to easily fight off. In other cases, pathogens proliferate in an organ and interfere with its function. Pneumonia, for example, can arise when bacteria or fungi proliferate in lung tissue and limit gas exchange. Sometimes, pathogens produce toxins that cause disease. Cholera, for instance, results from infection with a toxin-producing bacterium called *Vibrio cholera*. The toxin interferes with membrane transporters in the small intestine and causes diarrhea,

resulting in dehydration and sometimes death.

## The immune system distinguishes self from nonself.

Critical to the functioning of the immune system is the ability to recognize pathogens as foreign. That is, the immune system must be able to distinguish the molecules and cells of its own organism, described as host or **self**, from the molecules and cells of other

organisms, described as foreign or [nonself](#), and then respond only to those that are nonself.

The immune system is able to distinguish self from nonself largely by recognizing proteins that normally reside on the surface of cells. For example, in organ transplants, the immune system sometimes recognizes proteins on the surface of transplanted organs as nonself. The transplanted organs are then attacked by the immune system, leading to rejection of the transplant.

Sometimes, the immune system mistakes self and nonself. If the immune system reacts inappropriately to self, it can end up attacking its own cells or tissues. This type of reaction occurs in [autoimmune diseases](#), such as rheumatoid arthritis, type 1 diabetes, and multiple sclerosis. Alternatively, the immune system may sometimes recognize as nonself harmless substances such as pollen or dust, leading to allergic reactions. In some cases, the immune system may not react when it should, so that it does not adequately protect an organism. Such a weak immune system is most likely to occur at the extremes of age or when infections or diseases compromise its function, a condition called [immunodeficiency](#).

The activity of the immune system is carefully regulated. When functioning properly, immune cells and proteins remain in an inactive state until they come into contact with a foreign molecule or cell. In this way, the immune system reacts only when it is needed to attack a pathogen.

The distinction between self and nonself is a useful way to think

about how the immune system functions, but it has limitations. For example, as we will see, the immune system is able to recognize and attack self cells that are diseased or infected, but it also tolerates bacteria and other nonself microorganisms that make up our microbiome ([Case 5 The Human Microbiome](#)). French immunologist Polly Matzinger proposed that another way to think about the immune system is that it recognizes and attacks agents that cause injury or damage, not necessarily those that are foreign. Her idea suggests that we have more work to do to fully understand how the immune system functions.

## The immune system consists of innate and adaptive immunity.

The immune system consists of two parts that work in different ways and interact with each other to protect against infection. Each part is made up of different cell types and pathways. The first type of immunity, called [innate immunity](#) (or natural immunity), provides protection against all kinds of infection in a nonspecific manner. Innate immunity is present in fungi, plants, and animals and is an evolutionarily early form of immunity. It is considered *innate* because it does not depend on prior exposure to a pathogen.

By contrast, the second form of immunity, called [adaptive immunity](#) (or acquired immunity), is specific to a given pathogen. Adaptive immunity “remembers” past infections, meaning that subsequent encounters with the same pathogen generate a stronger response. In other words, the immune system *adapts* over time, and immunity is *acquired* after an initial exposure. Adaptive immunity

evolved later than innate immunity and is unique to vertebrates.

**Table 41.1** summarizes the major differences between these two forms of immunity.

**TABLE 41.1 Comparison of the Innate and Adaptive Immune Systems**

|                                              | INNATE IMMUNE<br>SYSTEM | ADAPTIVE IMMUNE<br>SYSTEM |
|----------------------------------------------|-------------------------|---------------------------|
| Targets                                      | Diverse pathogens       | Diverse pathogens         |
| Ability to distinguish self from<br>nonself? | Yes                     | Yes                       |
| Specificity?                                 | No                      | Yes                       |
| Memory?                                      | No                      | Yes                       |
| Organisms                                    | All organisms           | Vertebrates               |

#### Self-Assessment Questions

1. How are the innate and adaptive immune systems similar?
2. How are the innate and adaptive immune systems different?

## 41.2 INNATE IMMUNITY

The innate immune system provides general, nonspecific defenses against a broad array of pathogens. In animals, it includes tissues, such as the skin, that act as a barrier to infection, cells that act as sentries against pathogens, and proteins and other molecules circulating in the blood that signal the presence of infection. All these defenses are nonspecific, act immediately, and do not depend on past exposure to elicit a response.

### The skin and mucous membranes provide the first line of defense against infection.

Organisms have a barrier that surrounds them. Examples include the cell wall of bacteria, the bark of trees, the cuticle of leaves, the exoskeleton of insects, the scales of fish, the shells of eggs, and the skin of mammals ([Fig. 41.2](#)). These structures act as physical barriers against infection.

Sources: a. Christian Beier/AGE Fotostock; b. Michael P. Gadomski/Science Source; c. Charles J. Smith; d. Inga Spence/Alamy; e. Janaka Dharmasena/Shutterstock.

FIG. 41.2 Physical barriers against infection. (a) Tree bark; (b) leaf cuticle; (c) insect exoskeleton; (d) egg shell; (e) skin.

To understand the importance of this barrier, consider what happens when it is breached. Burn victims who lose the outer layer of their skin are particularly vulnerable to infection. The bite of a dog or the sting of an insect can insert viruses, bacteria, or parasites directly into the bloodstream, bypassing the protective layer of skin. Even a small puncture wound can provide entry for the bacterium *Clostridium tetani*, the cause of tetanus.

Any surface that comes in contact with the external environment is a potential entry site for pathogens. Like the skin, the mucous membranes of the respiratory, gastrointestinal, and genitourinary tracts act as physical barriers. However, they have additional protective

mechanisms. For example, parts of the respiratory tract have [cilia](#), hairlike projections that sweep mucus containing trapped particles and microorganisms out of the body. Saliva and tears contain enzymes that help to protect against bacteria. The stomach, with its low pH and enzymes that break down food, is inhospitable to many microorganisms.

In addition to acting as a physical and chemical barrier, the skin and mucous membranes provide a home to many nonpathogenic microorganisms. These microorganisms in some cases provide protection against harmful pathogens by competing with them for food and space. They may also maintain health in other ways, such as by aiding digestion. In this way, the human body engages in a mutualistic relationship with these microorganisms ([Case 5 The Human Microbiome](#)).

## White blood cells provide a second line of defense against pathogens.

If a pathogen makes it past the skin and mucous membranes of an animal, a second line of defense may rise to combat it: [white blood cells](#) (leukocytes). Many different types of white blood cells are present in the body, but all arise through differentiation from stem cells in the bone marrow ([Fig. 41.3](#)). Just as the skin and mucous membranes are an external defense against pathogens, white blood cells are an internal defense. Some white blood cells mount an early response to a pathogen; these are nonspecific innate immune cells. If they are unable to clear the pathogen, they alert the more specialized white blood cells of the adaptive immune system. Here, we focus on

the role of white blood cells in innate immunity.

FIG. 41.3 White blood cells. Many different types of white blood cells function in the innate and adaptive immune systems. They develop from stem cells in the bone marrow.

**Phagocytes** (literally, “eating cells”) are white blood cells that engulf and destroy foreign cells or particles. The engulfing of a cell or particle by another cell is called **phagocytosis**. The Russian microbiologist Ilya Mechnikov first described this remarkable process. For this discovery, he shared the Nobel Prize in Physiology or Medicine with the German scientist Paul Ehrlich in 1908.

The phagocytic process begins when a phagocyte encounters a cell or particle that it recognizes as foreign and binds to it. The phagocyte then extends its plasma membrane completely around the cell or particle until it is contained in a compartment or vesicle inside the phagocyte (**Fig. 41.4**). In some cases, the vesicle merges with a lysosome, and enzymes within the lysosome digest the foreign cell or

particle. Phagocytosis can also trigger a respiratory burst, a process that generates reactive oxygen species, such as superoxide radicals and hydrogen peroxide, and reactive nitrogen species, such as nitrogen oxide and nitrogen dioxide. These molecules have antimicrobial properties that directly damage pathogens.

Three major types of phagocytic cells are present in the body: **macrophages**, **dendritic cells**, and **neutrophils** (see [Fig. 41.3](#)). In each case, the name gives clues about the cell's shape and size.

Macrophages are large cells that patrol the body (*macro* means “large”). Dendritic cells have long cellular projections that resemble the dendrites of neurons ([Chapter 34](#)). Both macrophages and dendritic cells are typically part of the natural defenses found in the skin and mucous membranes. Neutrophils are members of a group of cells called **granulocytes** because of the presence of granules in their cytoplasm. The granules of neutrophils take up both acidic and basic dyes, so their staining pattern is considered neutral. Neutrophils are abundant in the blood and are often the first cells to respond to infection.

The innate immune system includes several other white blood cell types in addition to phagocytic cells (see [Fig. 41.3](#)). Two types of granulocytes, **eosinophils** and **basophils**, defend against parasitic infections, but also contribute to allergies. **Mast cells** release **histamine**, an important contributor to allergic reactions and inflammation. Finally, **natural killer cells** do not recognize foreign cells, but instead identify and kill host cells that are infected by a virus or have become cancerous or otherwise abnormal.

## Phagocytes recognize foreign molecules and send signals to other cells.

Phagocytes attack foreign cells that they encounter but leave host cells alone. How is a phagocyte able to distinguish a foreign cell from a host cell? All cells have on their surface an array of proteins and other molecules, as we saw in [Chapters 5](#) and [9](#). Phagocytes detect surface

molecules that are common to pathogens, but not to the host.

**Toll-like receptors (TLRs)** are proteins on the surface of phagocytes that recognize and bind to molecules on pathogens. First discovered in the fruit fly *Drosophila*, TLRs are found on cells in vertebrates and invertebrates, and similar molecules are found in plants and bacteria, indicating that they are an early, evolutionarily conserved part of the innate immune system. These proteins provide one of the earliest signals that an infection is present. TLRs recognize evolutionarily conserved surface molecules on a wide range of microorganisms. For example, one type of TLR recognizes a glycolipid on the cell wall of certain bacteria; another type recognizes a protein that is part of the bacterial flagellum.

Binding of TLRs to surface molecules on the pathogen is a signal to the phagocyte to engulf and destroy its target. Following binding of a foreign molecule to the TLR, phagocytes send a signal to the rest of the immune system that the body is under attack by releasing chemical messengers called **cytokines**. These chemical compounds recruit other immune cells to the site of injury or infection. Cytokines, like hormones, provide long-distance communication between cells (**Chapters 9** and **36**).

## Inflammation is a coordinated response to tissue injury.

Although some immune cells are already present at the site of tissue injury or infection, many more must be recruited to fight infection successfully. That recruitment happens as part of a process called

inflammation. The redness and swelling you see following an injury, a break in the skin, or an infection are signs of inflammation. More precisely, [inflammation](#) is a physiological response of the body to injury that removes the inciting agent if present and begins the healing process—for example, by initiating cell division to heal a wound. It works through the coordinated responses of the local tissue, the vascular system, and the innate immune system. Inflammation is typically beneficial, but if left unchecked or allowed to continue for a long time, it can be debilitating.

Inflammation is characterized by four signs, described by their Latin names: *rubor* (redness), *calor* (heat), *dolor* (pain), and *tumor* (swelling). The process begins following tissue injury, such as a cut or infection, as shown in [Fig. 41.5](#). Certain cells in the tissue, such as dendritic cells and mast cells, recognize a pathogen as foreign and release cytokines and other chemical messengers that recruit more white blood cells to the site or make it easier for them to reach the site quickly. For example, histamine, which is released by mast cells and basophils, acts directly on blood vessels to cause vasodilation. Vasodilation increases the blood flow to the site of infection or injury, which leads to the characteristic redness and heat of inflammation. In addition, histamine increases the permeability of the blood vessel wall. Fluid leaks out of the blood vessel, carrying white blood cells into the damaged tissue. The increased fluid in the tissue surrounding the blood vessels is visible as swelling. Some chemical messengers act directly on nerve fibers, causing pain.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

**FIG. 41.5 Inflammation.** Inflammation involves increased blood flow, leaky blood vessels, and activation of the immune system.

During inflammation, phagocytes in the blood often move from a blood vessel to the site of infection by **extravasation** (**Fig. 41.6**). In this process, the phagocyte travels along the vessel wall in a rolling motion, grabbing weakly onto the wall as glycoproteins on the phagocyte surface bind transiently to proteins on the endothelial cells. Stronger interactions put a brake on this rolling motion and allow the phagocyte to adhere more firmly to the vessel wall. As it nears the site of infection, the phagocyte encounters and binds to cytokines. The phagocyte then changes shape and moves in between cells lining the blood vessel and into the surrounding tissue.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 41.6 Extravasation. In extravasation, a phagocyte moves from a blood vessel to the surrounding tissue.

The complement system participates in the innate and adaptive immune systems.

We have seen that many white blood cells participate in innate

immunity, providing a general defense against pathogens. Other white blood cells participate in adaptive immunity, and white cells from both the innate and adaptive immune systems can be activated by a set of proteins that circulate in the blood. Collectively, these proteins make up the **complement system**. First described by Paul Ehrlich in the late 1800s, this system is so named because it supplements or *complements* other parts of the immune system; it is considered to be part of the innate immune system.

The complement system consists of more than 25 proteins, many of which are enzymes, that circulate in the blood in an inactive form. The system is activated when one of these proteins binds to molecules found only on invading microorganisms or to antibodies (discussed later in this chapter). Activation sets off a biochemical cascade in which the product of one reaction is an enzyme that catalyzes the next. This kind of sequential activation leads to amplification of the response, as we saw earlier in cell signaling ([Chapter 9](#)) and in the endocrine system ([Chapter 36](#)), where a small stimulus can have a dramatic response.

Activation of the complement system has three effects ([Fig. 41.7](#)). First, and most dramatically, complement proteins circulating in the blood assemble to form a pore, called a **membrane attack complex (MAC)**, in bacterial cells. The MAC causes the bacterial cell to break open, or lyse. Second, the complement system coats bacteria with a protein that phagocytes recognize, allowing those cells to target the bacteria for phagocytosis. The binding of a protein to a pathogen to target it for phagocytosis is called **opsonization**. Third, activated

complement proteins attract other components of the immune system. For example, some of these proteins stimulate mast cells, which release histamine and initiate the inflammatory response.

FIG. 41.7 The complement system. The proteins of the complement system contribute to the defense against pathogens by cell lysis, phagocytosis, and inflammation.

You can appreciate the importance of the complement system by considering what occurs in individuals who lack key components. Complement deficiencies are a form of immunodeficiency, a condition in which the immune system does not function properly. For example,

one type of complement deficiency makes individuals susceptible to bacterial infections because fewer pathogens undergo cell lysis and opsonization. The intensity and type of symptoms vary depending on which component of the complement system is lacking, ranging from very mild, to recurrent infections, to other immunological disorders. Because antibodies are an important signal that activates the complement system, and because the presence of complement proteins on a pathogen helps to activate the adaptive immune system, the complement system provides an important bridge between the innate, nonspecific part of the immune system and the adaptive, specific part, a topic we consider in the next section.

---

## CASE 7 BIOLOGY-INSPIRED DESIGN: USING NATURE TO SOLVE PROBLEMS

### How can we use a protein that circulates in the blood to treat sepsis?

One complement protein is known as mannose-binding lectin (MBL). MBL circulates in the blood, where it recognizes carbohydrates on the surface of diverse pathogens, including viruses, bacteria, fungi, and protists. MBL binds to carbohydrates on the surface of these pathogens and can activate the complement system.

Researchers at the Wyss Institute for Biologically Inspired Engineering at Harvard University made use of MBL to build a device to treat sepsis. Sepsis is a blood infection that can lead to organ failure

and death; it is a common cause of patients' deaths in the hospital. Because the identity of the pathogen is often not known, sepsis is typically treated with broad-spectrum antibiotics, which act against a wide variety of common bacteria. However, the antibiotics do not always work and many patients do not recover.

The researchers at the Wyss Institute took a different approach. They built a device that makes use of MBL, which recognizes and binds to many common bacteria, like those that cause sepsis. They began by coating magnetic beads with a modified form of MBL. The beads were inserted into a device that mimics the spleen, which helps to remove old cells and pathogens from the blood. Blood from a patient was circulated out of the body and passed through the device. Pathogens bound the MBL-coated beads, with the complex of pathogen–MBL–bead subsequently being removed from the blood by magnets. The blood was then returned to the patient, similar to what happens during dialysis ([Chapter 39](#)).

In experiments with rats, the biospleen, as the device is called, was able to remove 90% of bacteria in the blood. Furthermore, the survival rate of rats with sepsis increased significantly when rats were treated in this way compared to untreated control rats. The biospleen, if it proves effective in humans, has the potential to revolutionize the treatment of sepsis.

#### Self-Assessment Questions

3. What are the components of the innate immune system?

4. Certain diseases, as well as cigarette smoke, can damage cilia lining the respiratory tract. What effects would you expect from damage to respiratory cilia?
  5. How do cells of the innate immune system recognize pathogens?
  6. How do the four signs of inflammation relate to the changes that occur in the underlying tissues?
-

## 41.3 B CELLS AND ANTIBODIES

The innate immune system can react to diverse pathogens and has the capacity to distinguish self from nonself. The adaptive immune system shares these features, but also has two additional ones. The first is specificity: the adaptive immune system produces an array of molecules, each of which has the potential to target a specific pathogen it has never before encountered. As a result, it is often more effective at eliminating a pathogen than the innate immune system is. The second is memory: the adaptive immune system remembers past infections and mounts a stronger response on re-exposure.

Consider for a moment the number of pathogens that we might encounter—on the order of millions—and remember that they, too, are evolving all the time. How can the adaptive immune system tailor its response to each of these pathogens? And how does it remember past infections? We explore answers to these questions in the next two sections.

While many cells and tissues play a role in adaptive immunity, two types of white blood cells are particularly important: **B lymphocytes** (also called **B cells**) and **T lymphocytes** (also called **T cells**) (see [Fig. 41.3](#)). B and T cells are named for their sites of maturation. In birds, B cells mature in the bursa of Fabricius, an organ located off the digestive tract ([Fig. 41.8](#)). In mammals, B cells mature in the bone marrow. In most vertebrates, T cells mature in the thymus, an organ of the immune system located just behind the sternum, or breastbone. B

and T cells circulate in blood vessels and lymphatic vessels, which are thin-walled vessels that absorb excess fluid from tissues ([Chapter 37](#)). B and T cells also travel through the spleen, liver, and lymph nodes, where they sample the body for pathogens. We begin with a discussion of the role of B cells in adaptive immunity.

FIG. 41.8 Organs that participate in the immune system.

## B cells produce antibodies.

One of the hallmarks of adaptive immunity is the ability to target specific novel pathogens. Of course, many different viruses, bacteria, single-celled eukaryotes, fungi, and worms can lead to infection. How does the adaptive immune system recognize each one? The specificity of the adaptive immune system is in part the result of antibodies produced by B cells.

An **antibody** is a large protein found on the surface of B cells or free in the blood or tissues. An antibody binds to molecules on the surface of foreign cells, called **antigens**, which, by definition, are molecules that lead to the production of antibodies. (The word “antigen” is a contraction of “antibody” and “generator.”) Any molecule that naturally occurs on or in a microorganism can be an antigen. The great diversity of antigens on different microorganisms is matched by a great diversity of antibodies produced by an individual. It is estimated that humans produce approximately 10 billion different antibodies, each with the ability to recognize one or a few antigens on microorganisms.

Antibodies have a distinctive structure that reflects their specificity for a given antigen. The simplest antibody molecule, shown in **Fig. 41.9**, is a Y-shaped protein made up of four polypeptide chains: two identical **light (L) chains** and two identical **heavy (H) chains**, so named because of their relative molecular weights. Covalent disulfide bonds hold the four chains together.

FIG. 41.9 Structure of one type of antibody. An antibody has variable regions that distinguish it from the billions of other antibodies and allow it to bind a specific antigen.

The light and heavy chains are both subdivided into **variable (V)** and **constant (C)** regions (Fig. 41.9). The constant region, as the name implies, is the same in all antibodies of a given class. In contrast, the variable region is unique to each antigen that the antibody targets. Within the variable regions of the L and H chains are regions that are even more variable, called hypervariable regions. These hypervariable regions interact in a specific manner with just a portion of the antigen.

Binding of antibodies to antigens is the first step in recognition and removal of pathogens. Binding alone is sometimes enough to disable a pathogen. More often, the pathogen is killed by a different component of the immune system, such as by a phagocyte or the complement system. In this case, the function of an antibody is to recognize the pathogen, then recruit other cells of the immune system or activate the complement system.

## Mammals produce five classes of

## antibodies with different functions.

In mammals, there are five classes of antibodies, called immunoglobulins G, M, A, D, and E (abbreviated as **IgG**, **IgM**, **IgA**, **IgD**, and **IgE**, respectively), each with a different function (**Fig. 41.10**). IgG is the Y-shaped antibody depicted in **Figs. 41.9** and **41.10**. IgG circulates in the blood and is particularly effective against bacteria and viruses.

IgM is a pentamer in mammals and a tetramer in fishes. (A pentamer is a molecule made of five monomers; a tetramer is a molecule made of four monomers.) The individual units—the monomers—are linked by a joining chain. IgM also exists as a monomer on the surface of B cells. IgM is important in the early response to infection.

IgA is usually a dimer consisting of two antibody molecules linked by a joining chain. It is the major antibody on mucosal surfaces, such as those found in the respiratory, gastrointestinal, and genitourinary tracts. IgA is also present in secretions, including tears, saliva, and breast milk.

IgD and IgE are monomers. IgD is typically found on the surface of B cells. This immunoglobulin helps initiate inflammation. IgE plays a central role in inflammation, as well as in allergies, asthma, and other [immediate hypersensitivity reactions](#), in which the body mounts a heightened or inappropriate immune response to common antigens. Immediate hypersensitivity reactions result from the binding of IgE to receptors on the surface of mast cells and basophils. Binding leads to the release of histamine and cytokines, resulting in inflammation that can be life threatening.

## Clonal selection is the basis for antibody specificity.

A central question in immunology is how an individual can generate a great diversity of antibodies, each of which is specific for a given antigen. An organism might come across seemingly limitless types of antigens. How can B cells generate antibodies that interact only with specific antigens among this tremendous diversity?

Two alternative hypotheses have been proposed to explain antibody specificity. In 1900, Paul Ehrlich suggested that the body contains a large pool of B cells, each with a different antibody on its surface. The antigen binds to one or a few of these antibodies, stimulating the B cell

to divide. In this model, specificity exists before any exposure to the antigen. Ehrlich's model drew on concepts from chemistry such as the binding of an enzyme to a substrate in the manner of a lock and key ([Chapter 6](#)).

Later, in the early 1900s, a different hypothesis was suggested. This hypothesis proposed that the antigen instructs the antibody to fold in a particular way so that the two interact in a specific manner. In this model, the antigen plays a more active role in the process, and antibody specificity is determined only after interaction with the antibody.

Which of these two hypotheses is correct? Does the antigen *select* a B cell with a preexisting surface antibody with which it interacts specifically, as in the first hypothesis, or does it *instruct* the B cell to make a specific antibody, as in the second?

Experimental data on the genetic basis for antibody diversity (described later in this section) provided strong evidence for the first hypothesis. Every individual has a very large pool of B cells, each with a different antibody on its cell surface ([Fig. 41.11](#)). Collectively, these antibodies recognize a great diversity of antigens, but each individual antibody can recognize only one antigen or a few antigens. An antigen interacts with the antibody on the B cell, or a small set of B cells, that has the best fit for the antigen. Binding leads the B cell to divide and differentiate into two types of cells. Daughters of the B cell called [plasma cells](#) secrete antibodies that bind to the antigen and elicit an immune response against the pathogen. Long-lived daughters of the B cell called [memory cells](#) contain membrane-bound antibody having the

same antigen specificity as the parent cell. Since the resulting population of B cells arose from one B cell, they are all clones of one another.

The process by which antigen binding generates a clone of B cells is called **clonal selection**, and it is one of the central principles of immunology. Almost counterintuitively, antibody specificity is achieved before any exposure to the antigen. In this way, clonal selection resembles natural selection ([Chapter 20](#)). In natural selection, genetic variation occurs in a population; the environment then selects among this variation, allowing some individuals to survive and reproduce more than others. Similarly, in clonal selection, there is variation in a population of B cells, and the antigen selects among this variation, allowing some cells to proliferate more than others.

# Clonal selection explains immunological memory.

Clonal selection is the basis for antibody specificity. It also explains the second feature of the adaptive immune system: the ability to remember past infections—that is, to react more vigorously on re-exposure. The first encounter with an antigen leads to a **primary response** (Fig. 41.12). In this response, there is a short lag before antibody is produced. The lag is the time required for B cells to divide and form plasma cells and memory cells. The plasma cells secrete antibodies, typically IgM. The level of IgM in the blood increases, peaks, and then declines.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 41.12 Primary and secondary responses. The immune system responds more strongly to the second exposure to an antigen than to the first exposure because of the presence of memory B cells.

On re-exposure to the same antigen, even months or years after the first exposure, there is a [secondary response](#), which is quicker, stronger, and longer-lasting than the primary response ([Fig. 41.12](#)). During this response, memory B cells formed during the primary response differentiate into plasma cells that release IgG antibodies. These memory B cells respond more quickly to antigen exposure than naïve B cells (B cells that have not been previously exposed to antigen). In addition, the pool of memory B cells is larger than the pool of naïve B cells for a given antigen, explaining why the secondary response produces more antibodies for a longer period of time.

The presence of long-lived memory cells provides long-lasting immunity after an infection such as chickenpox. We have learned to make use of immunological memory in **vaccination**. A vaccine deliberately exposes an individual to an antigen from a pathogen to induce a primary response but not induce the disease, thereby providing future protection from infection by the same pathogen.

Vaccination was discovered by a combination of observation and experiment. Until the early 1700s, it was common practice to inoculate people with smallpox to induce a mild disease and prevent a more severe, even lethal, infection. It was also well known that milkmaids, exposed to the relatively benign cowpox virus from milking cows, were immune to the related but more deadly smallpox virus. In 1796, the English scientist Edward Jenner specifically tested the consequences of exposure to cowpox by inoculating a young boy with cowpox and demonstrating that he became immune to smallpox. In fact, the word “vaccine” is derived from the Latin *vacca*, which means

“cow.”

Today, vaccines take many forms: they can be a protein or a part of a protein from the pathogen, a live but weakened form of the pathogen, or a killed pathogen. They are among the most effective public health measures ever developed.

## Genomic rearrangement generates antibody diversity.

We pointed out earlier that antibody specificity is determined before exposure to the antigen. Clonal selection therefore requires a mechanism for producing a great diversity of antibodies. How is this diversity achieved? Diversity would result if each antibody were encoded by a separate gene. However, this cannot be the case, as the number of antibodies produced by an organism far exceeds the total number of genes in the genome. For example, the human genome consists of approximately 25,000 protein-coding genes, but humans can produce an estimated 10 billion different antibodies.

In 1965, American biologists William Dreyer and J. Claude Bennett suggested a novel hypothesis to explain antibody diversity. As they put it, this hypothesis was “radically different from anything found in modern molecular genetics.” Dreyer and Bennett proposed that a single antibody is made by separate gene segments that are brought together by recombination. According to this model, many copies of each gene segment are present, each slightly different from the others. Only one copy of each gene segment ends up in the final, recombined antibody gene (and hence in the antibody protein). Diversity is therefore

achieved by combining different copies of each segment in different B cells as they mature.

More than 10 years after Dreyer and Bennett proposed their model, direct experimental evidence showed that their hypothesis is correct (**Fig. 41.13**). As a B cell differentiates, different gene segments are joined in a process called **genomic rearrangement** that produces a specific antibody.

#### HOW DO WE KNOW?

### FIG. 41.13

## How is antibody diversity generated?

#### BACKGROUND

Humans produce an estimated 10 billion different antibodies. Antibodies are proteins, encoded by genes. However, the human genome contains only approximately 25,000 protein-coding genes. How can humans (and other vertebrates) produce such a diversity of antibodies from this limited set of genes? This was a central, unanswered question in immunology until the 1960s and 1970s.

#### HYPOTHESIS

In 1965, American biologists William Dreyer and J. Claude Bennett proposed a model in which there are many slightly different copies of two gene segments, which they called the V (variable) and C (constant) segments. According to this model, each unique antibody gene is assembled by recombining a single copy of each of these segments. At the time, there was no direct experimental evidence to support this hypothesis.

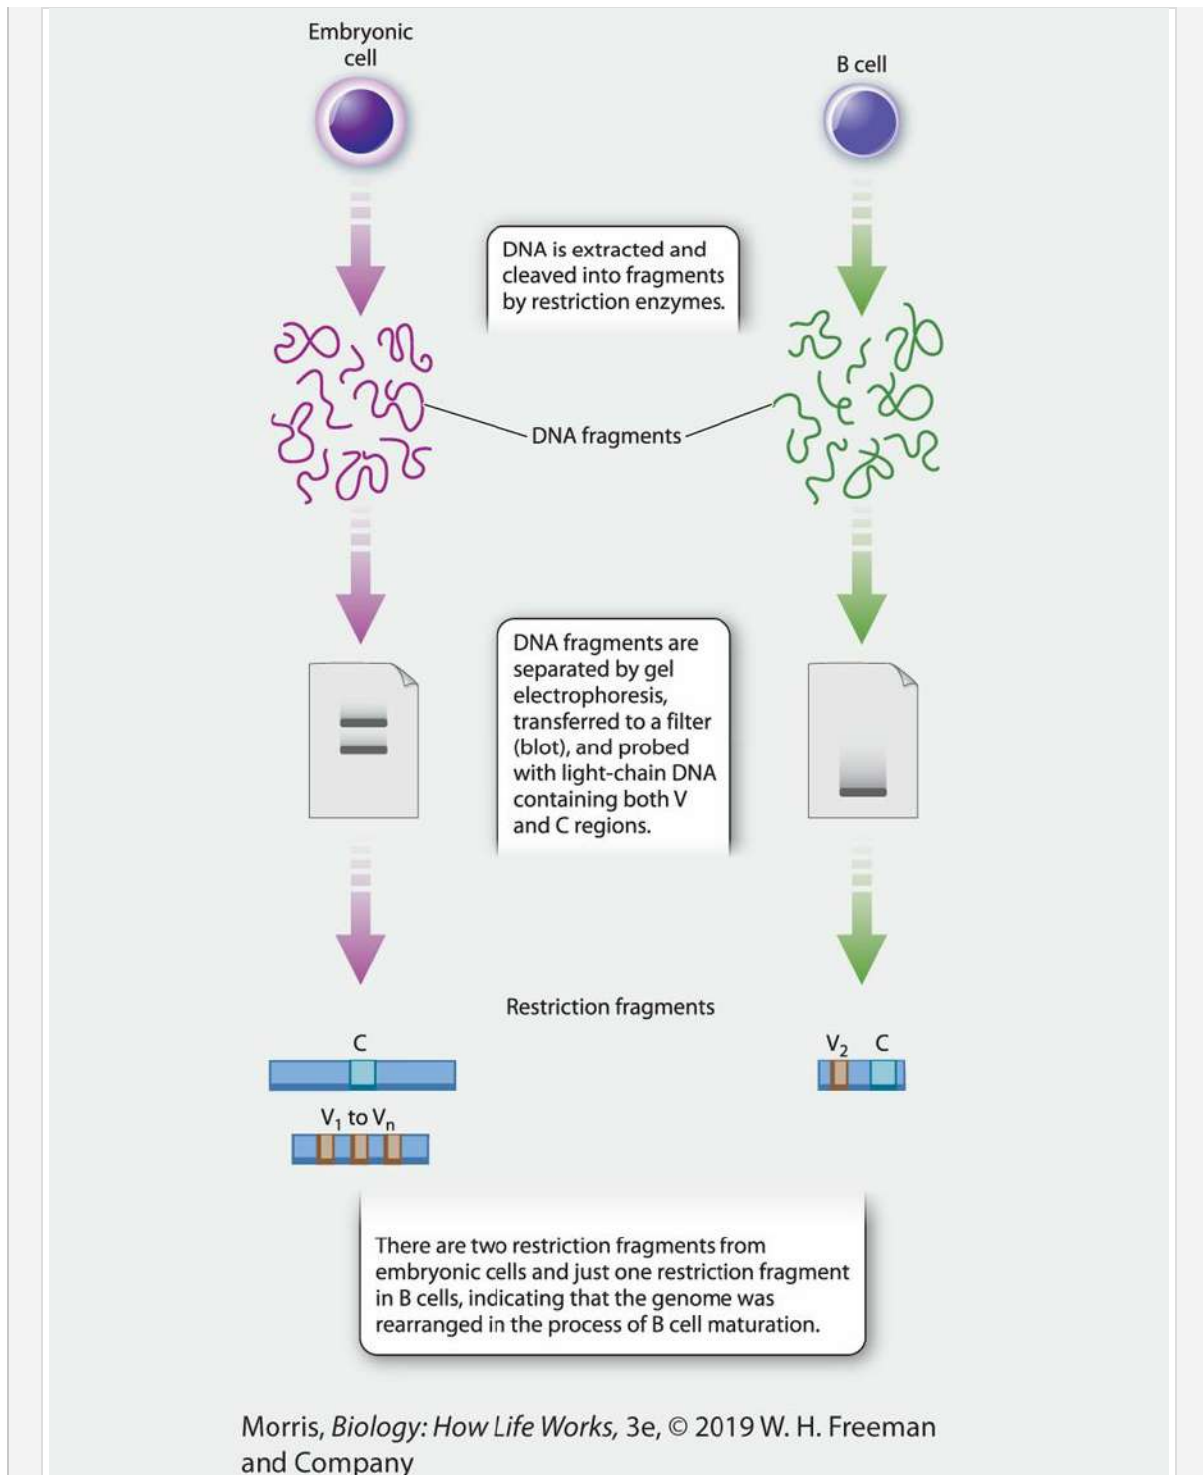

#### EXPERIMENT

In 1976, Japanese immunologists Nobumichi Hozumi and Susumu

Tonegawa tested the Dreyer and Bennett hypothesis. Using mice as a model system, they isolated DNA from embryonic cells (before recombination was thought to occur) and from adult B cell tumor lines that produce one type of antibody (after recombination was thought to occur). The procedure Hozumi and Tonegawa used was slightly different from what is described here, but conceptually the same. Extracted DNA is cut by restriction enzymes, the fragments are separated on a gel and transferred to a filter paper (blot), and light chain DNA (containing both V and C regions) is used as a radioactive probe to determine the size and positions of the V and C regions. (This technique, known as a Southern blot, is discussed in [Chapter 12](#).)

#### RESULTS

Hozumi and Tonegawa found that the V and C regions were in two different restriction fragments in embryonic cells and in one restriction fragment in adult B cells. Thus, the V and C regions are far apart in embryonic cells and close together in adult B cells.

## CONCLUSION

Antibody genes are assembled by recombination of individual gene segments during B cell differentiation, providing a mechanism for generating antibody diversity.

## FOLLOW-UP WORK

Further studies showed that there are multiple copies of several different gene segments, now called the V (variable), D (diversity), J (joining), and C (constant) regions for heavy chains, and V, J, and C regions for light chains. These are recombined in unique patterns in different B cells, so each B cell produces one antibody and a population of B cells produces a diversity of antibodies.

SOURCES Dreyer, W. J., and J. C. Bennett. 1965. "The Molecular Basis of Antibody Formation: A Paradox." *Proceedings of the National Academy of Sciences* 54:864–869; Hozumi, N., and S. Tonegawa. 1976. "Evidence for Somatic Rearrangement of Immunoglobulin Genes Coding for Variable and Constant Regions." *Proceedings of the National Academy of Sciences* 73:3628–3632.

Genes for H chains are composed of multiple different V (variable), D (diversity), J (joining), and C (constant) gene segments ([Fig. 41.14](#)). Genes for mice H chains, for example, can be composed of any of 100 different V segments, 30 D segments, 6 J segments, and 8 C segments. During B cell differentiation, the DNA for all of these gene segments undergoes recombination so that just one of each type of segment is present in the DNA, and the intervening DNA is deleted. The assembled VDJ segment encodes the variable portion, and the C segment encodes the constant region. L chain genes also contain multiple copies of gene segments, but they do not have a D gene segment, so the VJ segment encodes the variable portion and the C segment encodes the constant region. The result of this process is that each B cell encodes a single H chain and a single L chain, and each B cell expresses a unique antibody.

FIG. 41.14 Genomic rearrangement in mice. In genomic rearrangement, different gene segments recombine to generate a functional gene encoding the parts of an antibody.

It is worth pausing here to consider the significance of this mechanism. We generally think of DNA as being a stable blueprint present in identical copies in all of the somatic cells in our bodies. B cells are an exception. As a result of genomic rearrangement, the DNA in each mature B cell is different from the DNA in every other mature B cell, and is also different from the DNA in other cells in the body.

Genomic rearrangement is the primary mechanism that creates antibody diversity, but other mechanisms contribute as well. For example, the association of different L and H chains makes different kinds of functional antibodies. In addition, recombination is sometimes imprecise, creating different sequences at the junctions between the different gene segments. Other mechanisms add or replace nucleotides within VJ and VDJ segments. Finally, alternative splicing of mRNA

([Chapter 3](#)) allows a single B cell to express both membrane-bound and secreted antibodies.

As a group, B cells produce an enormous diversity of antibodies, whereas a given B cell makes one and only one antibody. But B cells are diploid, containing maternal and paternal copies of the genes that encode for antibodies. Maternal and paternal alleles of the antibody genes are similar, but not identical. Therefore, a B cell that is able to use both alleles would make two different antibodies, yet B cells always make one. Remarkably, once one allele undergoes genomic rearrangement, the other allele is prevented from doing so. As a result, B cells function as if they have a single allele for each antibody gene: they express the maternal gene or the paternal gene, but not both.

The mechanisms we have considered pertain to humans and mice. Whereas B cells mature in the bone marrow in humans and mice, they mature in gut-associated lymphoid tissue (GALT) in many other vertebrates. Furthermore, genomic rearrangement is less important in many vertebrates. Instead, other mechanisms appear to play a more important role.

#### Self-Assessment Questions

7. Draw a picture of an antibody molecule, labeling each of the components and the places where antigens bind.
8. How is immunological memory achieved?
9. Look again at [Fig. 41.12](#). Imagine that a different novel antigen is added on day 40 rather than a second injection of the same

antigen. Would there be a primary or a secondary response to this second antigen?

10. If a given B cell produces only one type of antibody, how do organisms produce a great diversity of antibodies?

## 41.4 T CELLS AND CELL-MEDIATED IMMUNITY

Antibodies are remarkable for their diversity and specificity. They provide protection against many kinds of bacteria, especially those enclosed in a polysaccharide capsule, such as the bacteria that cause pneumonia and meningitis. However, B cells and their antibodies have limitations. For example, B cells on their own can make antibodies against only some antigens; for other antigens, they require the assistance of other cells. Furthermore, they are sometimes ineffective against pathogens that take up residence inside a host cell, as do the bacteria that cause tuberculosis.

Another part of the adaptive immune system handles these and other kinds of pathogens. This aspect of the immune response depends on the second type of lymphocyte: the T cell. T cells do not secrete antibodies. Instead, they participate in [cell-mediated immunity](#), so named because cells, rather than antibodies, recognize and act against pathogens. T cells target infected or diseased cells. Their importance is most dramatically demonstrated by individuals taking immunosuppressive drugs or infected by HIV, both of which suppress the activity of T cells. The result can be overwhelming infections and even tumors.

### T cells include helper and cytotoxic cells.

There are two major subpopulations of T cells with different names, functions, and cell-surface markers: [helper T cells](#) and [cytotoxic T](#)

[cells](#) (see [Fig. 41.3](#)). Helper T cells do just that: they *help* other cells of the immune system by secreting cytokines. One of their key roles is to activate B cells to secrete antibodies. Although B cells can work on their own, particularly against encapsulated bacteria, in most cases they require the participation of helper T cells. Helper T cells also activate macrophages, cytotoxic T cells, and other cells of the immune system.

Cytotoxic T cells *kill* other cells—that’s what “cytotoxic” means. Like B cells, they are activated by cytokines released from helper T cells. Cytotoxic T cells are particularly effective against altered host cells, such as those infected with a virus or that have become cancerous.

These two types of T cells are distinguished by the presence of different glycoproteins on their surface: CD4 on helper T cells and CD8 on cytotoxic T cells. The ratio of these two classes of T cell can be used to assess immune function. In healthy individuals, the CD4 : CD8 ratio is usually about 2:1. A lower ratio, indicating the presence of fewer helper T cells relative to cytotoxic T cells, is typical of individuals infected with HIV. HIV infects and kills helper T cells, disarming a key player in the immune system. CD4 and CD8 assist receptors on T cells in carrying out their function. We discuss the function of T cells next.

**T cells have T cell receptors on their surface that recognize an antigen in association with MHC proteins.**

T cells, like B cells, originate in the bone marrow. However, unlike B cells, T cells mature in the thymus. A mature T cell is characterized by the presence on the plasma membrane of a **T cell receptor (TCR)**, a protein receptor that recognizes and binds to the antigen.

In many ways, TCRs are similar to antibodies on the surface of B cells. For example, TCRs recognize antigens with a specific structure. In addition, the many TCRs differ from one another, but each T cell has just one type of TCR on its surface. Binding of TCR to an antigen triggers the T cell to divide into clones, resulting in a pool of T cells that are each specific for a given antigen. Finally, as with the antibody diversity, the diversity of TCRs among T cells results from genomic rearrangement of V, D, J, and C gene segments.

However, TCRs are different from antibodies in important ways. First, they are composed of two, rather than four, polypeptide chains (**Fig. 41.15**). Second, they are not secreted like antibodies, but are always bound to the membrane on the T cell's surface. Third, the TCR does not recognize an antigen by itself. Instead, it recognizes an antigen in association with specific proteins that appear on the surface of most mammalian cells. These proteins are encoded by the **major histocompatibility complex (MHC)**. MHC proteins were first discovered in transplantation biology because their presence leads to acceptance or rejection of transplanted tissues.

FIG. 41.15 The T cell receptor (TCR). The TCR is a protein on the surface of T cells that binds antigens found in association with MHC proteins.

The MHC is a cluster of genes in mammals that encode proteins on the surface of cells. This complex is composed of many genes, all having a high rate of polymorphism, meaning that there is a lot of variation in the gene sequence (and consequently in the protein sequence) among different individuals. In humans and mice, the genes are divided into three classes: [class I](#) genes are expressed on the surface of all nucleated cells; [class II](#) genes are expressed on the surface of macrophages, dendritic cells, and B cells; and [class III](#) genes encode several proteins of the complement system and proteins involved in inflammation.

How do helper and cytotoxic T cells recognize and respond to antigens? Let's consider the activation of helper T cells first ([Fig. 41.16](#)). When an antigen enters the body, it may be recognized by an antibody directly or be taken up by [antigen-presenting cells](#). These

cells, which include macrophages, dendritic cells, and B cells, take up the antigen and return portions of it to the cell surface bound to MHC class II proteins. Through their T cell receptors, helper T cells recognize processed antigen along with MHC class II proteins. When TCR binds to antigen and MHC class II proteins, the helper T cells release cytokines that activate other parts of the immune system, including macrophages, B cells, and cytotoxic T cells.

FIG. 41.16 Three-way interactions among the T cell receptor, MHC protein, and processed antigen. Helper T cells recognize the processed antigen found in association with class II MHC protein, and cytotoxic cells recognize the processed antigen found in association with class I MHC protein.

Cytotoxic T cells also recognize antigens displayed by host cells, but only those antigens that are associated with MHC class I proteins

([Fig. 41.16](#)). Because class I proteins are present on almost all host cells, cytotoxic T cells recognize and kill any host cell that becomes abnormal in some way. For example, a virus-infected cell often expresses viral antigens with MHC class I proteins on its surface. Cytotoxic T cells recognize the antigen and MHC class I proteins and kill the virus-infected cell. Tumor cells express novel antigens along with MHC class I proteins, and in some cases may be eliminated by cytotoxic T cells. [Table 41.2](#) summarizes the major features of helper and cytotoxic T cells.

**TABLE 41.2 Comparison of Helper and Cytotoxic T Cells**

|                                      | HELPER T CELL                                                                                                   | CYTOTOXIC T CELL |
|--------------------------------------|-----------------------------------------------------------------------------------------------------------------|------------------|
| Functions                            | Activation of macrophages<br>Activation of B cells<br>Activation of cytotoxic T cells<br>Secretion of cytokines | Cell killing     |
| Surface molecule                     | CD4                                                                                                             | CD8              |
| MHC protein recognized by the T cell | Class II                                                                                                        | Class I          |

Once the helper or cytotoxic T cells become bound to the MHC–antigen complex, they divide and form clones. Some cells of each type are memory cells that provide long-lasting immunity following an initial infection, as in the case of B cells. Also like B cells, T cells can sometimes be activated too strongly. Earlier, we saw how IgE bound to mast cells and basophils can lead to immediate hypersensitivity reactions, like those characteristic of allergies and asthma. The counterpart in T cells is a [delayed hypersensitivity reaction](#), which,

as its name suggests, does not begin right away. For example, if you touch poison ivy, your skin will turn red and start itching only after a delay of several hours or days. Delayed hypersensitivity reactions are initiated by helper T cells. These cells release cytokines that attract macrophages to the site of exposure, which is typically the skin.

## The ability to distinguish between self and nonself is acquired during T cell maturation.

Of the many T cell receptors that may potentially be generated by genomic rearrangement, only some are useful. Useful T cell receptors must be able to react with the host's own MHC proteins, but not with other molecules that are normally present in or on a host organism's own cells. In other words, T cells must respond only to self MHC proteins in association with nonself antigens.

A sorting process ensures that only properly functioning T cells mature and others are eliminated ([Fig. 41.17](#)). As T cells mature in the thymus, they interact with cells of that organ's epithelium. The T cells that recognize self MHC proteins on epithelium cells are [positively selected](#) and continue to mature. The T cells that react too strongly to self antigens in association with MHC are [negatively selected](#) and eliminated through cell death. In spite of their names, both processes involve the elimination of some T cells.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 41.17 Positive and negative selection. Positive selection ensures that T cells react with self MHC proteins, and negative selection ensures that T cells do not react with other self antigens.

The results of this sorting process are twofold. First, T cells become

MHC restricted, meaning that they interact only with antigens that are associated with MHC proteins (helper T cells with antigen plus MHC class II proteins, and cytotoxic T cells with antigen plus MHC class I proteins). Second, T cells exhibit **tolerance**: they do not respond to self antigens, even though the immune system functions normally otherwise. Those antigens present as T cells mature are identified as self and do not elicit a response; those not present are nonself and, if encountered, do elicit a response.

B cells also exhibit tolerance to self antigens because they go through a similar process of negative selection in the bone marrow. During that process, B cells that react strongly to self antigens are eliminated through cell death. Although most self-reactive T and B cells are eliminated, some T and B cells that react to self antigens escape this developmental check and end up in the circulation. Additional mechanisms are in place to eliminate these self-reactive cells, either through the activity of T cells or through cell death.

The ability to distinguish self from nonself is critical. Failure to make this distinction leads to autoimmune disease, in which tolerance is lost and the immune system becomes active against antigens of the host. Autoimmune diseases can be debilitating, as T cells or antibodies attack cells and organs of the host. For example, in rheumatoid arthritis, self-reactive T cells attack the joints, causing chronic inflammation and tissue damage; in type 1 diabetes, the attack is directed against insulin-producing cells of the pancreas; and in multiple sclerosis, the target is the myelin sheath surrounding nerves of the central nervous system. It is not fully understood how these self-

reactive T cells evade checks on their development.

#### Self-Assessment Questions

11. How does T cell activation differ from B cell activation?
12. How do positive and negative selection lead to a population of T cells that react to MHC molecules in association with nonself antigens, but not to self antigens?
13. What happens when tolerance to self antigens is lost?

## 41.5 THREE PATHOGENS

Although we discussed the different components of the immune system one at a time, they actually work together to provide a coordinated response to pathogens. We have seen how B cells often require T cell help, how the complement system can be activated by antibodies produced by B cells, and how macrophages present antigens in association with MHC proteins to T cells. In turn, pathogens have evolved means of evading the immune system. In this section, we consider three pathogens: the flu virus, the bacterium that causes tuberculosis, and the malaria parasite. These pathogens illustrate how pathogens evolve and adapt in response to the immune system, and how the immune system in turn evolves and adapts in response to pathogens.

### The flu virus evades the immune system by antigenic drift and shift.

Everyone knows the symptoms: fever, chills, sore throat, cough, weakness, and fatigue, perhaps a headache and muscle pain. Many viruses cause these common flu-like symptoms. However, the common cold, stomach flu, and 24-hour flu are caused by unrelated viruses, not by the flu virus.

The flu (influenza) is caused by an RNA virus that infects mammals and birds. It is notable for causing seasonal outbreaks, or epidemics. Four times in the last century—in the Spanish flu of 1918, the Asian flu of 1957–1958, the Hong Kong flu of 1968–1969, and the swine flu of 2009—the virus spread more widely than usual and infected more

people, and the disease reached pandemic levels. The flu is more than just a nuisance: during pandemics, it causes hundreds of thousands of deaths worldwide.

Part of the success of the virus stems from its ability to spread easily. It can spread in the air by small droplets produced when an infected person coughs or sneezes. It can also spread by direct contact or by touching a contaminated surface, such as a doorknob. Hand washing, therefore, is one of the most effective means of protecting against the flu.

Another characteristic of the flu is its ability to evade the immune system. The flu virus can change the antigens on its outer coat, so memory cells, produced from earlier infections, no longer recognize them. There are three major types of flu virus (A, B, and C), and many different strains. For example, the swine flu pandemic of 2009 was caused by a type A flu virus of the strain H1N1. These strains differ in several respects, including the structure of a cell-surface glycoprotein called hemagglutinin (HA). HA binds to epithelial cells and controls viral entry into these cells. It can bind only to cells that display a complementary cell-surface protein. As a result, hemagglutinin determines in part which organisms the flu virus infects—humans, pigs, or birds—and which part of the body it infects—the nose, throat, or lungs.

Cells infected by viruses secrete cytokines that bring macrophages, T cells, and B cells to the site of infection, as we saw earlier. These cytokines, which are produced in abundance, lead to many of the

symptoms commonly associated with the flu. For example, the cytokine interleukin-1 causes fever.

Once in the cell, the virus replicates its genome and makes more virus particles ([Chapter 18](#)). However, viral replication is prone to error, so there is a high rate of mutation. As a result, the amino acid sequences of antigens present on the viral surface, including HA, change over time. This process, called **[antigenic drift](#)** ([Fig. 41.18a](#)), allows a population of viruses to evolve over time and evade memory B and T cells that remember past infections.

FIG. 41.18 (a) Antigenic drift and (b) antigenic shift. Virus populations evolve over time and evade the immune system's memory cells.

While antigenic drift leads to a gradual change of the virus over time, the flu virus is also capable of sudden changes by a process called **antigenic shift** (Fig. 41.18b). The viral genome consists of eight linear RNA strands. If a single cell is infected with two or more different flu

strains at one time, the RNA strands can reassort to generate a new strain. H1N1, for example, has genetic elements from human, pig, and bird flu viruses. Antigenic drift and shift make it difficult to predict from year to year which strains will be most prevalent and, therefore, which vaccine will be most effective.

## Tuberculosis is caused by a slow-growing, intracellular bacterium.

Our second example is tuberculosis (TB). Like the flu, it is spread through small droplets dispersed in the air when a person with active disease coughs or sneezes. Also like the flu, the TB pathogen replicates inside host cells. But unlike the flu, TB is caused by a bacterium, not a virus. TB results from infection by *Mycobacterium tuberculosis*, a bacterium with several unusual properties. It is very small and has a compact genome, lacks a plasma membrane outside the cell wall, and replicates exceedingly slowly. *M. tuberculosis* takes approximately 16–20 hours to divide, compared to 20 minutes for the common intestinal bacterium *Escherichia coli*.

Tuberculosis is very common, affecting an estimated one third of the world's population. Symptoms are absent in most cases because the bacteria are in a dormant state. Approximately 10% of cases, however, are active. Active cases are characterized by chronic cough, fever, night sweats, and the weight loss that gives TB its other name: consumption.

Tuberculosis primarily affects the lungs. The bacteria infect macrophages in the alveoli of the lungs and replicate. In response,

infected macrophages release cytokines, recruiting T and B cells to the site of infection. These lymphocytes surround the infected macrophages, forming a structure called a **granuloma** ([Fig. 41.19](#)). The granuloma helps to prevent the spread of the infection and aids in killing infected cells.

Many TB cases remain asymptomatic. However, the bacteria can sometimes overcome host defenses, especially if the immune system is compromised or suppressed, as in the case of co-infection with HIV. Treatment for active TB consists of a long course of multiple antibiotics. In many areas of the world, however, TB has evolved antibiotic resistance, a growing and alarming problem.

Diagnosis of TB poses challenges, especially in the case of asymptomatic infections. The tuberculin skin test is performed by injecting protein from the bacteria under the skin and observing whether a reaction occurs, evidenced by the formation of a hard, raised area. A positive skin test is an example of a delayed hypersensitivity

reaction. The reaction is caused by the recruitment of memory T cells to the site of inoculation, indicating that there had been an earlier infection with *M. tuberculosis*. Unfortunately, the tuberculin skin test is not always accurate, so newer tests are being developed.

Developing an effective vaccine to TB is challenging. The only vaccine currently available is BCG (Bacillus Calmette-Guérin, named for Albert Calmette, a French bacteriologist, and Camille Guérin, a French veterinarian, who developed it early in the twentieth century). BCG is a live but weakened strain of a related bacterium that infects cows. This vaccine was developed following the success of using cowpox to immunize against smallpox. However, BCG is only sometimes effective, and in 1930 a public health disaster in Germany resulted in the deaths of 73 newborns from contaminated vaccine. Consequently, BCG is not used in the United States.

## The malaria parasite changes surface molecules by antigenic variation.

“Bad air.” That’s the literal translation of “malaria,” a contraction of the Italian *mala* (“bad”) and *aria* (“air”). But malaria is not caused by the air, nor is it caused by a virus or bacterium. Instead, malaria is caused by a single-celled eukaryote of the genus *Plasmodium* ([Case 4 Malaria](#)). Several species infect humans, but *P. falciparum* is the most common and most virulent.

Malaria is both devastating and common. Approximately 500 million cases and 2 million deaths from this disease occur every year, mostly in sub-Saharan Africa, and mostly involving children. Malaria

causes cyclical fevers and chills and can lead to coma and death.

The malaria parasite is transmitted to humans by the bite of an infected mosquito ([Fig. 41.20a](#)). Using mosquitoes as a vector, the malaria parasite deftly bypasses the natural protective barrier provided by the skin. The malaria parasite spreads to the liver and then to red blood cells, where it completes its life cycle. The progeny can be taken up again by mosquitoes.

Malaria is an ancient parasite that has coevolved with humans. We have already seen how altered hemoglobin provides some protection against infection ([Chapter 20](#)). But the malaria parasite, too, has evolved: it is able to evade the human immune system.

The malaria parasite resides in liver cells and red blood cells. Infected red blood cells can be removed by the spleen, but the malaria

parasite has evolved a way to avoid this filtering action. It expresses an adhesive protein, PfEMP1 (*Plasmodium falciparum* erythrocyte membrane protein 1), that inserts itself on the surface of red blood cells. This protein interacts with proteins on the surface of cells lining blood vessels, helping infected cells stick to blood vessel walls and keeping them in the circulatory system and out of the spleen ([Fig. 41.20b](#)). PfEMP1 could conceivably be a target for antibodies or TCRs. However, it is encoded by any one of approximately 60 genes, each slightly different from the others. The parasite expresses just one of these genes at a time and can change which one is expressed, in a process called [antigenic variation](#). The great and ever-changing diversity of this protein, both in a single parasite and in the population as a whole, makes it a moving target for the immune system.

Despite continuing research, no vaccine against malaria has been developed. Researchers hope that the sequence of the malaria genome, completed in 2002, will provide new targets for vaccine research. In the meantime, efforts to control malaria focus on measures to control mosquitoes, such as insecticide-treated bed nets and spraying insecticides on areas where mosquitoes breed, and on treatment of patients with antimalarial medications. The evolution of resistance, however, is an all too familiar problem.

#### Self-Assessment Question

14. What are three mechanisms that allow pathogens to evade the immune system?

## CORE CONCEPTS SUMMARY

**41.1 AN OVERVIEW OF THE IMMUNE SYSTEM:** The immune system protects organisms from pathogens.

Pathogens are agents or organisms that cause disease. [page 923](#)

The immune system is able to distinguish host molecules and cells, called self, from foreign molecules and cells, called nonself. [page 924](#)

The immune system consists of two parts: the innate immune system acts nonspecifically and the adaptive immune system acts specifically against pathogens. [page 925](#)

**41.2 INNATE IMMUNITY:** The innate immune system acts generally against a diversity of pathogens.

The skin and mucous membranes are physical barriers consisting of chemicals, cells, and microorganisms that provide protection against pathogens. [page 925](#)

Phagocytes are white blood cells that engulf other cells and debris. [page 926](#)

Eosinophils, basophils, mast cells, and natural killer cells participate in the innate immune system. [page 927](#)

Toll-like receptors on the surface of phagocytes recognize evolutionarily conserved molecules on the surface of foreign molecules. [page 927](#)

Inflammation is the body's response to infection or injury. It

involves an increase in blood flow and blood vessel permeability, production of cytokines that signal phagocytes, and recruitment of phagocytes. [page 928](#)

The complement system consists of circulating proteins that activate one another. Activation results in the formation of a membrane attack complex that lyses bacteria, production of proteins that enhance phagocytosis, and generation of cytokines. [page 929](#)

**41.3 B CELLS AND ANTIBODIES:** The adaptive immune system includes B cells that produce antibodies against specific pathogens that reside outside cells in tissues.

B cells produce antibodies that bind to antigens. [page 930](#)

Antibodies have two light chains and two heavy chains joined by covalent disulfide bonds. [page 931](#)

Light and heavy chains have constant and variable regions. [page 931](#)

Mammals produce five types of antibodies: IgG, IgM, IgA, IgD, and IgE. [page 932](#)

Antibody specificity is achieved by clonal selection: when an antigen binds to antibodies on the surface of a B cell, the B cell differentiates into plasma and memory cells. [page 932](#)

The primary immune response is characterized by a long lag period and a short response. The secondary immune response is quicker and more robust, and provides the basis for immunity following

infection or vaccination. [page 933](#)

Antibody diversity is generated by genomic rearrangement, in which individual gene segments are joined to make a functional gene. [page 935](#)

**41.4 T CELLS AND CELL-MEDIATED IMMUNITY:** The adaptive immune system includes helper and cytotoxic T cells that attack infected, diseased, and foreign cells.

Two types of T cells are helper T cells and cytotoxic T cells. Helper T cells activate other cells of the immune system, including macrophages, B cells, and cytotoxic T cells. [page 936](#)

Cytotoxic T cells kill altered host cells. [page 936](#)

T cells are activated by the binding of a T cell receptor to an antigen in association with an MHC protein. [page 937](#)

As T cells mature in the thymus, they undergo positive and negative selection, so only T cells that recognize MHC, but not self antigens, survive. [page 938](#)

The ability to distinguish self from nonself antigens is critical for proper immune function; autoimmune diseases result when the immune system attacks cells of the host. [page 939](#)

**41.5 THREE PATHOGENS:** A virus, bacterium, and eukaryote illustrate how some pathogens have evolved mechanisms that enable them to evade the immune system.

The flu is caused by an RNA virus that can change its surface

proteins by antigenic drift and antigenic shift. [page 939](#)

The bacterium that causes tuberculosis grows slowly and resides inside cells, particularly macrophages. [page 940](#)

Malaria is caused by a single-celled eukaryote with a complex life cycle having stages in mosquitoes and in humans. The malaria parasite has evolved several mechanisms, including antigenic variation, that help it reproduce in humans without being eliminated by the immune system. [page 941](#)

## CHAPTER 42 Animal Diversity

Brian Farrell

### CORE CONCEPTS

#### 42.1 SPONGES, CNIDARIANS, CTENOPHORES, AND

**PLACOZOANS:** The simplest animals evolved multicellularity from single-celled ancestors.

**42.2 PROTOSTOME ANIMALS:** Protostomes are bilaterian animals and include lophotrochozoans and ecdysozoans.

**42.3 ARTHROPODS:** Arthropods, bilaterian animals named for their jointed legs, are extraordinarily diverse.

**42.4 DEUTEROSTOME ANIMALS:** Deuterostomes are bilaterian animals and include humans and other chordates, as well as acorn worms and sea stars.

**42.5 VERTEBRATES:** Vertebrates are deuterostomes with a bony cranium and typically a vertebral column, enabling them to become ecologically important in the water and on land.

---

The human body is complex, our diverse functions made possible by sophisticated, interacting organ systems: from muscle pairs attached to skeletons that allow us to run, jump, and dance, to lungs that exchange gases with the atmosphere and a brain and nervous system that enable us to sense our environment and respond to it. None of these organ systems is well developed in sponges, the simplest animals, and few can be found in sea anemones or jellyfish. How can we understand the evolutionary pathways that have given rise to animals as different as humans, jellyfish, and sponges?

In [Chapter 33](#), we began our exploration of animal biology with a brief discussion of phylogeny, the evolutionary relationships among organisms. In this chapter, we return to questions of biological diversity, building a phylogeny of all animals based on features of anatomy, embryology, and molecular sequences. How do the combinations of characters exhibited by different animal groups reflect

evolutionary history, and how do they relate to the distribution of species diversity among phyla?

[Chapter 22](#) introduced the logic of phylogenetic reconstruction. Synapomorphies—shared derived characters, whether they be morphological or molecular—enable us to identify sister groups that diverged from a common ancestor at some point in the past. As we add morphological or molecular characters, we identify successively more inclusive sets of sister groups, eventually building a tree-like phylogeny that shows the evolutionary relationships among animals with diverse body plans and functional capabilities.

While phylogenies are built from the tips down, we want to interpret them as evolutionary histories, read from the root upward. Which features were present in the earliest animals, and how did successive evolutionary innovations give rise to the patterns of taxonomic diversity and ecological distribution we observe today? Biologists recognize approximately 36 distinct phyla (the singular is “phylum”), each with a fundamentally distinct body plan that marks a major branch of the animal tree. These body plans reflect adaptations that enabled different groups to persist and diversify through time, and they also impose constraints on the evolutionary pathways followed by different groups. For example, the external skeleton of arthropods has enabled them to diversify in aquatic and terrestrial environments, but prevents them from growing as large as the largest vertebrates. The animal tree illustrates how more than 600 million years of evolution have resulted in patterns of diversity, ecology, and geography that we see when we look at animals across the globe.

# 42.1 SPONGES, CNIDARIANS, CTENOPHORES, AND PLACOZOANS

**Fig. 42.1** revisits the basic phylogeny introduced in [Chapter 33](#). It shows that animals as a whole are sister to the choanoflagellates, a group of single-celled eukaryotes (introduced in [Chapter 25](#)).

Choanoflagellates are mostly marine organisms that feed by ingesting bacteria, sometimes forming simple multicellular groups that appear to facilitate feeding by beating their flagella in a way that draws water carrying food particles past the cells. The close evolutionary relationship between choanoflagellates and animals suggests that the earliest animals were simple multicellular organisms that lived in the sea; they had little in the way of differentiated cell types, but were able to coordinate cell activity to facilitate feeding. This prediction is supported by [sponges](#) (Porifera; [Table 42.1](#)), in many ways the simplest of living animals.

SOURCE: Jørgen Olesen.

Sponges share some features with choanoflagellates but also exhibit adaptations conferred by multicellularity.

The common ancestor of animals and choanoflagellates carried out all functions as individual cells, from metabolism to reproduction.

Animals, however, are united by synapomorphies not shared by choanoflagellates, including persistent multicellularity and development from an embryo that includes a blastula ([Chapter 33](#)). The cells making up sponges retain much of the individuality of choanoflagellate cells while also having some benefits of multicellularity. Coordination among cells means that distinct kinds of cells can be specialized for different functions: some cells may form a protective skin, for example, while others secrete enzymes for digestion. Most dramatically, multicellularity permits sponges to develop bodies that extend above the seafloor, giving them access to food suspended in water currents.

The sponge body plan resembles a flower vase, with many small pores along its sides and a larger opening at the top ([Fig. 42.2](#)). The cells on the outer surface of the sponge form a tough layer that acts as the sponge's skin. The interior surface is lined by cells called [choanocytes](#), which have flagella and function in nutrition and gas exchange. Choanocyte cells have a collar of small cilia around their flagellum, much like the cells of choanoflagellates. Between the interior and exterior cell layers lies a gelatinous mass called the [mesohyl](#) ([Fig. 42.2](#)). Mesohyl is mostly noncellular, but it contains some amoeba-like cells that function in skeleton formation, reproduction, and the dispersal of nutrients.

FIG. 42.2 Anatomy of a sponge.

Sponges obtain nutrition through intracellular digestion ([Chapter 38](#)). The choanocytes that surround the interior chambers and passageways of the sponge beat their flagella, creating a current that draws water from outside the body, through the pores in its walls and upward through the central cavity of the sponge, where the water exits through the large opening at the top. The circulating water contains food particles and dissolved organic matter, which cells lining the cavity capture by endocytosis. Individual cells metabolize the food in their interiors, much in the same way that protozoans feed.

From this observation, we might conclude that a sponge is simply a group of uncoordinated cells, each working for itself, but that isn't the case. The choanocytes beat their flagella in a coordinated pattern, helping to draw water into the body interior through the pore system and outward again through the vase opening. Moreover, the shape of the sponge body itself directs water movement across feeding cell surfaces, facilitating food uptake. Many sponges obtain at least part of their nutrition from symbiotic microorganisms living within their bodies. In fact, sponge bodies are commonly full of bacterial cells. At least some of these bacteria are probably symbionts, but only a few experiments have demonstrated their function.

Sponge cells require oxygen for respiration and must get rid of the carbon dioxide that respiration generates. Gas exchange occurs across the cell membranes by diffusion, aided by the movement of water through the sponge cavity.

Sponges don't have highly developed reproductive organs. Instead, cells recruited from the choanocyte layer migrate into the mesohyl, where they undergo meiotic cell division and differentiate into sperm or eggs. Sperm released into the water from one sponge fuse with eggs in the mesohyl of other sponges.

Many sponges build skeletons of simple structures called spicules. Some sponges have spicules of glasslike silica ( $\text{SiO}_2$ ). Other sponges make their spicules—and sometimes massive skeletons—of calcium carbonate ( $\text{CaCO}_3$ ). Still other sponges have a skeleton made up of proteins (these are the sponges used in the bath). In sum, sponges are

intermediate in the sophistication of their bodies: their cells function much as single-celled protozoans do, but they coordinate their activities and so are more efficient in extracting food and oxygen from seawater.

The features shared by sponges reflect both their divergence from choanoflagellate-like ancestors and the evolutionary innovations that have shaped their unique anatomy and functions. Despite their anatomic simplicity, sponges are major contributors to seafloor communities. Approximately 9000 species of sponges have been described; most of them are ocean dwelling, but a few live in fresh water. Over the past decade, biologists have debated whether sponges form a monophyletic group, which includes all the descendants of their last common ancestor, or whether they are paraphyletic, sharing their last common ancestor with other animal groups. At present, most data indicate that sponges are a monophyletic group that is a sister to the eumetazoans, a large group that includes most or all other animals ([Fig. 42.1](#)).

## Cnidarians are the architects of life's largest constructions: coral reefs.

Most animal diversity falls within the [Eumetazoa](#), a group that includes animals as varied as jellyfish and elephants. Despite their tremendous anatomical diversity, eumetazoans are united by a number of synapomorphies, including the development of diverse cell types, distinct tissues, and gastrulation, which is the inward movement of cells of the ball-like blastula to form distinct layers during early development ([Chapter 33](#)).

**Cnidaria** form one major branch of the Eumetazoa. Many of us have encountered at least a few cnidarians. Jellyfish flourish in marine environments from coastlines to the deep sea; sea anemones cling to the seafloor, extending their tentacles upward to gather food and deter predators; corals secrete massive skeletons of calcium carbonate, forming reefs that fringe continents and islands in tropical oceans.

Jellyfish and sea anemones look strikingly different, but they share a body plan common to all cnidarians (**Fig. 42.3**). Synapomorphies of cnidarians include radial symmetry (**Chapter 33**) and a mouth surrounded by tentacles armed with stinging cells that subdue prey and defend against enemies. An anemone is like a jellyfish stuck upside down onto the seafloor with its tentacles and mouth facing upward. We call a free-floating jellyfish a medusa, and the stationary (sessile) form of an anemone a polyp. Some cnidarians develop into one form or the other, but many have life cycles that alternate between the two.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

 Science Source.

FIG. 42.3 Two cnidarians. (a) Jellyfish; (b) sea anemone.

Rather than individual cells metabolizing food particles as in sponges, eumetazoans have a digestive system in which food is taken into a specialized compartment, where it is digested using enzymes secreted by cells that line its walls. In cnidarians, the gastric cavity is closed: food and waste enter and exit through the same opening. Cnidarians can digest large food items, such as a whole fish, whose dissolved nutrients can then be absorbed through the walls of the cavity. As a consequence, cnidarians can consume many types of food that are unavailable to sponges.

The cnidarian body develops from a diploblastic embryo (one with two germ layers; [Chapter 33](#)). The embryo's outer layer, the **epidermis**, develops from the outer germ layer, or ectoderm; its inner lining of cells, the **endodermis**, derives from the inner germ layer, or endoderm ([Chapter 40](#)). These tissues enclose a gelatinous mass called the **mesoglea** (the “jelly” of jellyfish). This organization sounds a bit like the sponge body plan, but there are important differences, many of which involve characters shared between cnidarians and their sister group, bilaterian animals.

First, in cnidarians and bilaterians, the cells that form the epidermis and endodermis occur as closely packed layers of cells embedded in a protein-rich matrix, forming an epithelium ([Chapter 10](#)). The epithelium comprises an unusually tight layer of specialized cells, which are bounded by a matrix composed of protein and connected to one another by junctions that regulate the passage of ions or other molecules. These epithelial layers line compartments within eumetazoan animals, often absorbing or secreting substances, and thereby making possible tissues and organs such as those of the digestive system ([Chapter 38](#)). For many years, most biologists accepted that sponges do not form epithelia. More recently, careful anatomical studies have shown that more complex sponges can form epithelia, although these are somewhat simpler in terms of cellular connections than the epithelia of other animals.

Cnidarians also have a wider array of cell types than sponges do, permitting more sophisticated tissue function. Muscle cells allow jellyfish to swim through the ocean, and a simple network of nerve

cells permits cnidarians to sense their environment and respond to it through directional movement. No such cells occur in sponges. Although cnidarians lack a brain, a few have light-sensitive cells that function as simple eyes.

Moreover, whereas sponges filter water to gain food, cnidarians are predators, capturing prey with their tentacles and digesting it in the gastric cavity. Specialized cells on the tentacles contain a tiny harpoonlike organelle called a nematocyst, often tipped with a powerful neurotoxin that aids in capturing prey and defending the cnidarians against other predators ([Fig. 42.4](#)). Other specialized cells lining the gastric cavity of cnidarians secrete digestive enzymes that break down ingested food into molecules that can be taken up by the cells lining the cavity by endocytosis. There is no specialized passage for waste removal. Instead, waste is excreted back into the gastric cavity and leaves by way of the mouth. Oxygen uptake and carbon dioxide release occur by diffusion.

Many cnidarians reproduce asexually to form colonies. For example, corals form extensive rounded, fan-shaped, or hornlike colonies by budding; over time, they can build massive structures on the seafloor ([Fig. 42.5a](#)). In the Portuguese Man-of-War, different individuals in the same colony develop distinct morphologies: some are specialized for flotation, others for prey capture, and still others for reproduction ([Fig. 42.5b](#)). Among animals without complex organs, such colonies represent the height of morphological complexity.

Sources: a. ifish/Getty Images; b. George G. Lower/Science Source

FIG. 42.5 Colony formation in cnidarians. (a) In soft corals, the individual members of the colony are similar in form and function. (b) In the Portuguese Man-of-War, the members of the colony differentiate to serve distinct functions, such as floating, feeding, and reproduction.

Cnidarians exhibit a number of features that differentiate them from sponges, although they lack the complex organ systems that characterize their sister group, the bilaterian animals. Approximately 9000 species of cnidarians live in the oceans. Coral reefs are remarkable not only for the size of their skeletal colonies, but also for their mode of nutrition. Many have lost the ability to capture prey, but instead obtain nutrition from the symbiotic algae found in their surface tissues.

**Ctenophores and placozoans represent the extremes of body organization among phyla that branch from early**

## nodes on the animal tree.

Our exploration of nonbilaterian animals concludes with ctenophores (also called comb-jellies) and placozoans. Neither of these groups is diverse (just 100–150 species of comb-jellies have been named, and so far only one species of placozoan), but they may shed light on the evolutionary relationships among sponges, cnidarians, and bilaterians.

**Ctenophores** resemble cnidarians in body plan, and for many years most biologists thought that ctenophores and cnidarians were close relatives. Like cnidarians, ctenophores have radial symmetry and tissues, with an outer epithelium and an inner endodermis that enclose a gelatinous interior (**Fig. 42.6**). Ctenophores also have a simple nerve net, as well as rudimentary gonads. These predators feed by ingestion, digesting prey within their gastric cavity through the action of enzymes secreted from the cells lining the gut cavity. As in cnidarians, gas exchange occurs by diffusion. However, there are important differences between cnidarians and ctenophores. Ctenophores propel themselves through the oceans by the coordinated beating of cilia that extend from their epidermal cells. These cilia are usually arranged in comblike groups, which explains the common name for this phylum. Unlike in cnidarians, the digestive wastes generated by ctenophores move through a simple stomach for elimination through an anal pore opposite the mouth.

If ctenophores are the most complex animals discussed so far, **placozoans** are the simplest. Each of these tiny (millimeter-scale) animals contains only a few thousand cells arranged into upper and lower epithelia that sandwich an interior fluid crisscrossed by a network of fiber cells with multiple nuclei (**Fig. 42.7**). Placozoans have no specialized tissues and few differentiated cell types. Cilia on their cell surfaces allow movement, and gas exchange occurs by diffusion. Placozoans can absorb dissolved organic molecules, but commonly feed by taking in food particles and secreting digestive enzymes to break those particles down. Despite their morphological simplicity, placozoans have a genome that contains many of the genes for transcription factors and signaling molecules that are present in

cnidarians and bilaterian animals. The roles that these genes play in placozoan biology remain unclear.

## Branching relationships among early nodes on the animal tree remain uncertain.

As we saw in [Chapter 33](#), we can infer relationships among different groups from comparisons of observable morphological traits, from DNA sequence data, and even from similarities and differences in how their embryos develop (for example, the geometry of the first cell divisions and two versus three germ layers in early development). Molecular, anatomical, and embryological data suggest that bilaterally symmetrical animals form a monophyletic group whose sister is the radially symmetrical (and also monophyletic) Cnidaria. Increasingly, DNA sequence data place placozoans as the sister group to cnidarians and bilaterian animals. This placement reinforces the view that early

animals fed by the ingestion of particles and the absorption of organic molecules by individual cells, as observed in choanoflagellates and sponges. Only later did increasing complexity of tissues result in digestive systems specialized for this function. Note that many of the earliest animals found as fossils from the Ediacaran Period (see [Fig. 33.14](#)) also seem to have little more than upper and lower epithelia sandwiching a fluid-filled cavity; they fed by phagocytosis and absorption of organic molecules and exchanged gases by diffusion. Living placozoans, therefore, may help us to understand the phylogenetic relationships of the oldest known animal fossils.

Where to place ctenophores in this tree is less clear ([Fig. 42.8](#)). Traditionally, ctenophores were thought to branch along with cnidarians and bilaterians, as sister to the sponges, and some molecular data support this view ([Fig. 42.8a](#)). In a rather surprising twist, DNA sequence comparisons have recently been cited as evidence that ctenophores are the sister group to all other animals ([Fig. 42.8b](#)). If this second hypothesis is correct, it means either that the complex tissues of ctenophores evolved independently of those found in cnidarians and bilaterians or that the morphological simplicity of living sponges reflects the loss of features retained in other animals. DNA sequences and biochemical data indicate that wherever ctenophores belong on the animal tree of life, their nervous system evolved independently of those found in cnidarians and bilaterian animals. At present, we simply don't know the correct branching order of the animal tree.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 42.8 Phylogenetic trees of animals, showing the placement of placozoans and two hypotheses for the placement ctenophores in red. (a) The traditional hypothesis is that Porifera are sister to all other animals, with uncertainty in the branching relationships of placozoans and ctenophores. (b) The alternative hypothesis is that ctenophores are the sister group to all other animals.

### Self-Assessment Questions

1. How do muscle cells enable cnidarians to function in ways that sponges cannot?
2. Which synapomorphies unite sponges and eumetazoans as sister groups?
3. The hypothesis that ctenophores are sister to all other animals runs counter to the traditional view that sponges and a group containing all other animals diverged from the earliest node on the animal tree. What are the two possible ways of reconciling this new phylogenetic hypothesis with anatomical and morphological observations?

## 42.2 PROTOSTOME ANIMALS

The phyla discussed in the preceding section include approximately 18,000 species, a tiny fraction of all animal diversity. All other animals described to date reside on the bilaterian branch, the final stop in this broad tour. Synapomorphies of bilaterian animals include bilateral symmetry and complex organs that develop from a triploblastic (three germ layers) embryo. The anatomical complexity of bilaterian animals makes possible types of locomotion, feeding, gas exchange, behavior, and reproduction that are unknown in the other groups. These capabilities underpin the remarkable diversity of bilaterian animals.

As biologists discovered in the nineteenth century, bilaterians can be divided into two groups on the basis of early embryological development. In the **Protostomia**, the blastopore—the first opening into the embryo interior that is formed during gastrulation—usually develops into the organism’s mouth. In contrast, in the **Deuterostomia**, the blastopore develops into the anus (**Fig. 42.9**). Molecular sequence data support the protostome–deuterostome groupings of bilaterian animals and show that protostome animals can be further divided into two groups: the **Lophotrochozoa** (which include mollusks and annelid worms) and the **Ecdysozoa** (which include insects and other arthropods).

FIG. 42.9 A simple phylogenetic tree of bilaterian animals. Bilaterian animals can be divided into two major groups, the deuterostomes and the protostomes. Protostomes can be further subdivided into lophotrochozoans and ecdysozoans.

Lophotrochozoans account for nearly half of all animal phyla, including the diverse and ecologically important annelids and mollusks.

United largely by their molecular synapomorphies, the Lophotrochozoa include several very different types of animals. On the one hand, there are the brachiopods, bryozoans, and related phyla that have a tentacle-lined organ for filter feeding called a lophophore. On the other hand,

there are the mollusks, annelid worms, and their close relatives, which develop from a type of larva called a trochophore. The odd name “lophotrochozoan” is a contraction of the terms “lophophore” and “trochophore,” with “zoan” added to indicate that these organisms are animals (*zoon* is Greek for “animal”). The majority of lophotrochozoan species also have a distinctive form of spiral cleavage early in development.

Seventeen of the 36 recognized animal phyla branch from this limb of the animal tree ([Table 42.1](#)). Most lophotrochozoans are small animals that live on or within sediments or swim in the sea. A few, including the brachiopods, were once ecologically important but are abundant only locally today. And a few have diversified over time to become diverse and ecologically important animals in both marine and terrestrial environments. In this section, we focus on two phyla of lophotrochozoans: [annelid worms](#), well known to most of us as earthworms but far more diverse in the oceans, and [mollusks](#), which include clams, snails, and squid ([Fig. 42.10](#)). These two phyla are closely related but have evolved quite different anatomies in the half billion years since they diverged from one another.

 (bottom) Phillip Colla/Oceanlight.

FIG. 42.10 A phylogenetic tree of lophotrochozoan animals, showing all 17 phyla in this group. Phyla discussed in the text are shown in red. Uncertainties in branching order are shown by nodes with more than two branches.

The annelids most familiar to us are the earthworms, which, as their

name suggests, are commonly found in soil ([Fig. 42.11a](#) and [42.11b](#)). Most of the 15,000 known annelid species, however, live in the oceans ([Fig. 42.11c](#)). All annelids have a cylindrical body with distinct segments, and they illustrate the advantages of a bilaterian body plan, including a distinct head region (cephalization) and segments modified to become different structures ([Chapter 33](#)). In the case of annelids, the head at the front end has a well-developed mouth and, internally, a cerebral ganglion (a collection of nerve cells) that connects to an extensive nervous system. A digestive system extends through the body from the head to an anus, with a sequence of specialized organs for crushing ingested food, then digesting it, and finally excreting wastes, much like the digestive system in the human body. Working together, these features enable annelids to move through their environment, actively searching for food and digesting it efficiently after ingestion.

FIG. 42.11 Annelids. (a and b) Earthworms typify the segmented body plan found

throughout the Annelida. (c) The most diverse annelids are polychaete worms, which live in the oceans. (d) Leeches are specialized for ingesting blood from mammalian hosts. (e) Vestimentiferan worms live along hydrothermal rift vents in the oceans, gaining nutrition from chemosynthetic bacteria in specialized organs (red in the image).

Aquatic annelids have external gill-like organs for gas exchange, whereas terrestrial earthworms exchange gases through their skin. In both cases, a closed circulatory system moves oxygen and other dissolved gases through the body. Annelids have waste-filtering organs called nephridia, gonads (repeated in most segments), and a fluid-filled coelom, or body cavity. Fluids in the coelom form a hydrostatic skeleton that works in coordination with paired muscles in each segment to direct the organism's movement. Earthworms have a glandular ring in their epidermis called a clitellum that secretes fluids in which eggs are deposited.

Annelids all share some basic features of anatomy and development, but they have evolved impressive functional diversity, which is well illustrated by the ways in which they feed. Many annelids are predators that capture and ingest prey. Others, such as the earthworms, ingest sediment, digesting the organic matter it contains and excreting mineral particles. A few marine annelids have evolved tentacles that enable them to filter food particles from water, while leeches, a specialized group of freshwater annelids, attach themselves to vertebrates to suck out meals of blood ([Fig. 42.11d](#)). Remarkably, the meter-long vestimentiferan worms that live around hydrothermal vents in the oceans have given up ingestion altogether ([Fig. 42.11e](#)). These enormous worms, which lack mouths, gain nutrition from

chemosynthetic bacteria that live within a collar of specialized tissue found in the worm. Discovered in the 1970s, vestimentiferan worms were originally placed in their own phylum, but molecular sequence comparisons indicate that they are annelids.

Mollusks are the second major phylum of the Lophotrochozoa, and include such familiar groups as snails, clams, mussels, squids, and octopuses. Mollusks are distinguished from other lophotrochozoans by a unique structure called the mantle, which plays a major role in breathing and excretion, and which forms their shells (when shells are present). The mantle lines the visible body of a squid as well as what we commonly (but mistakenly) view as the head of an octopus. Mollusks develop from a distinctive larva called a trochophore that has a tuft of cilia at its top and additional cilia bands around its middle. Marine annelids develop from trochophores as well, and the presence of this unique form of larva in both phyla suggests a close evolutionary relationship between the two. This hypothesis is supported by molecular sequence comparisons. Nonetheless, mollusks and annelids share very few features in their adult body plans.

As is true of annelid worms, mollusks share a number of anatomical and developmental features but have diversified in terms of body plan, enabling them to thrive in a number of ecological roles and environmental settings. More than 80,000 species of mollusks have been described, most of them gastropods.

**Gastropods** (snails and slugs) provide an illuminating example of the versatile mollusk body plan (**Fig. 42.12**). Gastropods have a head

with a well-developed mouth that contains a toothlike structure called a radula for feeding. The mouth connects to a gut cavity that extends to an anus. Featherlike gills facilitate gas exchange, and a muscular foot is used for locomotion. A neural ganglion in the head coordinates a nervous system that extends through the body; the body also contains a well-developed circulatory system, gonads, and nephridia. Gastropods have a coelom, but the body cavity is generally reduced to small pouches that surround the heart and other organs. The outer surface of the body consists of the mantle. In many gastropods, the mantle tissues secrete an external skeleton of calcium carbonate, which forms a shell.

Some gastropods eat algae, but many others are predators. Approximately half dwell in the ocean, and the other half are freshwater or terrestrial species that primarily feed on plants. In land snails and slugs (the only terrestrial mollusks), the gills have been lost, and gas exchange occurs in an internal cavity that has been modified to function as a lung.

The second great class of mollusks is the **cephalopods**—about 700 species of squid, cuttlefish, octopus, and the chambered nautilus (**Fig. 42.13**). Cephalopods share a number of features with gastropods, including much of the internal anatomy, featherlike gills, and mantle. At the same time, they have distinctive adaptations for their unique modes of life. Most obviously, cephalopods have muscular tentacles that capture prey and sense the environment. These leglike appendages are found on the head region rather than on the sides of the body as in other animals; this structure explains their distinctive name, which is derived from the Greek *kephale*, meaning “head,” and *podos*, meaning “possession of a foot.”

Cephalopods are superb swimmers, able to dart through the water by means of a jet propulsion system that forces water through mantle

tissue that is fused to form a siphon. The combination of tentacles and rapid locomotion helps to make cephalopods important predators in the oceans. Moreover, cephalopods have exceptional eyesight and exhibit the most complex behavior of any invertebrate animals: they are able to learn visual patterns and solve puzzles to gain food. The chambered nautilus secretes a coiled shell of calcium carbonate ([Figs. 42.13a and 42.13b](#)). In contrast, in other cephalopods, such as squid and octopus, the shell is reduced or absent ([Fig. 42.13c](#)). In oceans of the Mesozoic Era (252–66 million years ago), shelled cephalopods called ammonites were among the most abundant and diverse predators.

A third major group of mollusks, the [bivalves](#), includes the familiar clams, oysters, and mussels. These animals also have a mantle and other anatomical features that point to their close relationship to snails and squids, but have some distinctive features that set them apart ([Fig. 42.14](#)). Notably, bivalves have (literally) lost their heads. As their name implies, bivalves have evolved a skeleton in which two hard shells (called valves) are connected by a flexible hinge.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
Photo source: Glenn Price/Dreamstime.com.

FIG. 42.14 *Mercenaria mercenaria*, a bivalve mollusk commonly harvested from coastal waters of eastern North America.

Most bivalves obtain food by filtering particles from seawater. However, many bivalves live within marine sediments, burrowing into sand or mud with their muscular foot. How can bivalves filter food from seawater while buried in the sediment? Once again, natural selection has modified the mantle in these mollusks, making possible a new function. Flaps of mantle tissue have fused to form a pair of siphons that extend upward from the bivalve's body to the surface of the seafloor above it. One siphon draws water containing food and oxygen into the body. The second siphon returns water and waste materials to the environment.

Approximately 9000 species of bivalves have been described, mostly from the oceans, but also many from fresh water. Bivalves include the longest-lived animals in the world, the mahogany clams of the North Atlantic, for which the record is more than 400 years of age. These bivalves would make excellent subjects for study of rates of mutation and DNA repair ([Chapter 21](#)).

**Ecdysozoans are animals that episodically molt their external cuticle during growth.**

The second major group of protostome animals is the Ecdysozoa ([Fig. 42.15](#)), which gets its name from the process of ecdysis, or molting. Uniquely among animals, ecdysozoans secrete a protein- or

polysaccharide-rich cuticle that covers their bodies. This tough cuticle acts like a suit of flexible, lightweight armor, protecting the animal's body from injury and from physical challenges of the environment such as drying. This “armor” has a special property: the hard cuticle can be used to form appendages that function as tools, weapons, or even wings. Like a suit of armor, the cuticle is always a perfect fit for the wearer but does not stretch, so it must be exchanged episodically during growth for a larger size to fit a larger, growing body.

Ecdysozoans molt their external cuticle during growth, revealing a very soft, larger replacement underneath that soon hardens into a new protective covering.

FIG. 42.15 A phylogenetic tree of ecdysozoan animals, showing all eight phyla in this group. Phyla discussed in the text are shown in red. Uncertainties in phylogenetic position are shown by nodes with more than two branches.

The Ecdysozoa include eight phyla, but two dwarf the others in abundance and diversity: nematodes and arthropods (see [Table 42.1](#)). The most numerous of all animals are the small roundworms known as **nematodes** ([Fig. 42.16](#)). Most nematodes are so tiny that you've probably never noticed them, but they occur by the billions all around you and may well be inside your body as you read this. Approximately 20,000 nematode species have been described, but estimates of their true diversity run as high as half a million. Most nematodes are microscopic, preying on microorganisms in soils and marine sediments. Their elongated cylindrical bodies have a mouth at one end, an intestine for digestion, and an anus in the rear. Other organs are quite simple: nerve cords extend along the main axis from a ring in back of the mouth, rudimentary muscles line the body, and gonads expel sperm and eggs for reproduction. As in other ecdysozoans, the nematode body is covered by a tough cuticle that molts during growth. Parasitic nematodes are common and well known to doctors; hookworms, in particular, are major sources of illness in the tropics.

 Photo source: Gerd Guenther/Science Source.

FIG. 42.16 A nematode. Nematodes are small but remarkably abundant animals.

The second major group of ecdysozoan animals is the [arthropods](#), whose members include insects, which we discuss in the next section.

#### Self-Assessment Questions

4. Of the morphological traits of present-day snails, squids, and clams, which features do you think were present in the common ancestor of all three?
5. The protostomes form one major branch of bilaterian animals. Which features do they share with other bilaterians, and which

features distinguish them as a separate group within the bilaterians?

## 42.3 ARTHROPODS

If nematodes are the most numerous animals, arthropods are the most diverse, accounting for a majority of all known animal species. Which features have led to the remarkable evolutionary success of this phylum?

### The Arthropoda is the most diverse animal phylum.

Perhaps the most obvious feature of arthropods is the one for which they are named: jointed legs (*arthro* means “jointed,” and *pod* means “foot” or “leg”). The jointed leg is the most versatile part of the arthropod body; it has been modified through evolution into structures that function as paddles, spears, stilts, pincers, needles, hammers, and more. The jointed leg allowed arthropods to colonize land by providing a multipoint, independent suspension—much like that of an all-terrain vehicle—able to support a relatively large body and move over the most uneven ground. So well adapted for locomotion is the arthropod leg that NASA engineers use it as a model for planetary exploration vehicles. Researchers have conducted many studies to understand how this one type of limb could give rise to so many diverse structures with different functions ([Fig. 42.17](#)).

#### HOW DO WE KNOW?

#### FIG. 42.17

How did the diverse feeding structures of arthropods arise?

## BACKGROUND

Arthropod species diversity is matched by the diversity of form and function of their appendages, including legs, wings, jaws, and feelers. One challenge for scientists has been recognizing and relating the equivalent parts of the very different front ends of arthropods as varied as insects, crabs, spiders, and centipedes.

## HYPOTHESIS

Researchers hypothesized that the diverse structures in the head region of different arthropods develop from similar limb buds clearly visible in developing embryos. This hypothesis was based in part on the observation that the same limb buds in different vertebrate embryos develop into a wide range of structures, such as bird wings, whale flippers, and human arms.

## EXPERIMENT

The early stages of arthropod embryos have a definite head region and several body segments. Each segment has a pair of appendages. *Hox* genes specify the identity of each body segment ([Chapter 19](#)). Researchers can visualize the expression patterns of different *Hox* genes by using labeled probes on whole embryos. In this way, researchers can compare the development of appendages on the same segment in different arthropods.

The dark bands show the expression of a *Hox* gene in the paired limb buds that can be seen in the embryo of the spider *Cupiennius salei*.

## RESULTS

Studies of the embryos reveal the various feeding structures that develop from each segment of different arthropods. For example, the maxillae of insects and crustaceans form from the same segment of the developing embryo. By contrast, in chelicerates (such as spiders and scorpions), this segment develops into legs. Moving one segment forward (toward the head), the jawlike mandibles (top row of photos) of insects and crustaceans form from the same segment. In chelicerates, this segment develops into pedipalps (sensory organs in spiders, pincers in scorpions). Moving another segment forward, the second pair of antennae in crustaceans forms from the segment that gives rise to chelicerae (fangs in spiders and their counterparts in scorpions; bottom row of photos) in chelicerates.

Feeding structures in the head regions of arthropods develop from paired appendages in the embryo.

Blue segments in the head region of the developing arthropod embryos develop into various feeding structures. The white ovals indicate the position of the mouth.

\*Crustaceans are paraphyletic.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

Photo source: Piotr Naskrecki.

## CONCLUSIONS

The diverse feeding structures of arthropods arise from limb buds in the first segments of the developing embryo. In closely related groups, such as insects and crustaceans, the same segments develop into similar structures. In more distantly related groups, such as insects and spiders, the same segments develop into quite different structures. Evolution has modified simple limb buds into a remarkable diversity of forms, enabling structures as specialized as the grinding mandibles of crabs and the sharp fangs of

spiders.

#### FOLLOW-UP WORK

There has been recent controversy over the front appendages of sea spiders. Researchers have questioned whether they are equivalent to large clawlike appendages—called “great appendages,” aptly enough—on some Cambrian arthropod fossils.

SOURCE Damen, W. G. M., et al. 1998. “A Conserved Mode of Head Segmentation in Arthropod Revealed by the Expression Pattern of *HOX* Genes in a Spider.” *Proceedings of the National Academy of Sciences USA* 95:10665–10670.

The arthropods’ other defining characteristic is the material that forms their hard external skeleton: a strong, lightweight and nearly indestructible polysaccharide called **chitin**. Chitin, as you may recall from [Chapter 32](#), also forms the wall of fungal cells. Next to the cellulose that forms the wall of plant cells, chitin may be the most abundant biomolecule on Earth.

There are four main groups of arthropods ([Fig. 42.18](#)), of which the most diverse group by far is the **insects**. The other three groups of arthropods are **chelicerates**, which include spiders, scorpions, and their relatives; **myriapods**, which include centipedes and millipedes; and **crustaceans**, which include lobsters, shrimp, crabs, and their relatives.

\*Crustaceans are paraphyletic. All other lineages are monophyletic.

Photo sources: (top to bottom) B. G. Thomson/Science Source; Tom McHugh/Science Source; Michael S. Nolan/SeaPics.com; Christian Hütter/imageBROKER/AGE Fotostock.

FIG. 42.18 Arthropods. This diverse phylum includes four main groups: chelicerates (spiders, scorpions, and ticks), myriapods (centipedes and millipedes), crustaceans (including lobsters, shrimp, and crabs), and insects.

Chelicerates, named for their pincerlike claws called chelicerae, are the only arthropods that lack antennae. The chelicerates are mostly carnivores, except for plant-eating mites. Scorpions and spiders use venom to subdue prey. In spiders, the venom is injected through chelicerae modified to form fanglike appendages. In scorpions, the venom is injected through the curved tail segment of their abdomen. Other familiar chelicerates include the harvestmen (often called daddy long-legs in the United States), ticks, and horseshoe crabs (which are not crustaceans despite their name). Giant sea scorpions called eurypterids, up to 2 m long, were dominant predators in warm shallow

seas 450–252 million years ago. The chelicerates were among the very first animals to invade land, more than 400 million years ago, aided by their protective cuticle and supported by their arrays of jointed legs.

Myriapods are named for their many pairs of legs, which make them easy to recognize. Centipedes (“hundred legs”) may have as many as 300 pairs of legs and are fast-moving predators with front legs modified into venomous, fanglike organs. Millipedes (“thousand legs”) may have several hundred pairs of legs (though never a thousand) and are slow-moving herbivores and detritivores (eaters of dead organisms). Millipedes often have glands lining their long bodies that produce a substance containing cyanide, which they secrete to defend against predators.

Crustaceans also have distinctive appendages, notably their branched legs. Although crustaceans share a number of anatomical synapomorphies, they are a paraphyletic group: the descendants of their common ancestor also include insects and their closest relatives, which diverged from their crustacean sister group more than 400 million years ago.

Crustaceans navigate their world with the aid of two pairs of sensory antennae, the larger of which has two branches. The unique crustacean larva, called a nauplius, swims with the aid of the smaller antenna and has a single eye that typically disappears by adulthood. Most crustaceans are aquatic, but a few, including land crabs and woodlice, live on land. In the sea, these versatile arthropods fill many of the ecological roles that insects play on land, eating plants, other

animals, or detritus. The tiny shrimplike plankton known as krill occur in vast numbers in polar seas, supporting ecosystems of fish, birds, and mammals such as whales. One Antarctic krill species is estimated to total more than 500 million tons of biomass, exceeding the global total for humans. Many lobsters and crabs are detritivores, scouring the ocean bottoms for dead and dying animals. Some crustaceans are even parasites, attaching themselves to the skin or inside the mouths of fish or sea mammals so that they can feed. The strange creatures known as barnacles begin life resembling shrimp but soon settle on a surface for a life of filter-feeding. As barnacles mature, their bodies become covered with thickened plates of armor and their legs elongate and develop long brushes that sweep food into their mouths.

## Insects make up the majority of all known animal species and have adaptations that allow them to live in diverse habitats.

Insects are extraordinarily diverse; the approximately 1 million described insect species account for 80% or more of all known animal species. Insects' success may be a function of four adaptations that allow them to live in diverse habitats: desiccation-resistant eggs; wings; specialized respiratory systems; and [metamorphosis](#), a major change in form from one developmental stage to another.

Unlike other terrestrial arthropods, all insects have highly specialized eggshells that can withstand desiccation while still allowing gas exchange. The ability of insect eggs to resist drying out means that

they can be laid on almost any surface, Insects can therefore occupy habitats that are difficult for other terrestrial arthropods to access. For example, a butterfly or beetle can lay a single egg on a leaf far above the forest floor, where winds would quickly dry the eggs of a scorpion or spider.

The wings of insects allow them to reach habitats and feed in ways other animals cannot. Insects were the first animals—and the only arthropods—to evolve wings, nearly 350 million years ago. Modern-day mayflies and dragonflies still bear structural similarities to these first fliers. The earliest-branching members of this group, the silverfish and rockhoppers, are referred to as primitively wingless because they evolved before the origin of wings. Some other insects, such as fleas, have lost the wings that were present in their common ancestor, presumably because their current parasitic lifestyles are better served by jumping than flying. Like all arthropods, insects repeatedly shed their exoskeleton as they grow into adulthood. No insect can molt wings, however, so only adult insects can fly.

Insects have evolved another critical adaptation for life on land: specialized respiratory systems. Aquatic arthropods obtain oxygen through gills, but gills don't work well in air because their large surface area dries out. Some terrestrial chelicerates have evolved simple lungs, called book lungs. These structures are filled with hemolymph and have a large surface area for gas exchange, but are kept moist inside a protective pocket. Some crabs are able to make extended forays on land by keeping their gills moist underneath their shell. In contrast, insects exchange gases through small pores in their

exoskeletons called [spiracles](#). The spiracles connect to an internal system of tubes, the [tracheae](#), that directs oxygen to and removes carbon dioxide from respiring tissues, much like air exchange ducts in a building ([Chapter 37](#)).

Within the insects, the main evolutionary dividing line is between those that undergo metamorphosis, such as butterflies and fruit flies, and those that do not, such as grasshoppers and water bugs. Insects that do not undergo metamorphosis look much like miniature adults when they hatch, and the main change in body form involves the appearance of wings. Dragonflies, which spend much of their early lives in lakes or ponds, also may change the form of their legs or eyes as they leave the aquatic environment.

Some insects do undergo metamorphosis, a remarkable transformation from a wormlike larval form specialized for feeding to an adult form specialized for mating and reproduction ([Fig. 42.19](#)). During the pupa stage, the body tissues undergo a dramatic change from the relatively simple larva to a very different-looking adult, such as a fly, butterfly, wasp, or beetle. Insects undergo a nearly complete dissolution of their muscles and other body parts during metamorphosis. The pupa must be immobile within its chitinous exoskeleton and so is sometimes (in moths) encased in a cocoon spun from silk. Hidden from view, it transforms from something as simple as a maggot, which lacks even an obvious head or tail, into an animal as sophisticated as a fly, which is able to walk on water, hover motionless in front of a flower, or fly at 60 mph. This evolutionary step has little parallel elsewhere in life and is one of the keys to insect

diversification.

Complete metamorphosis involves a pupal stage (center) in which the tissues of the larva (caterpillar on left) are reorganized into a very different adult form (butterfly on right).

#### Self-Assessment Question

6. Which four adaptations account at least in part for the success of insects? Why?

## 42.4 DEUTEROSTOME ANIMALS

Having introduced diversity within protostome animals, we now turn our attention to the other great bilaterian group, the Deuterostomia. As noted previously, one character that unites deuterostomes and separates them from protostomes is a feature of early development: the blastopore develops into the mouth instead of the anus. Deuterostome animals ([Fig. 42.20](#)) include three major phyla: [Hemichordata](#) (acorn worms), [Echinodermata](#) (sea urchins and sea stars), and [Chordata](#) (vertebrates and closely related invertebrate animals such as sea squirts).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

Photo sources: (top to bottom) Darlyne A. Murawski/Getty Images; Azure Computer & Photo Services/Animals Animals; © www.konig-photo.com; Reinhard Dirscherl/WaterFrame/Getty Images/Dwight Kuhn.

FIG. 42.20 A phylogenetic tree of deuterostome animals, showing all phyla (and the major subdivisions of the chordates) in this group. Phyla discussed in the text are shown in red.

## Hemichordates include acorn worms

## and pterobranchs, and echinoderms include sea stars and sea urchins.

We begin with the deuterostomes most distantly related to the vertebrates: the hemichordates and echinoderms. Hemichordates include acorn worms, approximately 75 species of wormlike animals that move through seafloor sediments in search of food particles. Pterobranchs, which are also hemichordates, consist of about a dozen species of animals that attach to the seafloor and use tentacles to filter food from seawater ([Fig. 42.21](#)). All hemichordates have a mouth on an elongated protuberance called a proboscis that connects to the digestive tract by a tube called the [pharynx](#). The pharynx contains a number of vertical openings called [pharyngeal slits](#) separated by stiff rods of protein. Hemichordates also have a [dorsal nerve cord](#) that forms the basis of a nervous system. These characters are found, as well, in chordate species, at least at some stage of their development. Additional characters that relate hemichordates to other deuterostomes are apparent in embryological and larval development. Nonetheless, adult hemichordates have body plans quite distinct from those of chordates and echinoderms.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 42.21 Hemichordates. Hemichordates include (a) acorn worms that move through sediments in search of food and (b) pterobranchs, which have filter-feeding tentacles.

Another major group of deuterostomes is the echinoderms, among the most distinctive of all animal phyla. Echinoderms include sea stars and sea urchins (including sand dollars), as well as brittle stars, sea cucumbers, and sea lilies. All of these organisms share a unique fivefold symmetry on top of their basic bilaterian organization ([Fig. 42.22](#)). Echinoderms form distinctive skeletons made of interlocking plates of porous calcite, a form of calcium carbonate. This structure

makes most of them hard and stony and protects them from predators. Another unique feature of echinoderms is their [water vascular system](#), a series of fluid-filled canals that permit bulk flow of oxygen and nutrients. [Tube feet](#), small projections of the water vascular system that extend outward from the body surface, allow echinoderms to crawl, sense their environment, capture food, and breathe. Sea stars can use the tube feet on their powerful arms to pull open the valves of clams. Approximately 7000 echinoderm species reside in present-day oceans, but the fossil record suggests that this phylum was more diverse in the past.

Zoologists have long known that echinoderm and hemichordate larvae share many features. Molecular sequence data now confirm that echinoderms are the closest relatives of hemichordates, with chordates

being a sister group to the group formed by echinoderms and hemichordates (see [Fig. 42.20](#)).

## Chordates include vertebrates, cephalochordates, and tunicates.

The other great branch of the deuterostome tree is the chordates, the phylum that includes vertebrate animals ([Table 42.1](#)). Within the phylum Chordata, there are three subphyla: the [cephalochordates](#), the [tunicates](#), and the [vertebrates](#) (also called [craniates](#)). Like the hemichordates, all chordates have a pharynx with pharyngeal slits (illustrated by the invertebrate chordate amphioxus in [Fig. 42.23](#)). In fish, the pharyngeal slits form the gills, but in terrestrial animals such as humans, these slits can be seen only in developing embryos. The [notochord](#), a unique feature of chordates, is a stiff rod of collagen and other proteins that runs along the back, providing resistance for the muscles along each side in some chordates. In vertebrates, the notochord is apparent only during early embryogenesis and is replaced functionally by a [vertebral column](#) later in development. Also forming during early development is the [neural tube](#), a cylinder of embryological tissue that develops into a dorsal nerve cord. Body musculature is organized into a series of segments called [myotomes](#), most visible in fish as the flakes of muscle that become separated when the fish is cooked. Chordates have a tail (reduced but still internally present in humans and other apes) that extends posterior to the anus, and some chordates have muscularized appendages that include the fins of fish and limbs of terrestrial vertebrates.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Photo source: © www.konig-photo.com.

FIG. 42.23 *Amphioxus*, a cephalochordate. *Amphioxus* has many features in common with vertebrates, including those labeled here, but it lacks a well-differentiated head and has no cranium or vertebrae.

*Amphioxus* ([Fig. 42.23](#)) is a cephalochordate. Cephalochordates share key features of body organization with vertebrates but lack a well-developed brain and eyes, have no lateral appendages, and do not form a mineralized skeleton. Nonetheless, their many similarities to vertebrates suggest they are closely related, and molecular sequence comparisons confirm this hypothesis.

The tunicates also share key features of the chordate body plan during early development, such as the notochord, neural tube, and a long tail with muscles arranged in myotomes ([Fig. 42.24](#)). However, tunicates have a unique adult form, with the pharynx and its pharyngeal

slits being the only obvious similarities to other chordates. Tunicates include approximately 3000 species of filter-feeding marine animals, such as sea squirts that are anchored to the seafloor and salps that float in the sea. The adult tunicate body is a basketlike structure that is highly modified for filter-feeding, not unlike the shapes of barnacles, which are also adapted to this feeding mode.

A tunicate might be mistaken for a sponge, but its complex internal structure shows that it lies far from sponges on the animal tree. The tunicate's body wall, or tunic, has a siphonlike mouth at one end that draws water through an expanded pharynx; this pharynx captures food particles and exchanges gases. Water and wastes are expelled through an anal siphon.

For many years, zoologists considered cephalochordates to be the closest relatives of vertebrate animals. Molecular data now suggest

that, in fact, the tunicates are our closest invertebrate relatives ([Fig. 42.20](#)). The common ancestor of tunicates, cephalochordates, and vertebrate animals was a small animal much like amphioxus in organization. After the divergence of the three major groups of chordates, however, the tunicates' adaptation for filter-feeding led to the unique anatomy they have today.

#### Self-Assessment Questions

7. Draw a phylogeny of deuterostomes, indicating the most likely relationships among chordates, hemichordates, and echinoderms, with common examples of each group.
8. You do not have a notochord, a long tail, or pharyngeal slits. How do you know that you are a chordate?

## 42.5 VERTEBRATES

In many ways, the last stop in our exploration of animal diversity is the most familiar because it includes our own species, *Homo sapiens*. The animals known as vertebrates are named for their jointed skeletons, which run along the main axis of the body and form a series of hard segments collectively termed **vertebrae** (singular, **vertebra**). In addition to features shared with other chordates, vertebrate animals are distinguished by a cranium that protects a well-developed brain, a pair of eyes, a distinctive mouth for food capture and ingestion, and an internal skeleton commonly mineralized by calcium phosphate (**Fig. 42.25**). Vertebrates also have a coelom in which the organs are suspended and a closed circulatory system. Like the other chordates, vertebrates have pharyngeal slits in at least their early embryonic stages.

Many of the features that separate vertebrates from invertebrate chordates can be found in the head, including a bony cranium that

protects the brain; in most vertebrates, the cranium joins with the mandible (or jawbone) to form a skull. This protective helmet for the delicate neuronal tissues permits the development of a larger brain than would otherwise be possible. The mandible permits vertebrates to eat foods such as other living animals that are often protected by hard shells and plants containing tough cellulose and lignin. Because hagfish, which branched from an early node on the vertebrate tree, have a cranium but not vertebrae (or a mandible), some biologists use the name “Craniata” for this group, rather than the traditional “Vertebrata.”

## Fish are the most diverse vertebrate animals.

We sometimes think of fish as one group, but the aquatic animals we commonly call “fish” include four distinct groups of aquatic vertebrates, not all of them monophyletic ([Fig. 42.26](#)).

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

FIG. 42.26 A phylogeny of the vertebrates. This phylogeny is favored by recent molecular data, but, like all phylogenies, it is a hypothesis. The placements of hagfish relative to other vertebrates and turtles relative to other sauropsids have provoked debate for many years.

The earliest-branching craniates are the [hagfish](#) and [lampreys](#) (Fig. 42.27). These animals have a cranium built of cartilage but lack jaws. Lampreys also have a vertebral column built of cartilage. Hagfish lack vertebrae, although current research suggests that this trait existed in a common ancestor of hagfish and lampreys but was lost in hagfish. These eel-like organisms eat soft foods without the aid of jaws: they diverged before jaws evolved from pharyngeal slits. Hagfish feed on

marine worms and on dead and dying sea animals, while lampreys live parasitically, sucking body fluids from their fish prey. Both hagfish and lampreys have a series of gill slits through which water enters to bring oxygen to the gills.

Sources: a. Tom McHugh/Science Source; b. F Hecker/AGE Fotostock.

FIG. 42.27 Hagfish and lampreys. Commonly grouped together as jawless fishes, (a) hagfish and (b) lampreys are the earliest-branching vertebrates still alive today.

Biologists have long debated the phylogenetic relationships among hagfish, lampreys, and other vertebrate animals. The presence of a vertebral column in lampreys and the absence of vertebrae in hagfish convinced many biologists that lampreys are the sister group to other

vertebrates, and that hagfish are the sister group to *all* vertebrates. However, several lines of molecular data now favor the view shown in [Fig. 42.26](#): hagfish and lampreys *together* form the sister group to all other vertebrates. Approximately 65 species of lampreys and hagfish live in fresh water and coastal oceans. Fossils record the existence of many extinct species of jawless fishes. When we include fossils, the jawless fishes as a whole are paraphyletic because one of their groups gave rise to fishes with jaws.

[Cartilaginous fish](#), formally known as Chondrichthyes, diverged from the next deepest node on the vertebrate tree. This monophyletic group includes approximately 800 species of sharks, rays, and chimaeras, all of which have jaws and a skeleton made of cartilage ([Fig. 42.28](#)). Cartilaginous fishes form deposits of hard calcium phosphate minerals like those in human bones, but only in their teeth and in small toothlike structures called denticles embedded in the skin. The best-known cartilaginous fishes are the sharks, many of which are predators that put those mineralized teeth to good use. The same group also includes Whale Sharks, filter-feeding animals that, at a length up to 12 m (40 feet), are gentle giants of the sea. Rays are closely related to sharks but have a flattened body adapted for life on the seafloor, where they feed on clams and crabs. The cartilaginous fish can retain levels of urea in their tissues that would poison other vertebrates, a physiological adaptation that helps them to maintain their salt balance without well-developed kidneys ([Chapter 39](#)). Nearly all cartilaginous fishes occur in the oceans, but Bull Sharks (*Carcharhinus leucas*) commonly swim into rivers—they've been recorded well up the Mississippi—and several species of rays live in fresh water.

Source: Michael Patrick O'Neill/Alamy.

FIG. 42.28 Cartilaginous fish. The skeletons of sharks are made of cartilage.

Moving up one more branch in the vertebrate tree, we encounter the **bony fishes**, or Osteichthyes (see [Fig. 42.26](#)). Bony fish have a cranium, jaws, and bones that consist of mineralized calcium phosphate. Numbering some 28,000 freshwater and marine species, these are the fish that humans most commonly encounter ([Fig. 42.29](#)). Bony fish are by far the most diverse group of vertebrates, possessing several unique features that facilitate their occupation of diverse habitats. First, they have a system of movable elements in their jaws that allows them to specialize and diversify their feeding on many different types of food. Second, they possess a unique gas-filled sac called a swim bladder that permits exquisite control over their position in the water column through changes in buoyancy. Third, bony fish have kidneys that allow them to regulate water balance, so that they can occupy waters over a wide range of salinities.

Source: JOEL SARTORE/National Geographic Creative.

FIG. 42.29 Bony fish. The char, well known to those who fish in fresh water, illustrates the principal anatomical features of bony fishes: a cranium, jaws, and mineralized bones.

The swim bladder plays a special role in vertebrate evolution. Early vertebrates evolved a gut sac that enabled them to gulp air to obtain additional oxygen. In some fishes, this sac evolved into the swim bladder, but in one group the sac was modified to become a lung. Charles Darwin was among the first to recognize that the swim bladder and the vertebrate lung are homologous organs.

## The common ancestor of tetrapods had four limbs.

Most animal phyla occur in the oceans, and many are exclusively marine. A subset of animal phyla has successfully colonized fresh water, and a smaller subset has radiated onto the land. Eleven groups on the animal phylogenetic tree contain both aquatic *and* terrestrial

species: nematodes, flatworms, annelids (earthworms and leeches), snails, tardigrades (microscopic animals with eight legs, sometimes called water bears), onychophorans (velvet worms), four groups of arthropods (millipedes and centipedes, scorpions and spiders, land crabs, and insects), and vertebrates. In each of these groups, the aquatic species branch from the earliest nodes, and the terrestrial species diverge from later nodes. No two of these groups share a last common ancestor that lived on land; thus, they all made the transition independently. Earlier, we outlined the extraordinary diversity of terrestrial arthropods. Here, we focus on vertebrates as the other great animal colonists of the land.

Most bony fish have fins supported by a raylike array of thin bones. About half a dozen closely related species, however, have pectoral and pelvic fins that extend from a muscularized bony stalk. These [lobe-finned fish](#) include the [coelacanth](#) and [lungfish](#) ([Fig. 42.30](#)).

Although these animals resemble other fish, the coelacanth and lungfish are the closest relatives of [tetrapods](#) (four-legged animals). Lungfish can survive periods when their watery habitat dries up by burying themselves in moist mud and breathing air. Coelacanths first appeared more than 400 million years ago and were thought to have gone extinct more than 80 million years ago, until a specimen was discovered in a fisherman's catch off South Africa in 1938. Hence, they are sometimes referred to as living fossils. There are two living species of coelacanths and three species of lungfish, one each in South America, Africa, and Australia. As shown in [Fig. 42.26](#), tetrapods descended from the same ancestor that is common to all four fish groups. Thus, there is no monophyletic group that corresponds to our

popular notion of “fish.”

Sources: a. Gerard Lacz/Animals Animals–Earth Scenes; b. D. R. Schrichte/SeaPics.com.

FIG. 42.30 Lobe-finned fish. The fish most closely related to tetrapods are the lobe-finned fishes: (a) the coelacanth and (b) the lungfish. These fishes have paired fins with an anatomical structure similar to that of tetrapod legs.

Fossils document the anatomical transition in vertebrate animals as they moved from water to land, showing changes in the form of the limbs, rib cage, and skull ([Fig. 22.22](#) discusses *Tiktaalik* and other fossils that connect tetrapods to lobe-finned fishes). Living tetrapods include amphibians, such as frogs and salamanders; lizards, turtles, crocodilians, and birds; and mammals. The last common ancestor of all these animals had four limbs, which is the source of the name **Tetrapoda** (“four legs”). Some, like snakes and a few amphibians and lizards, lost their legs in the course of evolution.

The more than 4500 species of **Amphibia** (“double life”) range in size from tiny frogs a few millimeters in length to the Chinese Giant Salamander, which is more than 1 m long. Their name reflects their distinctive life cycle ([Fig. 42.31](#)). Most amphibian species have an aquatic larval form with gills that permit breathing under water and a terrestrial adult form that has lungs for breathing air. Because their

eggs dry out easily, amphibians must reproduce in the water or in moist habitats, so they are not completely terrestrial. Whereas many amphibian larvae graze on algae, the adults are predators and often have a muscular tongue for capturing prey. Many amphibians are protected by toxins they secrete from glands in their skin, sometimes advertised by their brilliant color patterns. Most amphibian adults have simple lungs and so require moist skin as a secondary means of obtaining oxygen, with toads and red efts being notable exceptions. This is why frogs in particular have fallen victim to a fungus that affects the skin's ability to breathe ([Chapter 48](#)).

FIG. 42.31 The amphibian life cycle.

## Amniotes evolved terrestrial eggs.

Like insects, some vertebrates evolved an egg adapted to tolerate dry conditions that accompany life on land. The [amniotic egg](#) has a desiccation-resistant shell and four membranes that permit gas exchange and management of waste products produced by the embryo ([Chapter 40](#)). These eggs must be fertilized internally before the eggshell is produced by the female because sperm cannot penetrate the shell. The amniotic egg can exchange gases while retaining water, which enables the group of vertebrates known as [amniotes](#) to live in dry terrestrial habitats that amphibian eggs cannot tolerate. Amniotic eggs permit long development times, with the embryo's nutrition being supplied by a large yolk or a placenta. They keep wastes separated from the embryo so they do not poison it, giving the embryo time to build more complex bodies than otherwise would be possible.

Amniotes include lizards, snakes, turtles, and crocodilians (approximately 6000 species of scaly animals commonly referred to as reptiles), as well as birds (at least 10,000 species) and mammals (5500 species; [Fig. 42.32](#)). Most mammals, many lizards, and some snakes have evolved live birth rather than laying eggs. Nonetheless, their eggs retain the specialized membranes characteristic of all amniotes. Instead of being wrapped around the embryo inside a tough egg shell, these membranes surround and protect the embryo inside the womb.

Sources: a. Gary Meszaros/Science Source.; b. François Dorothé/Getty Images; c. Sarah Peters/Getty Images; d. NASA/Jim Grossmann.

FIG. 42.32 Amniotes. (a) Turtles, (b) lizards, (c) mammals, and (d) birds.

As shown in [Fig. 42.26](#), amniotes form a monophyletic group with two major branches. One consists of the mammals, whereas the other branch contains turtles, birds, and the amniotes traditionally grouped together as reptiles. Like fish, however, reptiles are not monophyletic. As discussed in [Chapter 22](#), fossils show that birds diverged from dinosaur ancestors, and molecular sequence comparisons indicate that crocodiles are the closest living relatives of birds. Unlike their closest living and fossil relatives, birds lack teeth, most of their scales have been modified into feathers (except on the legs and toes), and they are generally adapted for flight. Adaptations for flight include hollow bones that are light but remain strong, and a method of breathing that

extracts much oxygen from each breath, permitting high-performance flight ([Chapter 37](#)).

One consequence of this streamlined, lightweight bird body is a lack of the heavy jaws that many other tetrapods use to grind up plant leaves or other low-nutrition foods. Instead, birds have a grinding organ, the gizzard (also found in alligators and crocodiles), inside their bodies near their center of gravity, where it interferes less with flight.

All [mammals](#) are covered with hair and feed their young milk from the mammary glands for which the class Mammalia is named. Like many other groups of animals and plants, the early-branching mammals show intermediate stages in the evolution of the body plans that dominate on Earth today.

The first fossils that clearly show evidence of hair appeared approximately 210 million years ago, during the Triassic Period. Like feathers in birds, hair permits retention of body heat. The earliest-branching living mammals, the monotremes, lay eggs, like birds or lizards ([Fig. 42.33](#)), but their hatched young drink milk secreted from pores in the skin of the mother's belly. Living monotremes, the platypus and four species of echidna, or spiny anteater, are found only in Australia and New Guinea.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Photo sources: (top to bottom) Dave Watts/NHPA/Photoshot; C. Wermter/AGE Fotostock; David Macias/Science Source.

FIG. 42.33 A phylogenetic tree of mammals. There are three major groups of mammals: monotremes, marsupials, and placental mammals.

The first mammals that gave birth to live young appeared in the Jurassic Period, about 160 million years ago. These animals gave rise

to the two major living groups, marsupial and placental mammals.

**Marsupials** include kangaroos, koalas, and related groups native to Australia, as well as the opossums found in the Americas. Their young are born at an early stage of development, and the tiny babies complete development while attached to mammary glands equipped with nipples that provide them with milk. In some marsupials, notably kangaroos, this development occurs inside a pouch. Only later do fully formed juveniles venture outside to begin life on the ground.

The **placental mammals** are named for a temporary organ called the **placenta** that develops in the uterus along with the embryo, providing nutrition that enables the offspring to be larger and more quickly independent when born ([Chapter 40](#)). Most living mammals fall into this group. Placental mammals include the carnivores, such as lions and weasels; the primates, including monkeys, apes, and humans; and the hooved mammals, which include cattle, pigs, deer, and—perhaps surprisingly—their marine relatives, the whales.

The most diverse mammals belong to two groups of mostly small animals, the bats and the rodents. Bats, which evolved flight and a form of sonar called echolocation to find food at night, include more than 1000 species. The largely plant-feeding rodents are as diverse as the large mammals and bats combined, numbering more than 2000 species. Beavers, gophers, rats, mice, hamsters, and squirrels are all rodents. Rodent evolutionary success is often attributed to innovations in tooth development. Their teeth are unusual in that they grow continually throughout life. This constant growth permits constant wear, allowing these animals to gnaw through hard protective

coverings to obtain nutrition from a remarkably wide variety of otherwise hard-to-access sources such as the contents of seeds.

**Fig. 42.34** shows animal phylogeny in the context of life's broader diversity. Clearly, the diversity that surrounds us today has evolved over the immense time scale of Earth history, on a planet that has changed markedly through time. The dynamic interplay of life and environment underpins ecology as well as diversity, and it provides a fundamental challenge for sustaining biological diversity in the changing world of the twenty-first century ([Chapter 48](#)).

FIG. 42.34 VISUAL SYNTHESIS: Diversity Through Time Integrating concepts from [Chapters 24](#), [25](#), [31](#), [32](#), [33](#), and [42](#)

### Self-Assessment Questions

- Why do bird feet have scales like those found on snakes and lizards?

10. Which features are common to bony fishes, amphibians, amniotes, and mammals?
11. Which features underpin the ecological success of tetrapods on land?
12. Name two features that are unique to mammals and suggest their importance for mammal evolution.

## CORE CONCEPTS SUMMARY

### 42.1 SPONGES, CNIDARIANS, CTENOPHORES, AND

**PLACOZOANS:** The simplest animals evolved multicellularity from single-celled ancestors.

Sponges, which are widespread in the oceans, have a simple anatomical organization and feed by drawing water containing food particles into their interiors. [page 946](#)

Cnidarians form multiple tissues, differentiate nerve and muscle cells, and feed as predators by means of specialized stinging cells. [page 948](#)

Ctenophores, or comb-jellies, resemble cnidarians but move by beating cilia, have an anal pore for waste excretion, and have a rudimentary mesoderm germ layer. Ctenophores are a difficult limb to place with confidence on the animal tree of life. [page 949](#)

Placozoans have a simple organization, but genomic data support the hypothesis that they are the sister group to cnidarians and bilaterians. [page 950](#)

The evolutionary relationships among sponges, placozoans, and ctenophores remain a subject of research. [page 951](#)

**42.2 PROTOSTOME ANIMALS:** Protostomes are bilaterian animals and include lophotrochozoans and ecdysozoans.

Protostomes are divided into lophotrochozoans and ecdysozoans. [page 952](#)

Lophotrochozoans consist of 17 phyla, including annelid worms and mollusks. [page 952](#)

Annelid worms include earthworms and leeches, but most species of annelids live in the oceans. [page 952](#)

Mollusks include gastropods (snails, slugs), cephalopods (squid, octopuses), and bivalve mollusks (clams, oysters). [page 953](#)

Ecdysozoans include several phyla, notably the nematodes and arthropods, that molt their cuticles. [page 956](#)

**42.3 ARTHROPODS:** Arthropods, bilaterian animals named for their jointed legs, are extraordinarily diverse.

Arthropods can be organized into four main groups: insects, chelicerates (spiders, scorpions), myriapods (centipedes, millipedes), and crustaceans (lobsters, shrimp). [page 957](#)

The jointed legs of arthropods have been modified to include a remarkable diversity of structures. [page 957](#)

The most diverse group of arthropods is the insects. [page 959](#)

All insects have desiccation-resistant eggs. [page 959](#)

Insects were the first animals to evolve wings. [page 959](#)

Insects efficiently exchange gases through spiracles and tracheae. [page 959](#)

Some insects undergo metamorphosis, a dramatic developmental change from a pupa to an adult. [page 960](#)

**42.4 DEUTEROSTOME ANIMALS:** Deuterostomes are bilaterian animals and include humans and other chordates, as well as acorn worms and sea stars.

Deuterostomes include three main phyla—Chordata, Hemichordata, and Echinodermata. [page 960](#)

Well-known echinoderms include sea stars and sea urchins, which have a fivefold symmetry superimposed on their basic bilateral body plan. [page 961](#)

Chordates include vertebrates, cephalochordates, and tunicates. [page 961](#)

**42.5 VERTEBRATES:** Vertebrates are deuterostomes with a bony cranium and typically a vertebral column, enabling them to become ecologically important in the water and on land.

The group commonly known as “fish” consists of four distinct groups of aquatic vertebrates: hagfish and lampreys, cartilaginous fishes, bony fishes, and lobe-finned fishes. [page 964](#)

Lungfish are the closest relatives of tetrapods, which include amphibians, lizards, turtles, crocodilians, birds, and mammals. [page 966](#)

Amphibians have an aquatic larval form and a terrestrial adult form. [page 967](#)

Amniotes, such as lizards, snakes, crocodiles, birds, and mammals, have an amniotic egg, permitting these animals to colonize dry, terrestrial habitats. [page 967](#)

## CASE 8

### Conserving Biodiversity

#### *Rainforest and Coral Reef Hotspots*

When we think about mass extinctions, the demise of the dinosaurs is often the first example that springs to mind. But many conservationists believe we are on the brink of a mass extinction today. The International Union for the Conservation of Nature has estimated that more than 800 plant and animal species in habitats around the world have died out in the last 500 years, and more than 20,000 are currently at risk of extinction.

*Conservationists must make difficult choices, prioritizing which species to protect. To get the most bang for every conservation buck, ecologists have identified 25 priority areas, or biodiversity hotspots.*

The cause of this die-off isn't an asteroid impact or a cataclysmic volcanic event. Instead, human activity is dramatically altering the planet and its biological diversity.

We cannot save every single species threatened with extinction. Conservationists must make difficult

choices, prioritizing which species to protect. To get the most bang for every conservation buck, ecologists have identified 25 priority areas, or biodiversity hotspots.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

**Biodiversity hotspots.** The areas highlighted in orange have a particularly high diversity of species found nowhere else. *Data from Macmillan Publishers Ltd: N. Meyers et al., 2000, "Biodiversity Hotspots for Conservation Priorities," Nature 403:853–858.*

These hotspots are areas with disproportionately large concentrations of endemic species—that is, species found nowhere else. For example, scientists estimate that as many as 44% of all vascular plants and 35% of vertebrate species are confined to these 25 hotspots. Those figures are impressive, considering that the hotspots make up just 1.4% of Earth's land surface.

The islands of the Caribbean—the West Indies—constitute one such biodiversity hotspot. The Caribbean Sea contains more than 7000 islands rich in biological diversity, including an estimated 6550 native

plant species. All of the Caribbean islands are flush with flora and fauna, but one island in particular epitomizes the concept of a biodiversity hotspot. Hispaniola, the second largest of the Caribbean islands, was the site of the first European colonies in the New World, founded by Christopher Columbus. Today, Hispaniola is shared by two countries, Haiti to the west and the Dominican Republic to the east.

Hispaniola is roughly the same size as Ireland, but it contains a striking assortment of habitats, including desert, savanna, rainforests, dry forests, pine forests, coastal estuaries, and interior mountains. With such a rich abundance of habitats, Hispaniola is, in some ways, a microcosm of the planet's many ecosystems. And like the Earth's other natural places, Hispaniola faces many challenges to its native biological diversity.

Of all the habitats on Hispaniola, the forests contain the greatest variety of plants, animals, and other organisms. Ferns, orchids, and bromeliads (spiky relatives of the pineapple) grow in treetops far above the forest floor. These plants, known as epiphytes, absorb water from dew, rainwater, and even the air. Their roots never reach the soil.

The forest is alive with activity. Ants march silently. Crickets and cicadas buzz and whine in the treetops. Vertebrate vocalists such as frogs and birds fill the air with chirps and whistles, making themselves known to both potential mates and rivals. Bats swoop through the darkened skies, using ultrasonic calls to locate insect prey. An estimated 30,000 species of multicellular organisms are found on Hispaniola, and a third of those are endemic. One example is the

Hispaniolan solenodon, a long-nosed mammal that resembles an overgrown shrew and secretes toxic saliva. Listed as endangered, the solenodon has flirted with extinction for decades.

How did all these species come to live on the island? Over tens of millions of years, organisms traveled to Hispaniola by air and by sea. Geographically separated from their ancestors on the mainland, many of these organisms evolved to become distinct species. As they adapted to fill distinctive niches on the island, animals such as *Anolis* lizards, frogs, and crickets evolved an impressive diversity of forms.

In some cases, scientists have been able to explore Hispaniola's evolutionary history directly. They have found the remains of insects and other species that became entombed in amber, which is fossilized tree resin, 30–23 million years ago. Many of these preserved specimens resemble species still living on Hispaniola. Others are unlike any creatures found on the island today.

The stunning diversity displayed on Hispaniola doesn't exist just on land. Conservationists consider the warm, shallow reefs of the Caribbean to be one of the world's marine biodiversity hotspots. Coral reefs in general are among the world's most biologically diverse ecosystems, with species from all recognized phyla of animals populating the reefs.

Around the world, reefs support many thousands of species, including snails, corals, lobsters, and fish. Many, but not all, of these creatures spend their entire life in this habitat. Reefs also act as vital nursery grounds for animals that live in other parts of the ocean, from

sea turtles to sharks. Reef biodiversity is also critical to maintaining fisheries that provide food and income for millions of people.

Hispaniola's rainforests and reefs—indeed, all the biodiversity hotspots identified by conservationists—are notable for more than just their biological richness. They have also been given priority status because they face serious threats.

Reefs around the world are being damaged by human activities. Overfishing and pollution take their toll on reef ecosystems. Climate change is increasing seawater temperature, and increasing CO<sub>2</sub> is altering ocean chemistry. Those changes threaten the coral organisms that form the backbone of the reefs.

Likewise, ecosystems on land face significant challenges. The Caribbean islands now have only approximately 11% of their original vegetation. Humans have cleared great swaths of land for agriculture and chopped trees to use as fuel. Humans have also introduced non-native, or invasive, species to the islands, both intentionally and accidentally. On Hispaniola, Europeans introduced the Javanese mongoose to control rats in sugarcane fields. The mongoose has devastated local populations of reptiles, amphibians, and birds.

If Hispaniola serves as a microcosm of the planet's ecosystems, it also serves as a cautionary tale. Two divergent paths have emerged on the single island. Haiti has historically suffered greater poverty than the Dominican Republic, and it has much greater population density. Those factors have put more pressure on the environment in Haiti, contributing to much greater deforestation on the western half of the

island.

The case of Hispaniola illustrates the complex challenges facing conservationists. Solutions to environmental challenges must take into consideration the effects of poverty, culture, and other social pressures. Balancing the needs of humans with the needs of natural ecosystems is no easy task. But as a relatively small island, Hispaniola may actually be in a better position to turn things around than larger, more politically complex countries. The world's biodiversity hotspots might yet lead the charge in finding ways for humans and the rest of the planet's inhabitants to coexist peacefully.

**Coral reefs.** Coral reefs support many species but are threatened by warming, changing seawater chemistry, overfishing, and pollution.

## DELVING DEEPER INTO CASE 8

**For each of the Cases, we provide a set of questions to pique your curiosity. These questions cannot be answered directly from the Case itself, but instead introduce issues that will be addressed in chapters to come. We revisit this Case in [Chapters 43–48](#) on the pages indicated below.**

1. How do populations colonize islands? See [page 1015](#).
  2. Can competition drive species diversification? See [page 1023](#).
  3. How is biodiversity measured? See [page 1032](#).
  4. How do evolutionary and ecological history explain biodiversity?  
See [page 1090](#).
  5. How has global environmental change affected coral reefs around the world? See [page 1100](#).
  6. What are our conservation priorities? See [page 1111](#).

# CHAPTER 43 Behavior and Behavioral Ecology

Dan L. Perlman/EcoLibrary.org

## CORE CONCEPTS

**43.1 TINBERGEN'S QUESTIONS:** For any behavior, we can ask what adaptive function it serves, what causes it, how it develops, and how it

evolved.

**43.2 DISSECTING BEHAVIOR:** Animal behavior is shaped in part by genes acting through the nervous and endocrine systems.

**43.3 LEARNING:** Learning is a change of behavior as a result of experience.

**43.4 INFORMATION PROCESSING:** Orientation, navigation, and biological clocks all require information processing.

**43.5 COMMUNICATION:** Communication involves an interaction between a sender and a receiver.

**43.6 SOCIAL BEHAVIOR:** Social behavior is shaped by natural selection.

---

There is no Nobel Prize for biology. Instead, for biological research, the Nobel Committee awards the Prize for Physiology or Medicine. Biologists specializing in other areas, such as behavior and ecology, are not even in the running for science's ultimate prize. However, in 1973, in an unprecedented move, the Nobel Committee bent its own rules and awarded the Prize for Physiology or Medicine to three scientists with no physiological or medical credentials: Niko Tinbergen, Konrad Lorenz, and Karl von Frisch. The award was given in recognition of their roles in pioneering the study of animal behavior under natural conditions.

What exactly does the expression “under natural conditions” mean and why is it important to emphasize? In the early 1900s, Carl von Hess, a prominent visual physiologist, claimed that bees are color

blind, a conclusion based on experiments in laboratory settings. However, by training bees to go to food sources associated with differently colored cards in a natural context, the Austrian behavioral biologist Karl von Frisch demonstrated in 1914 that, in fact, bees have excellent color vision. Von Frisch's work illustrated that behavior—in this case, foraging for food—cannot be studied in isolation, but can be fully understood only when studied in a natural context. Von Frisch emphasized this point at a scientific meeting where he showed how he had trained bees to associate blue cards with food. Von Frisch's presentation caused quite a stir for more than just scientific reasons. By chance, the audience was wearing blue name tags, which proved highly popular with the blue-fixated bees!

In this chapter, we explore animal behavior: how animals learn, communicate with one another, form social groups, and choose mates. In each case, we can consider animal behavior on multiple levels. At the individual level, behavior is determined in part by a complex interplay of the nervous and endocrine systems. Behavior is also influenced by the environment, as von Frisch's bee studies illustrate. Finally, behaviors, like all traits, are shaped by natural selection.

# 43.1 TINBERGEN'S QUESTIONS

We begin our exploration of animal behavior by asking a simple question: why does an animal exhibit a particular behavior? In 1963, the Dutch behavioral biologist Niko Tinbergen divided this overarching question into four separate questions, each one focusing on a different aspect of the behavior ([Table 43.1](#)).

TABLE 43.1 Tinbergen's Four Questions

|                                     |                                                                                                      |                                                                                                 |
|-------------------------------------|------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------|
|                                     | <b>PROXIMATE:</b> Short-term processes acting within an individual's lifetime affecting the behavior | <b>ULTIMATE:</b> Long-term evolutionary processes affecting the behavior                        |
| <b>ORIGIN OF A BEHAVIOR</b>         | <b>Developmental:</b> How is the behavior acquired over an individual's lifetime?                    | <b>Evolutionary:</b> Where and how did the behavior arise in the past?                          |
| <b>IMPLEMENTATION OF A BEHAVIOR</b> | <b>Mechanistic:</b> How is the behavior caused through neural, muscular, and other processes?        | <b>Adaptive:</b> How does the behavior enhance the survival and/or reproduction of individuals? |

## Tinbergen asked proximate and ultimate questions about behavior.

Let's consider an example: why does a bird sing? While apparently straightforward, this question can be broken down into more specific questions using Tinbergen's approach and then answered in a number of different ways:

1. Adaptive function. What is the behavior for? How does the

behavior promote the individual's ability to survive and reproduce? In this case, the answer to the question might be that a male bird sings to attract a mate and then reproduce.

2. Mechanistic causation. What physiological mechanisms cause the behavior? This question can have multiple answers. A bird sings because its hormone levels have changed in response to changes in day length. Or, more immediately, a bird sings because air passing through its specialized singing organ, the syrinx, causes membranes to vibrate rhythmically.
3. Development. How did the behavior develop? Here, the focus is on the role of genes and the environment in shaping the development of the behavior. In birds, typically the male sings, and he has learned the song from his father or other males.
4. Evolutionary history. How did the behavior evolve over time? Complex bird songs may have evolved from vocalizations made by ancestors that became increasingly standardized over time, so much so that we can often identify a bird species simply by hearing it sing. A behavior may have originated to fulfill a function different from the one it currently serves. For example, the song of a particular species may have first evolved to claim a territory but now is used to attract mates.

Tinbergen's analysis allows us to see that different answers to the question "Why does a bird sing?" can all be correct. The first two categories, mechanistic causation and development, provide *proximate* explanations of behavior because they deal with *how* the behavior came to be. The second two categories, adaptive function and evolutionary history, provide evolutionary explanations of how natural

selection has shaped a behavior over time; these *ultimate* explanations of behavior deal with *why* the behavior came to be. Tinbergen's four questions are complementary ways of looking at the same problem, and are a good starting point for the analysis of behavior.

The answers to Tinbergen's questions rely on an interplay between genes and the environment. The influence of genes is especially clear in **innate** behaviors, which are instinctive and carried out regardless of earlier experience. Male silkworm moths of the genus *Bombyx* exhibit an innate behavior when they fly upwind toward the source of a female-produced pheromone, an airborne chemical signal to members of the same species; in this case, the communication acts to attract members of the opposite sex (**Fig. 43.1**). Pheromones released from a female's abdominal gland are sensed by small hairs on the male's antennae. In the presence of pheromones, the antennal sensory hairs fire action potentials (**Chapter 34**). When approximately 200 hairs are being activated per second, a male flies upwind distances of a kilometer or more, tracking the increasing pheromone concentration until he finds the female. The male moth does not need to learn this behavior; he performs it spontaneously. His genes encode molecular receptors to which the pheromone binds, and this binding triggers a cascade of events that result in the moth's heading up the pheromone's concentration gradient.

In contrast to an innate behavior, which is instinctive, a **learned** behavior depends on an individual's experience. As we will see throughout this chapter, even neurologically simple organisms have a considerable capacity to learn. Fruit flies, for example, learn to avoid certain locations or substances if they associate them with an unpleasant experience.

We can consider, then, the extent to which a particular behavior is genetically encoded (part of the animal's nature) and the extent to which it is conditioned by the environment in which the animal develops (part of the animal's nurture). However, as we discussed in [Chapter 17](#), nature and nurture are inextricably linked. For example, most human behaviors are the product of an interaction between nature and nurture. Consider language in the context of Tinbergen's second

question concerning the development of behavior: humans have an innate ability to acquire language, but the specific language that we acquire depends entirely on our nurture. A baby in Italy learns Italian, and one in Finland learns Finnish.

#### Self-Assessment Questions

1. Analyze the behavior of the male silkworm moth described in this section in terms of the four questions that Tinbergen might have asked about it.
2. Explain the difference between innate and learned behaviors, and provide one example of each type of behavior.

## 43.2 DISSECTING BEHAVIOR

Behavior can be influenced by a large number of factors, both genetic and environmental. For that reason, complex behaviors can sometimes defy analysis. By choosing simple behaviors that can be more easily studied and understood, scientists can identify, isolate, and investigate the separate components of more complex behaviors.

### The fixed action pattern is a stereotyped behavior.

Some of the first behaviors to be carefully analyzed were [displays](#).

Displays are species-specific patterns of behavior that tend to follow the same sequence of actions whenever they are repeated, in a way that is similar from one individual to the next. Because these behaviors are so similar whenever they occur, they are considered “stereotyped.”

Presumably, natural selection favors display behaviors that send unmistakable signals. Consider, for example, courtship displays in birds that are preparing to mate ([Fig. 43.2](#)). Experiments have shown that, in some species, a bird raised in complete isolation from other members of its species still performs the stereotyped courtship display with great precision, suggesting that the behavior is genetically encoded; that is, it is instinctual rather than learned.

Source: Bruce Beehler/AGE Fotostock.

FIG. 43.2 Courtship display in the Raggiana Bird-of-Paradise. The male (top) is performing a highly stereotyped set of behaviors to entice the female to mate with him.

Many displays are **fixed action patterns (FAPs)**: a sequence of behaviors that, once triggered, is followed through to completion. A classic example, originally studied by Tinbergen, is the response of a goose to an egg that has fallen from its nest (**Fig. 43.3**). The **key stimulus** initiates the behavior. In the goose's case, the key stimulus is the sight of the misplaced egg. This sight provokes in the goose an egg-retrieval FAP, which consists of rolling the egg back to the nest with the underside of its beak (**Fig. 43.3a**). This response cannot be broken down into smaller subunits and is always carried out to the end, even if

it is interrupted. In fact, even if the researcher ties a string around the misplaced egg and removes it while the goose is in mid-action, the goose will continue the task of rolling the now-absent egg ([Fig. 43.3b](#)).

FIG. 43.3 A fixed action pattern. A goose displays and completes the behavior to retrieve an egg (a), even if the behavior is interrupted (b) or the stimulus altered (c).

To better understand this behavior, the researcher can vary attributes of the key stimulus (in this case, the misplaced egg). A remarkable finding is that many geese respond most strongly to the largest round object provided, even a soccer ball, as illustrated in [Fig. 43.3c](#). A soccer ball not only elicits the egg-retrieval FAP, but does so even more strongly than a normal egg. The soccer ball is considered a **supernormal stimulus** because it is larger than any egg the goose would naturally encounter and elicits an exaggerated response. Natural selection has likely favored geese that recognize and respond to large eggs that have rolled outside the nest. However, because eggs never

grow to the size of soccer balls, selection has not shaped an appropriate response to unrealistically large egg-shaped objects.

## The nervous system processes stimuli and evokes behaviors.

How do animals recognize the stimulus that leads to a particular behavior? In the example of the goose retrieving an egg outside its nest, how does the goose recognize that the object in question is sufficiently egg-like to elicit the behavior? At its root, this is an extraordinarily difficult problem. The world is full of stimuli and many things look like an egg. Thus, the challenge for the animal is to filter out the correct signal (the egg) from the surrounding noise (everything else). Animals have to process many different kinds of information in three dimensions.

We know that stimulus recognition is often carried out by [feature detectors](#), specialized sensory receptors or groups of sensory receptors that respond to important signals in the environment. Frogs provide a good example. Male frogs call to attract females and warn off other males. A single pond may contain many species of frogs, each with its specific call. A heavily populated frog pond can be a noisy place, but it is critical that an individual frog is able to distinguish the call of other members of its own species from those of other species. A further complication is that different species of frogs can have similar calls, which are often virtually indistinguishable to the human ear.

One approach to the problem of understanding how frogs recognize their species-specific call is experimenting with recordings of frog

calls. By recording frog calls, altering aspects of the call in specific ways, playing them back, and then monitoring the responses of frogs, we can identify the impact of different components of the call—pitch, duration, and pulse frequency, for example. Such studies have demonstrated that the frog’s auditory nerves act as a feature detector, with each one “tuned” to a specific component of the call. The combination of different feature detector neurons stimulated by different components adds up to the frog’s recognition of a specific call, as shown in [Fig. 43.4](#). Once the sound is correctly identified, the appropriate behavior follows.

**FIG. 43.4 A feature detector.** In its natural environment, a frog is subjected to a barrage of sound stimuli. Each species has a feature detector tuned to its species-specific call, allowing it to distinguish the call of its own species (red arrow) from the calls of other frogs (blue arrows).

---

## Hormones can trigger certain behaviors.

The effect of a neuron is typically short lived and local: a neuron may, for example, connect to another neuron or cause a muscle to contract ([Chapter 34](#)). One way in which a stimulus may provoke a more widespread and prolonged effect is through the production of hormones. Hormones can affect multiple cells in target organs simultaneously ([Chapter 36](#)).

*Anolis* lizards demonstrate the important role of hormones in sexual behavior, showing both how social stimuli can affect the release of hormones and how hormones can affect behavior ([Fig. 43.5](#)). If females of *Anolis carolinensis* are isolated from males during the breeding season, approximately 80% of individuals will be found to have active egg follicles in their ovaries ([Fig. 43.5a](#)). If one male is added to a group of females, that figure increases to 100% ([Fig. 43.5b](#)). The courting behavior of the male lizard stimulates the females to produce hormones that cause the full development of the ovaries, making all the females reproductively active. Now consider what happens if a group of males, instead of a single male, is added to an all-female population: only 40% of the females undergo ovarian development ([Fig. 43.5c](#)). This unexpected result seems to occur because the males fight among themselves rather than court the females; for some of the females, then, the courtship stimulus is lacking. Castrated males (which do not produce testosterone) that are added to a group of females have no significant effect on rates of ovarian development, which remains approximately 80% ([Fig. 43.5d](#)).

They fail to court because the courting behavior is caused in part by testosterone. In contrast, a castrated male that is injected with testosterone does display courting behavior; his presence has the same effect as the presence of a single male, inducing all the females to undergo ovarian development ([Fig. 43.5e](#)).

These simple laboratory experiments demonstrate the complex interplay between hormones and behavior. Testosterone mediates both the male–male interactions and the male–female interactions that cause females to produce hormones promoting their reproductive development.

**Breeding experiments can help determine the degree to which a behavior is genetic.**

The nervous and endocrine systems that in part shape behaviors are the product of genetic instructions. Thus, on the one hand, all behaviors have a genetic component. After all, it is the instructions in the genome that build the nervous system, muscles, and glands whose actions lead to a behavior. On the other hand, all behaviors can be considered environmental since, without the appropriate environment, an organism would not develop normally and would therefore lose the ability to perform the behavior. On a very basic level, an organism in an environment without appropriate nutrients would lack the necessary energy to perform a given behavior. How, then, do we study the genetic basis of behavior? Modern approaches harness the power of molecular genetics, but more traditional analyses are also highly informative.

Artificial selection ([Chapter 20](#)), in which humans breed animals and plants for particular traits, provides strong evidence of the role of genetics in influencing behavior. Dogs were domesticated from wolves approximately 10,000 years ago. Today, dogs display great diversity, although they are all the same species. Obviously, there has been extensive selection on physical traits: a Dachshund, for example, looks quite different from a German Shepherd or a Great Dane. Selection has also been applied to behavior: a Pointer has extraordinary “pointing” behavior that indicates the location of a hunter’s prey, and a Border Collie is an excellent herder ([Fig. 43.6](#)).

Sources: a. Adriano Bacchella/naturepl.com; b. Fred Lord/Alamy.

**FIG. 43.6 Artificial selection.** Artificial selection can alter behavior, as shown by the remarkable differences in behavior we see among breeds of dogs, such as (a) a Pointer and (b) a Border Collie.

In the late 1950s, William Dilger studied the nest-building behavior of lovebirds, which are members of the genus *Agapornis*. Some species transport their nesting material in their beaks, whereas others tuck pieces of the material into their tail feathers. Does the nesting behavior of these birds have a genetic basis? To answer this question, Dilger set up crosses between species with different nest-building techniques to produce hybrids. He then observed how the hybrids built their nests. Interestingly, the hybrid offspring showed nest-building behavior intermediate between that of the parents: they tried to tuck material under their feathers, but were not successful. These experiments suggest that this behavior has a genetic basis.

It was not possible to do a true Mendelian analysis of the lovebirds' behavior ([Chapter 15](#)). Such an analysis would require additional crosses, which were not possible because the hybrids were sterile. Like most behaviors, the lovebirds' nest-building behavior is probably controlled by a large number of genes, each of which has a relatively

small effect ([Chapter 17](#)). Given their multiple influences, it is difficult to identify which genes are responsible for the behavior. Even with molecular methods, mapping and identifying the underlying controlling genes in cases where many different genes govern a particular trait is a daunting task.

## Molecular techniques provide new ways of testing the role of genes in behavior.

Molecular biology is changing the way we approach behavioral genetics. Some studies have identified complex behaviors that are strongly influenced by a single gene. One well-understood instance of a single gene's effect on behavior comes from the fruit fly *Drosophila*.

In *Drosophila*, different alleles of the *foraging* (*for*) gene, *for<sup>S</sup>* and *for<sup>R</sup>*, are present in populations. The two alleles have different effects on the behavior of *Drosophila* larvae. The gene encodes an enzyme expressed in the brain that affects neuronal activity and alters behavior. In the absence of food, both “sitter” (*for<sup>S</sup>*) and “rover” (*for<sup>R</sup>*) larvae move about in search of food. In the presence of food, however, sitters barely move, feeding on the patches on which they find themselves, whereas rovers move extensively both within a patch of food and between patches ([Fig 43.7a](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Source: M. B. Sokolowski, 2001, "Drosophila: Genetics Meets Behaviour," *Nature Reviews Genetics* 2:879–890, doi:10.1038/35098592.

FIG. 43.7 The effect of genotype at the foraging locus on the feeding behavior of *Drosophila melanogaster* larvae. (a) When food is present, rover larvae travel more extensively than sitter larvae. (b) Both types of larvae exist in natural populations.

Both alleles are present in natural populations ([Fig. 43.7b](#)); typically, 70% are rovers, 30% are sitters. That both strategies are found in populations suggests that both are adaptive. Otherwise, if one

strategy were markedly inferior, we would expect natural selection to eliminate it. Furthermore, studies have shown that rovers are selected for in crowded environments in which seeking new food sources carries a survival advantage, and sitters are selected for in less crowded environments because sitters take maximum advantage of their current food source. In this case, variation at a single gene affects a complex behavior in fruit flies.

The *foraging* gene is present in other insects as well, including honeybees, suggesting that the gene has been evolutionary conserved. Honeybees with low levels of *for* expression in their brain tend to stay in the hive, whereas those with high levels of *for* expression are likely to be foragers ([Fig. 43.8](#)).

#### HOW DO WE KNOW?

### FIG. 43.8

## Can the same gene influence behavior differently in different species?

#### BACKGROUND

In fruit flies (*Drosophila melanogaster*), variation in the *foraging* (*for*) gene affects feeding behavior of larvae. Two alleles of the *for* gene exist in natural populations: *for<sup>s</sup>* larvae (“sitters”) tend to stay on a patch of food and *for<sup>R</sup>* larvae (“rovers”) tend to move from patch to patch.

Honeybees (*Apis mellifera*) also forage for food, but, in contrast to fruit flies, bee foraging behavior changes with age. Young honeybees (“nurses”) stay at the hive, and older ones (“foragers”) forage for nectar. The *for* gene is present in honeybees, raising the possibility that this gene is involved in the developmental change in foraging in honeybees.

## HYPOTHESIS

In 2002, Yehuda Ben-Shahar and colleagues at the University of Illinois hypothesized that foraging in honeybees is influenced by the expression of the *for* gene, with nurses having lower expression levels than foragers.

## EXPERIMENT 1

Levels of *for* mRNA were measured in honeybee nurses and foragers in two different colonies.

## RESULTS

Levels of *for* mRNA are significantly higher in foragers than in nurses ([Fig. 43.8a](#)). However, foragers are older than nurses. Thus, based on the results of just the initial measurements, it was unclear whether the increased gene expression in foragers compared with nurses is associated with differences in age or differences in behavior. To answer this question, the researchers repeated the experiment and measured levels of *for* mRNA in honeybees that forage at the age at which bees are normally nurses. These young foragers were also found to have higher *for* mRNA levels than nurses ([Fig. 43.8b](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

## EXPERIMENT 2

The *for* gene encodes a cGMP-dependent kinase that phosphorylates other proteins ([Chapter 9](#)). In a second experiment, the researchers treated honeybee nurses with cGMP to activate the kinase and monitored their subsequent behavior. They used a related compound, cAMP, which has a chemical structure similar to cGMP but does not affect the kinase, as a control to ensure that any effect observed was specific for the cGMP pathway and not, say, a generalized stress response to being experimentally manipulated.

## RESULTS

Treatment with cGMP changed the behavior of nurses, causing them to forage ([Fig. 43.8c](#)). Furthermore, the higher the dose, the more foraging behavior was observed. No effect on foraging was seen in the control treatment ([Fig. 43.8d](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

## CONCLUSION

The same gene that is involved in two different behavioral phenotypes in fruit flies (sitters versus rovers) is also involved in a developmental behavioral change in honeybees (nurses versus foragers). This finding suggests not only that genes influence behavior, but also that a gene can have related but different functions in different species.

## FOLLOW-UP WORK

With the availability of increasingly more powerful tools to analyze genomes and genetic regulation, we now have a more detailed understanding of the behavioral switch between nurses and foragers in honey bees. It appears that reversible epigenetic control of gene expression ([Chapter 18](#)) plays a role in the nurse/forager switch. If nurse bees are experimentally removed from a bee colony, foragers revert to being nurses, in the process reversing the epigenetic changes that resulted in their previous nurse-to-forager transition.

SOURCE Ben-Shahar, Y., et al. 2002. "Influence of Gene Action Across Different Time Scales on Behavior." *Science* 296:741–744.

Studies of the North American vole, in the genus *Microtus*, have also revealed how genes influence behavior ([Fig. 43.9](#)). The Prairie Vole is monogamous: couples pair-bond for life and mate only with each other. By contrast, the Prairie Vole's close relative, the Montane Vole, is promiscuous: a male mates and moves on, and a female over her lifetime produces litters by several different males. What differences underlie these different behaviors?

Sources: a. Todd Ahern/Quinnipiac University; b. Rick & Nora Bowers/Alamy.

FIG. 43.9 Differing mating behavior in voles. The different behaviors in (a) monogamous Prairie Voles and (b) promiscuous Montane Voles results from variation at a single gene.

Hormones and their receptors provide an answer. In all mammals, antidiuretic hormone (ADH) controls the concentration of urine ([Chapter 39](#)). The receptor for ADH is expressed not only in the kidney, but also in the brain, where it affects behavior. Both the monogamous Prairie Vole and the promiscuous Montane Vole produce ADH, but the hormone receptors in the two species are different. In the 1990s, the American neuroscientist Thomas Insel analyzed and compared the genes that encode the ADH receptor in the two vole species. He found a difference in the region of the gene that determines

under which conditions and in which cells it is expressed. Because of this difference, the distribution of ADH receptors in the brain differs in the Prairie Vole and in the Montane Vole.

Does the difference in gene expression explain the different sexual behaviors of the two species? The answer seems to be yes. Insel and his colleague Larry Young inserted the Prairie Vole's ADH receptor gene, complete with its regulatory region, into a laboratory mouse (a member of a promiscuous species, like the Montane Vole).

Interestingly, Insel and Young observed a marked change in the mouse's behavior. Rather than mating with a female and then moving on to another mate, the transgenic male mouse pair-bonded with the female. In short, the addition of a single gene affected a complex behavior such as pair bonding, making the otherwise promiscuous mouse more likely to pair bond.

#### Self-Assessment Questions

3. What is fixed about a fixed action pattern?
4. Why are feature detectors a key aspect of sensory systems?
5. Why are long-term changes in behavioral state—for example, from sexually immature to mature—typically mediated by hormones?
6. Why is it typically difficult to identify individual genes that govern particular behaviors?
7. Explain, with an example, how crosses between closely related species can help us understand the genetic basis of behavior.

## 43.3 LEARNING

As we have noted, genes are not the only determinants of behavior. We all know that experience often leads to changes in behavior, a process we call **learning**. Humans are extraordinary learners, but we are not alone in this ability. Even many relatively simple organisms respond to experience. Researchers have identified several types of learning. The categories are not strictly delimited, and there is some overlap among them, but they are a useful way to organize our thinking and give us deeper insights into the subject.

### Non-associative learning occurs without linking two events.

**Non-associative learning** is learning that occurs in the absence of any particular outcome, such as a reward or punishment. One type of non-associative learning is **habituation**, the reduction or elimination of a behavioral response to a repeatedly presented stimulus. Chicks presented with silhouettes of predators flying overhead provide an example. Initially, any overhead silhouette provokes a defensive crouching posture, but eventually chicks habituate to overhead silhouettes that have proved to be benign. In the absence of any consequences, chicks no longer crouch in response to a harmless silhouette passing repeatedly overhead.

**Sensitization** is another form of non-associative learning. Sensitization is the enhancement of a response to a stimulus that is achieved by presenting a prior strong or novel stimulus. This initial stimulus makes the animal more alert and responsive to the next

stimulus. The sea slug, *Aplysia*, a model organism among scientists interested in the neuronal basis of behavior, exhibits sensitization. *Aplysia* withdraws its gills in response to a touch on the siphon (the tube through which it draws water over its gills). Interestingly, if the animal is given a weak electric shock first, its response to a touch on its siphon is much more rapid, suggesting that the shock has made the slug more sensitive to later stimuli.

## Associative learning occurs when two events are linked.

**Associative learning** (also called **conditioning**) occurs when an animal learns to link (or associate) two events. Perhaps the most famous example of conditioning is the response of Ivan Pavlov's dogs. In the course of experiments on animal digestion during the 1890s, Pavlov, a Russian physiologist, first presented dogs with meat powder, and they salivated in response. He then presented the dogs with an additional cue, a ringing bell, whenever he presented the dogs with meat powder. After repeatedly experiencing the two stimuli together, the dogs salivated at the sound of the bell alone, in expectation of the meat reward. This form of conditioning, in which two stimuli are paired, is called **classical conditioning**.

A second form of associative learning, which links a behavior with a reward or punishment, is called **operant conditioning**. Operant conditioning involves a novel, undirected behavior that becomes more or less likely over time. If the behavior is rewarded (positively reinforced), it is more likely to occur the next time around. It is not just out of the goodness of her heart that the trainer at Sea World gives a

sea lion or dolphin a fish reward at the end of each trick that the animal performs. In contrast, if behavior is punished (negatively reinforced), the response becomes less likely.

In classical conditioning, an association is made between a stimulus and a behavior, whereas in operant conditioning, an association is made between a behavior and a response. In classical conditioning, one stimulus is exchanged for another (in the case of Pavlov's dogs, the smell of food was exchanged for the sound of a bell). As a result, a novel stimulus evokes a behavior. In operant conditioning, a behavior is associated with a reward or punishment, so the behavior becomes more likely (with a reward) or less likely (with a punishment).

## Learning is an adaptation.

The capacity to learn often has adaptive functions. Much learning, including human learning, is based on [imitation](#), in which one individual copies another. Learning by imitation was famously observed in the days when people in Britain had milk deliveries left outside on the doorstep. As we saw in [Chapter 23](#), a number of birds, including Great Tits and Blue Tits, learned to open foil-topped milk bottles, and this behavior spread rapidly through populations of birds as other birds copied the successful birds' approach. Individuals can also learn by imitating individuals of a different species. An octopus can learn to open a jar with a reward inside by watching a human or another octopus do it.

The capacity to learn a particular task seems in many instances to be innate. Consider female digger wasps, which are foragers. Tinbergen

showed that a digger wasp learns the landmarks around her nest and then uses this information to find her way back to it from hunting. In his experiment, illustrated in [Fig. 43.10](#), Tinbergen placed a ring of pine cones around a wasp's nest and, after she had flown out and returned a few times, moved the circle of pine cones to the side of the nest. The returning wasp then flew past her own nest and went directly to the center of the ring. This innate ability to learn landmarks is adaptive: it improves the survival or reproductive success of the individual.

#### HOW DO WE KNOW?

### FIG. 43.10

## To what extent are insects capable of learning?

#### BACKGROUND

European digger wasps, *Philanthus triangulum*, live in the sand. These wasps are sometimes called “bee wolves” because they hunt honeybees to feed their developing young. After mating, each female digs a long burrow with a few chambers at the end where she lays her eggs. She then forages for honeybees that she brings back to these chambers for her larvae to eat. The wasp faces a navigational challenge: having captured her prey, how can she find her way back to and recognize her nest? As part of his PhD studies in the early 1930s, Niko Tinbergen noticed that wasps lingered briefly near a new nest before heading off to hunt; he hypothesized that they were learning local landmarks associated with the nest.

#### HYPOTHESIS

Wasps learn visual cues around their nests to help locate the nest upon their return.

## METHOD

Tinbergen recognized that a good test of the learning abilities of an insect should take place in its natural environment. He combined his skills as a naturalist and as an experimentalist to devise an elegant demonstration of the way in which female wasps learn landmarks for navigation. He placed a ring of pine cones around the nest of a wasp ([Fig. 43.10a](#)); then, once she had left to hunt, he shifted them to a new location away from the nest entrance ([Fig. 43.10b](#)). If visual cues are key to the wasp's ability to locate the nest, the wasp should return to the displaced pine cone ring. In contrast, if cues are, for example, olfactory, the wasp should return directly to the nest.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

## RESULTS

Female digger wasps carried out a brief landmark-learning flight on departure from the nest. When the landmarks were displaced, the females returned to the wrong location ([Fig. 43.10b](#)).

## CONCLUSION

Female digger wasps learn and use local landmarks, such as the experimental ring of pine cones, as cues to the nest location.

SOURCE Tinbergen, N. 1958. *Curious Naturalists*. New York: Basic Books.

This adaptive aspect of animal learning is also revealed by taste aversion experiments, in which an animal typically learns to avoid certain flavors associated with a negative outcome. Rats learn to avoid flavored water if consuming it is associated with nausea. However, they do *not* learn to avoid flavored water if it is associated with a different kind of negative reinforcement, such as a mild electric shock. This result indicates that rats can make some associations, but not others. The ones they can learn are the biologically meaningful ones, those that favor survival. In the course of evolution, the rat's ancestors encountered poisoned food that resulted in nausea and the aversion response evolved. Until humans started doing experiments on them, however, rats had never encountered a meal that resulted in an electric shock. It is not surprising, then, that the ability to pair these two phenomena never evolved. These experiments also show that the specific evolutionary history of the species in question matters when analyzing animal behavior.

In addition to adaptive predispositions for *what* can be learned and not learned, many species exhibit predispositions for *when* learning

takes place. This is particularly evident in imprinting, a form of learning typically seen in young animals in which they acquire a certain behavior in response to key experiences during a critical period of development. In 1935, Austrian ethologist Konrad Lorenz made imprinting famous by exploiting the observation that newly hatched goslings and ducklings rapidly learn to treat any sufficiently large moving object they happen to see shortly after hatching as their mother. Lorenz found that, if he was the first person the hatchlings saw, they would follow him as though he were their mother ([Fig. 43.11](#)).

Sources: a. Nina Leen/Time Life Pictures/Getty Images; b. Jeffrey Phelps/Getty Images.

FIG. 43.11 Imprinting on (a) Konrad Lorenz and (b) an ultralight aircraft. By manipulating newly hatched birds' first sight of a moving object, it is possible to induce powerful attachments in the birds.

This behavior is adaptive because the first being that a hatchling usually sees is a parent; the resulting close parent–offspring association ensures that the parent can provide care and protection. This [filial imprinting](#) is most common in bird species whose offspring leave the nest and walk around while still young, such as ducklings. By comparison, filial imprinting is rare in species of birds whose young stay in the nest until they are able to fly away.

Experiments have shown that filial imprinting typically occurs during a specific, sensitive period in the animal's life and that the results are usually irreversible. After Lorenz's baby ducks had imprinted on him, they would not change their minds about who their parent was even when presented with their real mother duck. The timing of the sensitive period varies from species to species. In some cliff-nesting sea birds, imprinting on auditory stimuli (such as the call of the parents) begins while the chick is still in the egg.

#### Self-Assessment Questions

8. Both classical and operant conditioning involve learning to associate two events. How do the two kinds of conditioning differ?
9. Distinguish between associative and non-associative learning, and provide an example of each form of learning.
10. What is the adaptive value of imprinting in goslings?

## 43.4 INFORMATION PROCESSING

Learning is a form of information processing in which experience shapes behavior. At a cellular level, learning typically involves a change in the strength of connections between neurons. The central nervous system of even relatively simple animals is capable of extraordinary feats of information processing. The ways in which animals' nervous and endocrine systems and the input of experience are integrated to generate adaptive behaviors are remarkable. Some of these adaptive behaviors include ways of moving, navigating, and keeping time, which we examine in this section.

### Orientation involves a directed response to a stimulus.

Even the simplest bacteria and protozoa are capable of moving in response to stimuli. A *Paramecium* that finds itself in an unfavorable environment, such as water that is too warm or too salty, increases its speed and begins to make random turns. When it encounters favorable conditions, such as cooler water, it slows and reduces its turning rate. These random, undirected movements are termed [kineses](#) (singular, [kinesis](#)).

In contrast, [taxes](#) (singular, [taxis](#)) are movements in a specific direction in response to a stimulus. An interesting example of a taxis is movement oriented to a magnetic field. In 1975, American microbiologist Richard Blakemore was the first to use the term *magnetotaxis* to describe this behavior. Blakemore found that

anaerobic bacteria in the genus *Aquaspirillum*, which swim by means of flagella, tend to swim toward magnetic north. These bacteria can be attracted to the side of a dish with a bar magnet. Little bits of magnetized iron oxide, arranged in a row inside the *Aquaspirillum* bacterial cell, allow the bacteria to sense the magnetic field. Blakemore hypothesized that the bacteria swim north in an effort to swim deeper. In the Northern Hemisphere, the north magnetic pole is inclined downward. At Woods Hole, Massachusetts, where these bacteria were found, the magnetic pole is at approximately a 70-degree incline. *Aquaspirillum* are anaerobic and must stay buried in sediment to survive; the bacteria remain buried by moving downward along the magnetic gradient.

To test his hypothesis, Blakemore looked for and found bacteria in New Zealand that exhibited similar behavior to the Woods Hole bacteria, except that they swam toward the *south* magnetic pole, bringing them downward in the Southern Hemisphere. Finally, he took New Zealand cultures back to Woods Hole, where the bacteria responded inappropriately to the unfamiliar magnetic field of the Northern Hemisphere, swimming up into the oxygen and dying. These experiments demonstrated that bacteria are able to sense a magnetic field and move in a directed fashion relative to that field.

## Navigation is demonstrated by the remarkable ability of homing in birds.

Many animals use environmental cues to migrate long distances. The navigational achievements of homing pigeons are legendary. They can home—that is, find their way back to the place where they are housed

and fed—over extremely long distances, even of more than a thousand miles. These pigeons use a wealth of cues when homing. A compass may tell you which way is north, but you also need [map information](#)—which tells you where you are with respect to your goal—if the compass is to be useful for finding a particular location. Homing pigeons, therefore, must have both compass and map senses. That map sense is presumably based on landmarks. Given the long distances for which the pigeons travel, these landmarks must vary in their type and probably include olfactory as well as visual cues.

The pigeon compass relies on different kinds of information. For example, pigeons can navigate during the day using the sun as a compass, and at night using the stars. And, like *Aquaspirillum*, pigeons can detect Earth's magnetic field. This magnetic navigation system may be important to pigeons on cloudy days. Researchers have performed experiments with pigeons wearing magnetic helmets, which disrupt the birds' ability to detect Earth's magnetic field. On cloudy days, the pigeons wearing the helmets are unable to navigate home. On sunny days, however, the pigeons' sun compass overrides the erroneous magnetic information of the helmets.

The sun compass requires information about time as well. Every hour, the sun moves  $360/24 = 15$  degrees through the sky. To determine where north is, a pigeon needs information from the sun as well as some way to keep time. It turns out that pigeons have a clock—a biological one.

## Biological clocks provide important

## time cues for many behaviors.

Like us, other animals live in space *and* time. For many species, time is a life-or-death matter. When to migrate or mate is a critical decision in a seasonal environment. Researchers are beginning to unravel the neural and genetic underpinnings of the clocks in some species. In model organisms such as *Drosophila*, for example, researchers have identified a number of genes that, when mutated, cause the organism's biological clocks to run slow or fast.

A biological clock is produced by a set of interacting proteins that cycles on its own to provide a regular rhythm. Different clocks work on different timescales. Daily cycles are governed by a [circadian clock](#). Circadian clocks regulate many daily rhythms in animals, such as those of feeding, sleeping, hormone production, and core body temperature. Some species, especially seacoast species living in habitats where the tides are important, time their activities by a [lunar](#) (moon-based) [clock](#). There are also [annual](#) (yearly) [clocks](#). For example, periodical cicadas are insects in the genus *Magicicada* that have a generation time of either 13 or 17 years: in a given location, a cicada outbreak occurs every 13 or 17 years.

Circadian clocks are observed in many organisms, including plants, fungi, and animals. Humans also have circadian clocks, as jet lag never fails to remind us. The circadian clock is based on a set of “clock genes” whose protein products oscillate through a series of feedback loops in a roughly 24-hour cycle. Thus, when animals that, like humans, are active during the day and inactive at night are placed in artificial conditions that are always lit, they continue to follow a basic

day–night, active–inactive cycle. The clocks are not perfect, though: as the period spent in constant light is prolonged, the circadian clock drifts slowly until the animal is eventually no longer synchronized with the true day–night cycle.

Biological clocks remain synchronized with the day–night cycle because they are often reset by external inputs. For the circadian clock, light is the primary input. The natural light–dark cycle keeps the clock from drifting. For clocks related to the seasons, day length (known as **photoperiod**) is the critical input because it serves as a good indicator of the time of the year ([Chapter 28](#)). For example, many mammals produce their offspring in the spring so that they can grow over the summer, when resources are most abundant. The ability to synchronize reproduction to a time when young have the greatest chance of survival has been selected for over many generations. Photoperiod governs the timing of many kinds of behaviors, including migration, development, and reproduction.

The importance of the sun compass coupled with the biological clock in homing pigeons can be demonstrated by experimentally disturbing the birds' clock, as shown in [Fig. 43.12](#).

#### HOW DO WE KNOW?

### FIG. 43.12

Does a biological clock play a role in birds' ability to orient?

#### BACKGROUND

One suggestion for how pigeons home is that they use a sun compass. A

sun compass requires information about time as well as direction. For example, if you are in the Northern Hemisphere and the time is 12 noon, then the sun is due south of you. But orienting yourself by this method is possible only if you know the time, so the question arises as to whether homing birds have the ability to tell the time. One way to answer this question is to “clockshift” the birds. That is, researchers can raise birds in an artificial day–night cycle that is out of sync with the actual one. In this way, the birds’ sense of time can be shifted by a set number of hours.

| Event             | Dawn    | Dusk        |
|-------------------|---------|-------------|
| Actual time       | 6 am    | 6 pm        |
| Clockshifted time | 12 noon | 12 midnight |

#### HYPOTHESIS

If a bird’s ability to home is dependent on an internal clock, clockshifting should affect the bird’s homing ability in a predictable way. Given that the sun travels 360 degrees in 24 hours, a 6-hour clockshift will result in a 90-degree error in homing direction because  $360/(24/6) = 90$ .

#### EXPERIMENT

In 1969, American biologist William Keeton clockshifted pigeons by raising them in a chamber under an artificial light. Two groups of birds, one clockshifted and one not, from Ithaca, New York, were released on a sunny day at Marathon, New York, approximately 30 km east of Ithaca. Release on a sunny day made it possible for the birds to use the sun’s position to navigate.

#### RESULTS

As expected, the control birds (those that were not clockshifted) were usually good at picking the direction of their home loft, heading approximately westward toward Ithaca. A minority did fly in the wrong the direction, suggesting that other factors sometimes override a pigeon’s clock-based sense of direction. The clockshifted birds, in contrast to the

non-clockshifted ones, miscalculated the appropriate direction more consistently, tending to head northward, as shown by the positions of the red triangles on the compass in the figure.

#### INTERPRETATION

Assume the birds are released at 12 noon, when the sun is due south. The control birds know to fly in a direction 90 degrees clockwise from the direction of the sun, but the clockshifted birds “think” it is 6 p.m., so they expect the sun to be in the west. Their 90-degree clockwise correction results in them flying due north.

#### CONCLUSION

The clear difference between control and clockshifted birds in this experiment shows that an internal time-based sun compass is an important component of the birds’ homing abilities. However, the scatter of points

(for both the experiment and control groups) suggests that other factors are important as well. This conclusion is reinforced by the observation that birds home well on cloudy days, when they cannot use a sun compass, suggesting that birds use multiple cues and navigational systems when they are homing.

SOURCE Keeton, W. T. 1969. "Orientation by Pigeons: Is the Sun Necessary?" *Science* 165:922–928.

#### Self-Assessment Questions

11. Differentiate between a kinesis and a taxis.
12. Why is photoperiod a widely used time cue?
13. Animals that migrate over long distances using the sun for directional information typically also have the ability to estimate the time of day. Why?

## 43.5 COMMUNICATION

Up to this point, this chapter has focused on individual behaviors. Behaviors often depend on environmental cues, as we saw with the examples of navigation and keeping time. In addition, behaviors are often shaped by interactions with other individuals. Learning sometimes depends on communication between a teacher and student, and, as anyone knows who has ever watched birds tending their young, communication is central to parenting.

**Communication is the transfer of information between a sender and a receiver.**

The sophistication of animal communication varies enormously, as can be seen by the various types of signal illustrated in [Fig. 43.13](#). Even our closest relatives, the chimpanzees, cannot rival the human facility with language, but a number of species have evolved forms of communication that convey remarkably complex and specific information. For example, a Vervet Monkey that perceives a threat to its group utters an alarm call that not only warns of a threat, but actually specifies the nature of the threat—whether it is a hawk, leopard, snake, or some other type of predator.

Sources: a. DWI YULIANTO/Shutterstock; b. Nataba/Getty Images; c. © Matthew E. Arnegard; d. Dan L. Perlman/EcoLibrary.org; e. Ron Rowan Photography/Shutterstock.

FIG. 43.13 Types of signals in different forms of communications. Signals can be (a) visual, as in frilled lizard's threat display; (b) auditory, such as bird song; (c) electrical, as in the species-specific electric pulses emitted by African electric fish; (d) chemical, such as the pheromones with which a queen termite controls her colony; and (e) mechanical, as when spiders "twang" webs to interact.

The simplest definition of **communication** is the transfer of information between two individuals, the **sender** and the **receiver**. The sender supplies a signal that elicits a response from the receiver. For example, the bright petals of a flower signal to an insect that nectar and pollen are available. This definition, however, has its problems. An owl hears the rustling of a mouse and responds accordingly. Most people would agree that the owl is not really communicating with the mouse, or vice versa. For this reason, some biologists prefer to define communication as a transfer of information between two individuals in which the sender attempts to manipulate in some way the behavior of the receiver.

How has communication evolved? Some communication may have

evolved through co-opting and modifying behaviors used in another context. This process, called [ritualization](#), involves (1) increasing the conspicuousness of the behavior, (2) reducing the amount of variation in the behavior so that it can be immediately recognized, and (3) increasing the separation of the behavior from its original function. The scent markings with which mammals mark their territory provide an example. The original function was simply the elimination of waste, but this function has been modified through evolution: strategically placed marks communicate with other individuals, indicating, for example, the extent of an individual's territory. The communication advantage is that an intruder detecting a territorial scent may be less likely to invade, thereby avoiding a potentially dangerous fight.

Many forms of communication have evolved that prevent animals from coming to harm through a "limited-war strategy." Instead of battling it out, two males may engage in elaborate displays to size each other up, either literally by standing side by side or through displays of physical prowess such as roaring, in an attempt to determine who is dominant. Fighting would be disadvantageous to both because even the winner might be seriously injured. In this case, communication may have evolved as a way for individuals to assess one another.

In some cases, communication in the natural world can be deceitful. A male may attempt to convince other males (or a female) that he is bigger (and stronger) than he really is. Possibly one reason why dogs circling in a fight raise the hair along their backs is to inflate their apparent size. A potential prey may attempt to convince a predator that it is not, in fact, prey. This form of deceit is especially evident in some

species of butterfly that mimic leaves or bark when their wings are at rest. Alternatively, predators may emit deceitful signals to entice their prey. Females of one species of firefly, for instance, mimic the flashes of the females of another species in an effort to lure males of the second species, which they then eat.

## Some forms of communication are complex and learned during a sensitive period.

Bird song is one of the best-known and richest forms of animal communication. Because of the clear connection between what birds hear and how they respond, songbirds often serve as a model system in the study of learning and communication. Bird songs are complex sequences of sounds, often repeated over and over. Like cricket and frog calls, bird songs are [advertisement displays](#), behaviors by which individuals draw attention to their status. For example, the displays might indicate that the birds are sexually available or are holding territory. Bird songs are typically produced by males during the breeding season.

This sex difference in patterns of communication often results from intersexual selection ([Chapter 20](#)), and can extend to other traits. For example, male birds usually have bright plumage and elaborate displays, and females do not. Why do we see such differences between males and females? The key is the level of investment that an individual makes in an offspring. The eggs a female bird produces are metabolically expensive, whereas the sperm a male bird produces are

metabolically cheap. Because of this and other costs associated with reproduction, a female typically has only one opportunity or just a few opportunities to reproduce. Given this reality, it is in her best interest to ensure that she has chosen a high-quality male, one that sings well or has especially fine plumage. By contrast, it is in the male's interest to maximize his access to females—that is, to be as sexually attractive as possible. Sexual selection therefore tends to produce showy, attractive males and females that choose males on the basis of their performance or appearance.

In many species of birds that sing, some or all of the song is learned, often during a specific, sensitive period. Detailed studies of the White-Crowned Sparrow, shown in [Fig. 43.14](#), pioneered in the 1960s by neurobiologist and ethologist Peter Marler, and extended by Luis Baptista, have yielded the following general picture of the process.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 After T. J. Carew, 2000, *Behavioral Neurobiology*, Sunderland, MA: Sinauer Associates, p. 244; Photo source: Paul Sutherland/  
 Getty Images.

FIG. 43.14 Song acquisition in the White-Crowned Sparrow. A sonogram shows differences between the unstructured twittering of early life and the final, structured song.

Song in White-Crowned Sparrows is learned by imprinting: the young male hears adult song during a sensitive period, 10 to 50 days after hatching. Shortly after this period, young male White-Crowned

Sparrows produce unstructured twittering sounds, known as a subsong, comparable to the babbling of human babies. If deprived of hearing adult song, perhaps because of isolation during the sensitive period, the bird sings for the rest of his life a song not much different from unstructured twittering, even if he hears another male sing both before and after the sensitive period.

Between about 250 and 300 days, the male sings an imperfect copy of the song (known as plastic song). By about 300 to 350 days after hatching, song acquisition is complete (this song is known as structured song). At this point, even if the bird is deafened in the lab, he will still sing correctly. The song he produces is typically a precise copy of the male's song he heard during the sensitive period, complete with most of its individual as well as species-specific characteristics.

White-Crowned Sparrows, then, have a programmed predisposition for *when* song learning takes place. Even more interesting, *what* can be learned is similarly constrained. If a tape of another species' song is played during the sensitive period, even the song of closely related Swamp Sparrows, the White-Crowned Sparrow male cannot learn that song; his adult song ends up not much different from unstructured twittering. However, if he is provided with a live tutor, such as a live male Swamp Sparrow rather than a tape, his ability to learn the other bird's songs is greatly improved. Furthermore, if he hears tapes of the song of his own species and that of a closely related species played together, he can pick out the correct elements specific to his own species and sing a perfect White-Crowned Sparrow song. Thus, birds of this species preferentially learn their species-specific song, but they

cannot sing a normal song without learning it from another member of their own species.

Song learning in White-Crowned Sparrows has been well studied, and provides just one example of song learning in birds. Some species, such as mockingbirds, starlings, and canaries, learn a wider range of songs than do White-Crowned Sparrows, and have a longer period of song learning, in some cases probably lifelong. By contrast, other species, such as many New World flycatchers, apparently have hard-wired (innate) songs: they produce the appropriate song even if raised in isolation from other birds. Researchers are just beginning to decode and understand other sound-based forms of communication, such as those produced by dolphins and whales.

## Various forms of communication can convey specific information.

Honeybees have an elaborate means of communication that is quite different from the sound-based communication of birds. Bees travel far and wide to forage for food for their hive and, upon returning home, use a variety of cues to inform outgoing foragers about the location and nature of the food resources they have found.

Returning worker bees pass samples of the collected food to other workers that gather around the foragers when they return to the hive. The returning foragers begin a series of movements in specific patterns that encode information about the direction and distance of food sources. This dance language of honeybees was originally discovered by Karl von Frisch in the 1920s.

If the food source is more than about 50 m away, the incoming forager does a waggle dance ([Fig. 43.15](#)). The forager moves quickly back and forth (“waggles”) as it moves forward, circles back and repeats the waggle, and then circles back the other way, and so on. This dance usually goes on for several minutes and may take much longer. The distance to the food source is conveyed by the length of time it takes to waggle up the middle of the circle. The direction, with reference to the position of the sun, is conveyed by the angle of the line of the waggle run: if the food source is in a direct line with the sun, the dancer’s waggle line points straight up; if the food is at an angle of 45 degrees to the left of the sun, the dancer’s line is 45 degrees to the left of vertical. The bees’ dance language is among the natural world’s most extraordinary and effective methods of communication.

The distance to the food source is communicated by the length of time it takes to move up the middle of the circle (the "waggle").

The direction of the food source relative to the sun is communicated by the angle of the waggle run relative to vertical.

FIG. 43.15 The waggle dance of honeybees. This form of communication provides information to other foragers about the distance to and direction of a food source.

#### Self-Assessment Questions

14. Explain why many biologists do not consider just any transfer of information between a sender and a receiver to be a form of communication.

15. Why do we hear regional “dialects” in the songs of some bird species but not in the songs of other species?

## 43.6 SOCIAL BEHAVIOR

Returning to Tinbergen's four questions, we can consider further the adaptive function and evolutionary history of animal behavior. The evolutionary advantages of most behaviors are readily apparent. The imprinting of Lorenz's goslings on the first moving object they encountered makes sense when you consider that this object is usually a parent (not Konrad Lorenz!) and that sticking close to a parent is an excellent survival strategy in a world filled with predators.

Social behaviors also have evolutionary advantages. Consider the cooperative hunting seen in killer whales. Killer whales participate in a behavior called wave washing, in which a pod of whales collectively creates waves to wash a prey species—typically a seal—off an iceberg ([Fig. 43.16](#)). By itself, a single killer whale is incapable of generating a big enough wave to dislodge the prey. Through cooperation, however, an individual can contribute to prey capture and gain some portion of the prey. This behavior is collaborative, and it is clear why each individual participates.

Sources: (top) John Durban/NOAA; (bottom) R. Pitman/NOAA SWFSC.

FIG. 43.16 Mutually beneficial cooperation. Killer whales cooperate to create a wave to wash prey off an iceberg.

Sometimes how a behavior enhances survival and reproduction is less clear. Perhaps the most prominent examples of this kind of behavior are sacrifices made by individuals apparently for the good of others. Formally, we describe an act of self-sacrifice that helps another as **altruistic**. Such acts seem to fly in the face of natural selection, which selects for traits that increase fitness and selects against traits that decrease fitness. Altruistic acts, by definition, decrease fitness and therefore should be selected against. This contradiction is particularly stark in the case of species like honeybees: honeybee workers, which

are females, do not reproduce but instead assist the reproduction of the queen. Darwin confessed that such behaviors caused him sleepless nights. How, Darwin wondered, could altruism arise?

## Group selection is a weak explanation of altruistic behavior.

Darwin eventually suggested a solution to the altruism problem that today we call **group selection**. The idea is that natural selection operating on individuals is a less powerful force than another form of selection that operates on groups. Consider two groups: in one group, individuals demonstrate altruism, helping one another out; in the other group, individuals act entirely selfishly. Darwin argued that, in a conflict between the two groups, the first group would defeat the second because the first group works better as a unit. In this example, selection in favor of altruism benefits the group and trumps selection in favor of selfish behavior.

Although an attractive idea, group selection is probably not important in the evolution of altruism. Altruism under group selection is typically not an **evolutionarily stable strategy**, meaning that this kind of behavior can be readily driven to extinction by an alternative strategy. As an example, consider lemmings, a species of Scandinavian rodent. It was once thought lemmings committed mass suicide by plunging into the ocean when the population became too large to sustain. This self-sacrificial, altruistic act would ensure that the population did not crash after exhausting available resources. This is an appealing story, but untrue. Lemmings do not actually commit suicide; they take to the water to swim to new territories during migration.

We can also see the evolutionary logic prohibiting the evolution of such altruistic behavior. An individual that “cheats” by not performing the altruistic act will survive and breed, and its altruistic companions will not. Now consider that this lemming behavior—to kill oneself or not—is genetically encoded. A mutation that arises in a lemming population that causes the individual to “cheat” and not kill itself will spread rapidly through the population by natural selection until, after many generations, it will completely replace the altruistic allele that causes the individual to kill itself. The altruistic lemming behavior, then, is not an evolutionarily stable strategy because natural selection favors an alternative strategy.

This description is oversimplified because such traits are unlikely to have a simple genetic basis, but the point stands: group selection is in general not an evolutionarily stable strategy because it can readily be outcompeted by “selfish” strategies.

## Reciprocal altruism is one way that altruism can evolve.

If group selection does not provide a strong explanation for the evolution of altruism, how can we explain altruistic behavior?

**Reciprocal altruism**, whereby individuals exchange favors, is one way that altruism can evolve. This idea is perhaps best summarized as “You scratch my back, and I’ll scratch yours.” For this kind of behavior to work, individuals must be able to recognize each other and remember previous interactions. In other words, if I did you a favor, I need to be able to recall who you are so that I can be sure I get the expected return.

A famous example of reciprocal altruism comes from vampire bats. Adult female vampire bats live in groups of 8 to 12, and often remain in these groups for years. In one study, two tagged females shared the same roost for 12 years. The female groups are occasionally joined by unrelated females, so not all of the bats are closely related. Because they have long-term associations, there is opportunity for reciprocal interactions.

Feeding for these bats is a “boom or bust” activity: either a bat has found and successfully fed on a blood source (boom), or a bat has failed to feed (bust). As a result, bats are often either overfed or underfed. Underfed bats are at risk of dying by starvation. Bats returning from a successful feeding expedition often regurgitate blood to unsuccessful ones. In turn, they will benefit on future occasions when they have been unsuccessful in the hunt for food, when those they have fed in the past have food to spare.

**Kin selection is based on the idea that it is possible to contribute genetically to future generations by helping close relatives.**

In the 1960s, researchers explored the idea that the relatedness of participating individuals plays an important role in the evolution of altruism. The key insight here is that there are at least two ways to contribute genetically to the next generation: either an individual can produce its own offspring, or it can produce no offspring and help close relatives reproduce instead. The latter strategy can become

established in a population through a process called [kin selection](#), a form of natural selection that favors the spread of alleles that promote behaviors that help close relatives (kin).

What relationships qualify as kin? Consider the family depicted in [Fig. 43.17](#). One animal (indicated by gray shading in the figure) has an allele *A* at a particular locus. If the animal reproduces, the probability of each offspring inheriting an *A* allele is 0.5. But what if the animal does not reproduce? According to Mendel's laws, there is a 50% chance that the animal's parents passed on the same *A* allele to the animal's sibling ([Chapter 15](#)). If the sibling does, in fact, inherit allele *A*, the probability that it passes allele *A* to each of its offspring is also 0.5. Given the two probabilities (that the sibling has an *A*, and that the allele passed on to an offspring), the probability that the animal's niece or nephew has *A* is 0.25. In other words, a diploid animal (such as humans) is twice as closely related to its own offspring as it is to its nephew or niece. Therefore, if the animal does not have its own offspring but instead helps its sibling have two offspring, the animal will make the same net genetic contribution to the next generation as it would by having one of its own offspring.

FIG. 43.17 Computing relatedness. One individual's relatedness ( $r$ ) to another individual is the probability that one shares, through inheritance, a given segment of DNA with that individual. In this illustration, relatedness is calculated with reference to the individual shown on the gray background.

This logic was formalized in 1964 in a famous paper by British evolutionary biologist William D. Hamilton. Hamilton defined three key variables:  $B$ , the benefit of the behavior to the recipient (how many individuals does the behavior save?);  $C$ , the cost of the behavior to the donor (how many offspring are lost?); and  $r$ , the degree of relatedness between the recipient and donor. Hamilton asserted that as long as  $rB$  exceeds  $C$ , altruism can evolve.

How does kin selection work in practice? Let's start with an extreme case of relatedness: clonal organisms that are genetically

identical to each other (meaning that the probability of a sibling having allele *A* is 1 or 100%). Many aphid species have a phase of their life cycle in which a “mother” aphid reproduces parthenogenetically to produce a small colony of clones of herself ([Chapter 40](#)). Any aphid in the colony is capable of reproducing in this way, but, in a case of reproductive altruism, some individuals do not reproduce at all. These “soldier” aphids instead defend the colony against predators, typically other insects. As specialized defenders, they are unable to reproduce. In this case, the Hamilton calculation is straightforward. By helping their clone-mates survive, the sterile soldier aphids are ensuring that their own genes survive to be passed on to the next generation.

The most famous cases of reproductive altruism occur in the insect group Hymenoptera, which includes ants, bees, and wasps. Many species of Hymenoptera are [eusocial](#), meaning that they have overlapping generations in a nest, provide cooperative care of the young, and feature clear and consistent division of labor between reproducers (the queen of a honeybee colony) and nonreproducers (the workers). Often called social insects, these species are one of evolution’s most extraordinary success stories.

Which features of Hymenoptera predisposed these insects to eusociality? Ant expert E. O. Wilson argues that natural selection has strongly favored group behavior in these insects through the group benefits derived from living in and defending a nest. For example, they can easily communicate with one another about the location of food resources such as nectar.

William Hamilton also noted that most Hymenoptera have an unusual mode of sex determination (called haplodiploidy): females (the queen and workers) are diploid, whereas males (drones) are haploid, produced from unfertilized eggs. As a result, the degree of relatedness,  $r$ , is higher for the sister–sister relationship (0.75) than for the mother–daughter one (0.5), as shown in [Fig. 43.18](#). Put another way, a haplodiploid female is more closely related to her sister than she is to her daughter. Therefore, it makes more evolutionary sense, in terms of genetic representation in the next generation, for a haplodiploid worker to help her mother, the queen, to produce more sisters than for her to produce her own offspring.

FIG. 43.18 Relatedness in haplodiploid insects, such as ants. Sisters are more related to each other (0.75) than they would be to their own offspring (0.5) if they

could reproduce.

This form of social organization can result in a huge colony of related individuals all working collectively, much as different cells work collectively within a body. Often members of these colonies specialize into castes: some ants are soldiers, defending the colony; others are foragers; and so on. If we extend the analogy of individuals acting like cells in a body, the multiple castes are equivalent to organs, all coordinating and working together. The term “superorganism” is sometimes used to describe a single social insect colony.

Some species are eusocial but not haplodiploid, including the naked mole rat ([Fig. 43.19a](#)). These examples suggest that, while haplodiploidy may predispose a species to eusociality, it is not required.

Photos source: a. Joel Sartore/Getty Images, b. Alamy Stock Photo.

FIG. 43.19 Social behavior in non-insects. (a) Naked mole rats are eusocial but not haplodiploid. (b) Florida Scrub Jays display altruistic behavior but are not eusocial.

Other species display altruistic behavior toward close relatives, as

predicted by Hamilton, but are not as extreme in their social behavior as eusocial species. Florida Scrub Jays ([Fig. 43.19b](#)) live in habitats that lack enough territories for all adult birds. As a result, the offspring of a breeding pair on a territory may remain in that territory and help its parents raise more young. If a young bird were to strike out on its own, it would likely fail to reproduce, so, in terms of making a genetic contribution to the next generation, it is better to help its parents raise more siblings.

#### Self-Assessment Questions

16. It's sometimes said that an animal does something "for the good of the species." Why is this argument incorrect?
17. Reciprocal altruism is unlikely to evolve in species with short life-spans. Why?
18. Describe how an altruistic behavior might evolve by kin selection.
19. How many cousins are genetically equivalent to a single offspring?

## CORE CONCEPTS SUMMARY

**43.1 TINBERGEN'S QUESTIONS:** For any behavior, we can ask what adaptive function it serves, what causes it, how it develops, and how it evolved.

Tinbergen suggested that we ask questions about animal behavior at four different levels of analysis, focusing on function, cause, development, and evolution. [page 979](#)

Tinbergen's four questions have different answers, and all may be correct explanations of the behavior. [page 980](#)

Behavior can be innate (carried out in the absence of experience) or learned (dependent on experience). [page 980](#)

**43.2 DISSECTING BEHAVIOR:** Animal behavior is shaped in part by genes acting through the nervous and endocrine systems.

Most behavior is produced by the interaction between genes (nature) and environment (nurture). [page 981](#)

A fixed action pattern is a stereotyped sequence of behaviors that, once initiated by a key stimulus, always goes to completion. [page 981](#)

Stimuli are recognized by feature detectors, which are specialized sensory receptors of the nervous system. [page 981](#)

Hormones can affect behavior through their wide-ranging and often long-term effects on multiple body systems. [page 982](#)

The extent to which genes influence a behavior can be determined

by crossing closely related species having different behaviors and analyzing the behavior of the offspring. [page 984](#)

Most behaviors are influenced by many genes, but a few are strongly influenced by a single gene. [page 984](#)

Molecular studies are providing new ways to understand the role of genes in behavior in laboratory animals. [page 984](#)

**43.3 LEARNING:** Learning is a change of behavior as a result of experience.

Non-associative learning is a form of learning that occurs without linking two events. [page 987](#)

Habituation, a form of non-associative learning, is the reduction or elimination of a response to a repeated stimulus. [page 987](#)

Sensitization, another form of non-associative learning, is the enhancement of a response to a stimulus that follows a priming stimulus. [page 987](#)

Associative learning occurs when an animal learns to link two separate events. [page 987](#)

Classical conditioning is a form of associative learning in which a novel association is made between a formerly neutral stimulus and a behavior. [page 987](#)

Operant conditioning is a form of associative learning in which rewarding or punishing a behavior makes that behavior more likely or less likely to occur, respectively. [page 987](#)

Imitation and imprinting are forms of learning. [page 988](#)

**43.4 INFORMATION PROCESSING:** Orientation, navigation, and biological clocks all require information processing.

Kineses are undirected movements, whereas taxes are directed movements. [page 989](#)

Long-distance navigation may require the processing of many external cues, including the position of the sun, Earth's magnetic field, and information about time. [page 990](#)

Biological clocks control some physiological and behavioral aspects of animal activity. [page 990](#)

**43.5 COMMUNICATION:** Communication involves an interaction between a sender and a receiver.

Communication is an interaction between two individuals, the sender and the receiver, and often involves attempts by the sender to manipulate the behavior of the receiver. [page 992](#)

Communication can evolve by the modification of noncommunicative aspects of an animal's behavior. [page 992](#)

Bird song is a rich form of communication that is often learned during a sensitive period. Acquisition of bird song proceeds through distinct stages. [page 993](#)

The dance language of honeybees communicates information about the location and direction of a food source. [page 994](#)

**43.6 SOCIAL BEHAVIOR:** Social behavior is shaped by natural

selection.

One of the most perplexing behaviors from the standpoint of natural selection is altruism, in which an organism reduces its own fitness by acts that benefit others. [page 995](#)

Group selection is the idea that altruistic behaviors can evolve if they benefit the group, not the individual; this idea is not widely accepted. [page 995](#)

Reciprocal altruism requires that individuals interact regularly and remember each other so that they can “pay back” past favors. [page 995](#)

Kin selection is the concept that altruistic behaviors can evolve if they benefit close relatives. [page 996](#)

## Chapter 44 Population Ecology

Eladio M. Fernandez

---

### CORE CONCEPTS

**44.1 POPULATIONS AND THEIR PROPERTIES:** A population consists of all of the individuals of a given species that live and reproduce in a particular place and time.

**44.2 POPULATION GROWTH AND DECLINE:** Population size can respond to changes in the physical and biological environment.

**44.3 AGE-STRUCTURED POPULATION GROWTH:** The age structure of a population helps ecologists understand past changes and predict future changes in population size.

**44.4 METAPOPULATION DYNAMICS:** The dynamics of populations are influenced by the colonization and extinction of smaller, interconnected populations that make up a metapopulation.

---

In 2004, undergraduates on a field trip to the Dominican Republic, on the island of Hispaniola, swept up an unfamiliar black-and-white butterfly in their nets. That butterfly was a Lime Swallowtail (*Papilio demoleus*), which is native to Asia. The students' specimen was the very first of this species to be captured in the New World.

Soon, the Lime Swallowtail spread to all corners of Hispaniola. This species posed a serious concern on the island because their caterpillars strip the leaves off young lime and orange trees. Within three years, the Lime Swallowtail had also established itself in nearby Puerto Rico and Jamaica, and it has now reached Cuba. From there, it is just a short flight to Florida and the multibillion-dollar citrus industry of the United States. Can we enlist basic principles of biology to help understand this butterfly's Caribbean expansion and predict its future as it continues to spread?

**Ecology** is the study of the relationships of organisms to one another and to the environment. Ecological relationships sustain a flow of energy and materials from the sun, Earth, oceans, and atmosphere

through organisms, with carbon and other elements eventually returning to the environment. It is these interactions that determine the shifting ranges of Lime Swallowtails, as well as all species on Earth.

In previous chapters, we discussed the anatomical, physiological, reproductive, and behavioral characteristics of organisms. These attributes are the products of evolution, and they determine the ways in which individual organisms interact with their physical and biological environment. Physical, or [abiotic](#), factors are nonliving aspects of the environment that affect organisms, such as temperature, water, nutrients, and toxins. Biological, or [biotic](#), factors are living organisms, including competitors, predators, parasites, and prey, as well as organisms that provide shelter or food.

Ecology and evolution are closely intertwined. In the following chapters, we develop the ideas of ecology in the context of interactions between members of the same and different species, and we explore the different strategies species can follow that maximize their survival and reproduction in their environment. We trace the processes that govern interactions from the evolved traits of individual organisms to continent-spanning patterns of diversity and biomes.

## 44.1 POPULATIONS AND THEIR PROPERTIES

When the first U.S. census was completed in 1790, the British scholar Thomas Malthus supposed that the remarkable growth of the American population, which had doubled in the previous 25 years, was a consequence of ample food supply and the active encouragement of marriages. In his 1798 book *An Essay on the Principle of Population*, Malthus argued that a similar periodic doubling of population in the British Isles would outstrip the more slowly increasing food supply in 50 years and lead to starvation. That is, increasing the number of births per year would eventually result in an increased number of deaths because the amount of food the land could produce was limited. This view of the human condition influenced the thinking of Charles Darwin, who as an inquisitive scholar read the most exciting works of the day. Darwin realized that the tension between population growth and resource limitation applies to all species, leading to a struggle for existence among and within species that results in adaptations that enhance survival ([Chapter 20](#)).

**A population includes all the individuals of a species in a particular place.**

In [Chapter 20](#), we introduced the concept of population as a fundamental unit of evolution: it is populations, not individuals, that evolve. In this chapter, we return to populations, this time as fundamental units of ecology. A population is all the individuals of a

given species that live and reproduce in a particular place. For example, populations of the American Red Squirrel (*Tamiasciurus hudsonicus*) occur in patches of conifer (spruce, pine, or hemlock) forests across the northern United States and Canada. Each group of American Red Squirrels that lives in a distinct area is considered a population. Collectively, all of the American Red Squirrels in all of the populations constitute the species.

Natural selection enables populations to adapt to the abiotic and biotic components of their environment. The various traits that arise in individuals and evolve to be prominent in populations under natural selection ultimately determine whether a population will grow or shrink (or even disappear) under a given set of physical and biological conditions in a local environment.

How are populations characterized? What controls changes in population size? In this chapter, we first consider key features of populations. Then we look at what happens when the number of births exceeds the number of deaths, and what happens when resources such as food start to run out. We also consider how individuals of different ages contribute to population growth, and how local populations are connected to one another. In [Chapter 45](#), we introduce the idea of interactions with other species and examine how those interactions shape the growth of populations.

**Three key features of a population are its size, range, and density.**

Populations are defined by three key features: size, range, and density

([Fig. 44.1](#)). Population size is the number of individuals of all ages alive at a particular time in a particular place. For example, the total size of the population of Antarctic krill (*Euphausia superba*) in the cold waters around Antarctica is estimated at 800 trillion, making them by mass the most abundant animals on Earth ([Fig. 44.1a](#)).

a. Size

The size of the Antarctic population of krill is estimated to be 800 trillion animals.

b. Range

Their range is approximately 19 million square kilometers in the Southern Ocean.

c. Density

800 trillion krill over 19 million square kilometers of the Southern Ocean means the population density is 42 million animals per square kilometer on average.

Mean no. krill ( $\times 10^6$ )/km<sup>2</sup>

|       |         |
|-------|---------|
| <2    | 32–64   |
| 2–4   | 64–128  |
| 4–8   | 128–256 |
| 8–16  | 256–512 |
| 16–32 | >512    |

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

Sources: Data from A. Atkinson, V. Siegel, E. A. Pakhomov, M. J. Jessopp, and V. Loeb, 2009, "A Reappraisal of the Total Biomass and Annual Production of Antarctic Krill," *Deep-Sea Research I* 56:727–740. Photos: Jean Paul Ferrero/ARDEA (inset) British Antarctic Survey/Getty Images.

FIG. 44.1 (a) Size, (b) range, and (c) density of a population. The places where populations occur can be mapped, and the numbers of individuals within those populations can be estimated.

A second key feature of a population is its geographic range: the area over which that population is spread. For example, the Antarctic krill population lives in an area of approximately 19 million square kilometers around Antarctica ([Fig. 44.1b](#)). The range of any species reflects in part the range of climates a population can tolerate and determines how many other species the population encounters. The range of a plant population, for example, influences how many kinds of insect eat it, and the range of an insect population determines how many kinds of plants it encounters.

Taken together, population size and range contribute to a third key attribute of a population: density. Population density is defined as a population's size divided by its range. In effect, density tells us how crowded or dispersed the individuals are that make up the population. For the Antarctic krill population, 800 trillion animals spread over 19 million square kilometers yields a population density of 42 million animals per square kilometer ([Fig. 44.1c](#)). This number describes the average density because krill, like most populations of organisms, vary in local density and individuals are not evenly spread out over the environment. As we will see, population density can affect population size.

This way of characterizing population density, as average density across the range of a population, is often useful, but it can be

misleading depending on how the organisms are distributed ([Fig. 44.2](#)). For example, individuals within a population may be distributed randomly. In such a case, a new individual has an equal chance of occupying any position within the range, and the location of one individual has no influence on where the next individual will be found ([Fig. 44.2a](#)). Sometimes, however, resources are distributed patchily within the range, or the chances of a new individual's survival are enhanced by the presence of other individuals. In these circumstances, the population may be clumped, with individuals clustered together ([Fig. 44.2b](#)). In still other cases, one individual of a population might prevent another from settling nearby, such as when all individuals depend on the same set of limited resources. Or predators, having located one prey individual, may search for other members of the same species nearby. Under these conditions, individuals may be distributed more evenly than would be predicted by chance. Ecologists call such populations uniform ([Fig. 44.2c](#)).

a.

The distributions of individual trees or other organisms can appear to be random, with no clear pattern to where they occur.

b.

If resources are clustered or spatial proximity to other individuals enhances fitness, individuals may be clustered.

c.

When resources are limited or predators target a single species, an individual might be better off if it is as far from others as possible, producing a uniform pattern of distribution.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 44.2 Distribution of individuals within populations. A population may be (a) randomly distributed, (b) clumped, or (c) uniform.

# Ecologists estimate population size by

## sampling.

Imagine trying to calculate the size of a population of Lime Swallowtails by counting every individual in the Dominican Republic. The task is hopeless. Like the Lime Swallowtail population, the populations of most species are either too large or too widely dispersed for every individual to be counted. Instead, ecologists estimate population size by taking repeated samples of a population and, based on these samples, estimating the total number of individuals. With an estimate of population size and range, ecologists can then determine population density.

For sessile, or sedentary, organisms such as milkweeds in a field or barnacles on a rocky shoreline, ecologists may lay a rope across the area of interest and count every individual that touches it, or they may throw a hoop and count the individuals inside it. Each such count is one sample. Based on the data for a number of samples, the ecologists can estimate the number and distribution of individuals in the population. For example, suppose 1-m<sup>2</sup> hoops are placed in three different spots in a field, encircling 4, 5, and 3 individual milkweeds, respectively. We can multiply the average number of individuals (in this case, 4) per 1-m<sup>2</sup> sample by the total square meters in the area of interest (in this case, the size of the entire field) to estimate the milkweed population size.

It is relatively easy to count sedentary organisms along a straight line or within a grid, but many species move around. How do ecologists estimate population size for turtles in a pond, or for mice in a forest? In these cases, a method called [mark-and-recapture](#) is

useful. Biologists capture individuals, mark them in a way that doesn't affect function or behavior, release them back into the wild, and then capture a second set of individuals, some of which were previously marked. [Fig. 44.3](#) illustrates how the mark-and-recapture method can be used to estimate the number of butterflies in an area. If a large number of butterflies are caught, marked, released, and then recaptured, it is possible to estimate the total population size by extrapolating from the proportion of the second sample that is marked.

#### HOW DO WE KNOW?

### FIG. 44.3

## How many butterflies are there in a given population?

#### BACKGROUND

Individuals in many populations of butterflies (and other animals) often live and die within the patch of habitat where they were born. Biologists estimate population sizes of such animals using mark-and-recapture, a technique that involves capturing and releasing organisms twice, on two different days. The assumption is that the population size is approximately the same on the second day as the first day. Biologists also assume that the captured and released animals mix with others in the population and do not intentionally avoid recapture on the second day. This technique was used to estimate the population size of Monarch Butterflies (*Danaus plexippus*) in Florida during their spring migration north from the butterflies' wintering grounds in Mexico.

#### METHOD

Biologists captured the butterflies in a field of milkweeds, their host plant; marked the butterflies with an identification sticker on the wing as shown

in the photo; and then released them. The number of marked butterflies was recorded. The next day, butterflies were caught and the number of marked and unmarked butterflies recorded. The butterflies that were already marked are called recaptures.

*Photo source: Doug Wechsler/Nature Picture Library.*

To determine the population size ( $N$ ), the total number of marked butterflies and unmarked butterflies caught on the second day ( $C$ ) is divided by the number of recaptures ( $R$ ). This number is then multiplied by the number of butterflies marked on the first day ( $M$ ), as follows:

$$N = (C/R) \times M$$

#### RESULTS

Let's say 100 butterflies are captured, marked, and released on the first day. On the second day, 120 butterflies are captured, 30 of which are recaptures. The rest are unmarked. We conclude that the population size is  $(120/30) \times 100$ , which in this example is 400 butterflies total in the sampled population.

#### RELATED METHODS

Mark-and-recapture techniques are extremely useful in estimating population sizes of organisms ranging from polar bears to disease victims.

In addition, some refinements to the mark-and-recapture approach take into account the movement of individuals between populations. These methods involve taking multiple samples and adding variables to the equation. Many animals have distinctive color markings, such as the blotches on humpback whale tailfins and skin-spotting patterns on frogs; these animals can be recorded without having to be marked.

SOURCE Knight, A., L. P. Brower, and E. H. Williams. 1999. "Spring Remigration of the Monarch Butterfly *Danaus plexippus* (Lepidoptera: Nymphalidae) in North-Central Florida: Estimating Population Parameters Using Mark–Recapture." *Biological Journal of the Linnean Society* 68:531–556.

These methods are simple, and they make a number of assumptions about the population. For example, we assume that the population has not changed in size between our first and second samples. Nonetheless, mark-and-recapture methods have proved effective in estimating the sizes of populations in nature. More sophisticated analyses are available for more complicated situations, as when more than two samples are caught, or when immigration or emigration occurs during the time between samples. For example, researchers tracking invasive populations of pythons in the Florida Everglades have placed radio-transmitters inside small samples of pythons caught and released back to the Everglades. Even though pythons are nearly impossible to recapture, mathematical models using radio-tracked python movements, coupled with counts of road-crossings by these and uncaptured pythons, help the researchers estimate their population sizes.

#### Self-Assessment Questions

1. What is the difference between a population and a species?
2. What basic facts about populations do we need to know to describe them?

## 44.2 POPULATION GROWTH AND DECLINE

The size of a population may increase, decrease, or stay the same over time. Trends in population size are a key focus of ecological research and its application to conservation biology. A decrease in size through time, for example, might signal declining health in a local population. This trend can be a matter of practical concern when the population in question is a commercially harvested fish or an endangered species. In the 1990s, for example, catastrophic declines in cod populations led to a ban on commercial cod fishing on the Grand Banks of Newfoundland in northeastern Canada. The declines affected both the cod and fishing communities, and led to changes in the Grand Banks ecosystems: crab and lobster populations have increased, as there are fewer cod to prey on them (see [Chapter 48](#)).

### Population size is affected by birth, death, immigration, and emigration.

Many factors affect population size. An obvious process that contributes to population increase is birth. Another is immigration: individuals may arrive in a population from elsewhere. In contrast, mortality (death) and emigration, the departure of individuals from a population, both act to decrease population size ([Fig. 44.4](#)).

FIG. 44.4 Factors affecting the size of a population: birth, mortality, immigration, and emigration.

We can describe the changes in a population's size mathematically, defining population size as  $N$  and the change in population size over a given time interval as  $\Delta N$ , where the Greek letter  $\Delta$  (delta) means "change in."  $\Delta N$  is the number of individuals at a given time (time 1) minus the number of individuals at an earlier time (time 0), which is notated as  $N_1 - N_0$ :

$$\Delta N = N_1 - N_0$$

The factors leading to a change in population size over time are births, deaths, immigration, and emigration. If  $B$  = number of births,  $D$  = number of deaths,  $I$  = number of immigrants, and  $E$  = number of emigrants, we can also quantify  $\Delta N$  as follows:

$$\Delta N = (B - D) + (I - E)$$

Commonly, ecologists want to know not just whether population size is increasing or decreasing, but also the rate at which population size is changing—that is, the change in population size ( $\Delta N$ ) over a given period of time ( $\Delta t$ ), or  $\Delta N/\Delta t$ . Let's say a population starts with 80 individuals and after two years has grown to 120 individuals. The population, then, has gained 40 individuals in two years, which gives us a rate of  $40/2 = 20$  individuals per year.

The importance we place on such a number strongly depends on the population size. An increase of 40 individuals in two years is significant if the starting population had 80 individuals, but it is less significant if the starting population included 10,000 individuals. Therefore, we are usually interested in the proportional increase or decrease over time, especially the rate of population growth per individual, known as the **per capita growth rate** (*capita* is a Latin term that means “heads”). The per capita growth rate, symbolized by  $r$ , is the change in population size  $\Delta N$  in a given period of time  $\Delta t$ , divided by the size of the population  $N$ :

$$r = (\Delta N/\Delta t)/N$$

The per capita growth rate is the average number of offspring per individual (that is, *per capita*). For example, an adult American woman has, on average, 2.3 children; this is the average for the population as a whole, since no one individual can actually have 2.3 children.

When  $r$  is positive, the population increases in size; when  $r$  is negative, it decreases in size; and when  $r$  equals 0, the size of the population does not change. In addition,  $r$  can change from one

generation to the next. In our example,  $r$  equals 40 individuals divided by two years, or 20 individuals per year, divided by 80 individuals (the starting population size), for an average per capita growth rate of 0.25 per year.

## Population size increases rapidly when the per capita growth rate is constant over time.

As we just discussed, we can use mathematical models, including equations and graphs of those equations, to describe natural phenomena. These models not only explain what we observe, but also help us make predictions. Ecologists have developed a variety of models to describe and predict how populations will change over time. These models often describe idealized populations and make certain assumptions. For example, many population growth models assume that the population is isolated, with no immigration into or emigration out of the population. These assumptions allow us to focus on the main factors that influence population growth, birth and death, without having to adjust for factors (such as migration of individuals) that are more difficult to estimate but also generally have less influence on populations.

Let's consider a model of population growth for species such as bacteria and humans, in which life cycles are not synchronized. In other words, organisms are born and develop at different times, and any individual that reaches sexual maturity in the population can reproduce immediately. The result is that the population increases or

decreases continuously. This type of population growth is known as continuous growth.

One of the simplest models of continuous population growth assumes that there are no constraints on population size and the growth rate of the population is constant. Even though the growth rate is constant, the actual number of individuals added per unit of time increases as the population grows. This is because each new individual also reproduces, so over time more and more individuals contribute to the growing population. As a result, the population grows extremely rapidly and exhibits exponential growth. Exponential growth occurs when the growth rate is constant, meaning the population grows in proportion to the number of individuals.

The characteristic shape of an exponential growth curve is shown in Fig. 44.5. The size of the population increases slowly at first, but then increases rapidly. Compound interest in a bank account works the same way; as you save more, you earn more even when the interest rate remains the same.

We can describe the curve in [Fig. 44.5](#) mathematically. Let's start with the formula for per capita growth we calculated previously, but rearrange it to solve for the change in population size over time, as follows:

$$\Delta N / \Delta t = rN$$

Because growth is continuous, we are interested in describing population growth at any instant of time, rather than the average growth over an interval of time. Therefore, we use the symbol “ $d$ ” instead of  $\Delta$ :

$$dN / dt = rN$$

Focusing on a single instant of time is useful for describing populations that reproduce continuously with overlapping generations because

choosing an interval in which to measure the population, such as a year or a decade, would be arbitrary. Similarly, in this equation,  $r$  is not the average per capita growth rate, but instead the per capita growth at an instant of time, called the **[intrinsic rate of increase](#)**.

Exponential growth is typical of small populations when resources are abundant, such as with the initial growth of bacteria in a laboratory culture or algae in a pond. The human population has also grown exponentially, a topic we return to in **[Chapter 48](#)**. When there are no environmental factors that limit population growth,  $r$  reaches its maximal value, symbolized as  $r_{\max}$ . Every species has a characteristic value for  $r_{\max}$ .

We can calculate the population size  $N$  at any time  $t$  using the following equation:

$$N_t = N_0 e^{rt}$$

where  $e$  is Euler's number, a mathematical constant approximately equal to 2.718. Euler's number is the base of natural logarithms.

Population growth is not continuous for all species. Consider an annual plant, in which each generation of organisms germinates at the same time, grows together to sexual maturity, reproduces, and then dies. The number of germinating seeds produced by organisms in any one generation determines the number of organisms in the succeeding generation. This type of population growth is known as **[discrete growth](#)** because the population size increases (or decreases) in one discrete step at the beginning of each new generation. It is typical of

organisms that breed seasonally or annually.

For discrete growth, the growth rate in one generation, symbolized by the Greek letter lambda ( $\lambda$ ), is determined by dividing the population at one point in time ( $N_1$ ) by the population size one generation earlier ( $N_0$ ):

$$\lambda = N_1 / N_0$$

For example, let's say the population size of annual plants is 804 in one year and 992 in the next year. The growth rate  $\lambda$  is  $992/804 = 1.23$ , which represents a 0.23 or 23% rate of growth in one year.

If we know the starting population size ( $N_0$ ) and the growth rate of the population ( $\lambda$ ), we can rearrange the formula to determine the population size one generation later ( $N_1$ ) as follows:

$$N_1 = N_0 \lambda$$

As with continuous growth, we can consider a situation in which the growth rate (in this case  $\lambda$ ) is constant in each generation and the population grows in proportion to the number of individuals. In this case, the population grows geometrically. In both geometric and exponential growth, the growth rate is constant; however, in geometric growth the population increases or decreases in steps (discretely), whereas in exponential growth it increases or decreases continuously.

If the growth rate is constant and we want to calculate the population size at any time  $t$  ( $N_t$ ), we can use the following formula:

$$N_t = N_0 \lambda^t$$

A chessboard example drives home the remarkable consequences of geometric growth. Suppose we place one grain of wheat on the first square of an  $8 \times 8$  chessboard that has 64 squares, two grains on the second square, four grains on the third, and so on, doubling the number on each successive square. In this example,  $N_0 = 1$ ,  $\lambda = 2$ , and  $t = 64$ . By the time we reach the 64th square, the total number of grains on the board ( $N_t$ ) is  $2^{64}$  or approximately  $1.8 \times 10^{19}$ , which is roughly equal to the number of grains of sand on Earth.

Malthus recognized that rapid population growth cannot continue for long in nature because the number of individuals eventually outstrips the resources available to support the population. Darwin, in turn, recognized that when the number of young produced at birth exceeds the number of adults that can be supported by available resources, individuals within the population compete to obtain the resources needed for growth and reproduction. This [intraspecific](#) (within-species) [competition](#) can result in natural selection when some individuals have genetic mutations that give them a competitive advantage over other individuals ([Chapter 20](#)).

Individuals can also compete for resources with individuals from different populations of species. Such [interspecific](#) (between-species) [competition](#) can result in either an increase or a decrease in population size. We focus for the most part on intraspecific competition in this chapter, reserving a detailed discussion of the effects of interspecific competition for [Chapter 45](#).

## Carrying capacity is the maximum

## number of individuals a habitat can support.

As a population grows, crowding commonly results in a decrease in the availability or quality of resources required for continuing growth. As a consequence, growth rate declines. On Hispaniola, for example, Lime Swallowtails have probably reached the limit of available citrus groves. Individual females have to search longer to find suitable plants on which no other females have already laid eggs. With that delay, and the pressure of eggs that are continuing to mature inside their bodies, females may end up laying too many eggs in one place or on poor-quality food, so there is not enough food for all larvae to survive. All of these factors lead to fewer births per female in the Lime Swallowtail population than occurred immediately after they first arrived in Hispaniola, when resources were not a limiting factor.

For many organisms, crowding affects the death rate as well as the birth rate. For example, as the fish population in a pond increases, there is less food available for each individual, and oxygen is used up by microbes that proliferate because of nutrients in the fish waste.

In other words, birth and death rates are themselves affected by population density, which we defined earlier as the number of individuals per unit of area or (for aquatic species) volume of habitat. Increasing density is not always detrimental to a population. For example, salmon or sturgeon eggs are more likely to be fertilized in rivers or streams swarming with their species than when relatively few reproducing adults are present. Generally, however, at some point increasing population density causes the environment to deteriorate

because of a scarcity of resources. When the density of a growing population reaches this point, the rate of growth slows and eventually levels off as the death rate increases to equal the birth rate.

The maximum number of individuals of a given species that a habitat can support is its carrying capacity ( $K$ ).  $K$  represents the interplay between the requirements of individuals for growth and reproduction and the environmental resources such as food and space available to support these needs.

Many factors can keep a population below  $K$ , including predation and parasitism. For example, increasing numbers of Lime Swallowtails on Hispaniola have no doubt attracted predators and parasites that feed on the butterflies. Similarly, a high population density of fish in a pond increases the likelihood of infection by viruses, bacteria, and fungi because these agents are transmitted from fish to fish. Predation and parasitism can reduce the population size below  $K$ , but they do not change  $K$  itself.

## Logistic growth produces an S-shaped curve and describes the growth of many natural populations.

When a population is small, resources are not a limiting factor and the population can grow at or near its maximum intrinsic rate of increase,  $r_{\max}$ . But as the population increases, drawing closer to its carrying capacity, worsening conditions due to crowding can slow the rate of growth. For any given population at any given moment, such as deer in

New England forests or striped bass in Chesapeake Bay, we may wish to know what fraction of the carrying capacity is available for further population growth. The answer, expressed mathematically, is  $(K - N)/K$ .

We can again model population growth, this time taking into account the carrying capacity. In this case, we get a curve like the one shown in [Fig. 44.6](#). Growth is exponential at first, but then slows as the population size approaches its maximum sustainable size,  $K$ . The resulting pattern of population growth, with its characteristic S-shaped curve, is termed [logistic growth](#). This curve can be described mathematically as follows:

$$dN/dt = r[(K - N)/K]N$$

growth curve, which is determined by  $r$  and  $K$ .

Logistic growth curves are S-shaped because they reflect two sets of processes, each related to population size. At first, growth reflects only the rate at which individuals can reproduce (when  $N$  is very small relative to  $K$ ), so the curve rises steeply. The second part of the curve, where it starts to level off, indicates a slower growth rate. This portion of the curve reflects the onset of additional factors that start to have a significant effect on survival and reproduction above a certain population size, such as decreasing availability of food and space.

Keep in mind that logistic growth is a model of population growth, not a graph of real data points from an existing population. Natural populations often show variations from this idealized S-shaped curve. Nevertheless, logistic curves apply to many other phenomena in biology, as well as in such diverse fields as chemistry, sociology, political science, and economics. For example, a logistic curve describes the rate at which oxygen binds to a population of hemoglobin molecules, as seen in [Chapter 37](#).

## Factors that influence population growth can be dependent on or independent of population density.

In the preceding discussion, the factors that limited population size depended on the density of the population. At low density, competition for food and other resources does not limit growth. However, as density increases, competition exerts more and more influence on

population growth, as resources become more limited. Similarly, at high population density, individuals may be more vulnerable to predation or to infection. Factors such as competition and predation are described **density-dependent** factors.

Not all changes in population growth rates result from population density. **Density-independent** factors influence population size without regard for the population's density. These factors include events such as a severe drought or a prolonged cold period, either of which can cause widespread mortality independent of population density. A graph of density-independent effects on populations often shows instantaneous, rather than gradual, drops in population size, and these changes can occur at different starting densities.

An example of a density-independent factor can be seen in a population of Scottish Red Deer (*Cervus elaphus scoticus*) (**Fig. 44.7**). Researchers found that the deer population's growth rate is influenced by the weather in the spring, when deer are born. A cold, wet spring reduces both birth weights and survival of newborn deer. The females that are born in such years are smaller in the following breeding seasons, reducing their average breeding success, and their survival as adults is lower, reducing their contributions to the population size. A factor such as weather acts on all individuals in a population regardless of density and can have lasting effects on population growth.

Data from S. D. Albon, T. H. Clutton-Brock, and F. E. Guinness, 1987, "Early Development and Population Dynamics in Red Deer. II. Density-Independent Effects and Cohort Variation," *Journal of Animal Ecology* 56(1):69–81.

FIG. 44.7 Density-independent effects on population size. Independent of population density, cold and rainy weather have an effect on birth weight and survival of newborn Scottish Red Deer.

### Self-Assessment Questions

- What four processes affect population size?
- If a population triples in size in a year, what is the per capita growth rate?
- Would you rather have a million dollars today, or start with one cent and double the amount each day for a month? Why?
- Draw an exponential growth curve and a logistic growth curve. What accounts for their different shapes?
- Name two density-dependent and two density-independent factors that can limit the size of a population.

## 44.3 AGE-STRUCTURED POPULATION GROWTH

Ecologists use direct counting and mark-and-recapture methods to assess the size and density of populations in a particular place.

However, not all organisms in a population contribute equally to population growth because some reproduce more than others.

Therefore, it is also useful to take into account individuals that have differing reproductive capacities. Variations in reproductive capacities most often depend on differences in age.

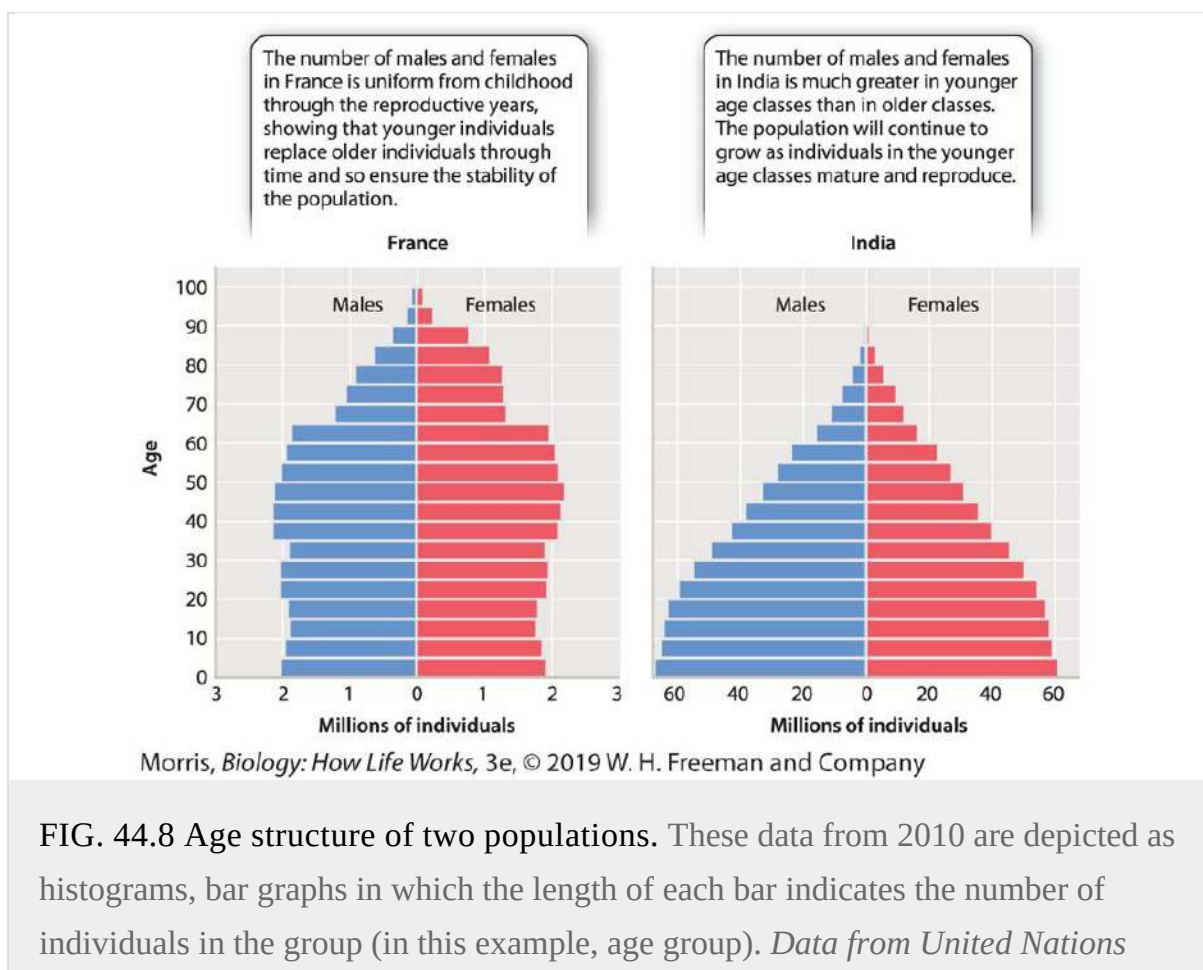

### Birth and death rates vary with age and environment.

To understand past changes and predict future changes in populations, ecologists consider birth rates, expected longevity of individuals, and the proportion of individuals in a population that is able to reproduce. Insights into these parameters come from the [age structure](#) of a population, the number of individuals within each age group of the population. A population in which most individuals are past the age of greatest reproduction or a population mostly composed of individuals that have not yet reached peak reproductive age will not increase as rapidly as one dominated by individuals capable of the greatest reproductive output.

To reconstruct the age structure of a population, researchers commonly divide the population, or a sample of the population, into age classes. Such classes may include, for example, individuals born within a single year or those born within an interval of several years.

Age may be determined by measuring an aspect of the organism's anatomy (for example, counting growth rings in fish scales or a tree trunk) or estimated by overall size (for example, fish length or tree height).

Estimating the number of individuals of differing ages enables ecologists to predict whether the size of a population will increase or decrease. A growing population usually shows a pyramid-shaped age distribution, with the youngest classes much more abundant than the older classes, whereas a stable population shows a more even distribution of age classes. [Fig. 44.8](#) shows the difference in age structure between France, a country with a stable population, and India, a country with a growing population.

In humans, differences in age structure may reflect, in part, socioeconomic variation among countries, but differences in the age structure of other species reveal threats from various sources. **Fig. 44.9** shows the effects of overfishing on the age structure of a species of long-lived Pacific rockfish, determined by comparing the ages of fish sampled in unfished waters with those in heavily fished waters. In the unfished population, the curve shows many individuals close to and past the age of 10 years, when reproductive ability starts to climb. In the fished populations, the curve shows a sharp decline in the number of individuals older than 6 years because mostly older and larger fish are caught. Because older fish produce most of the eggs and young fish, the annual reproductive effort of fished populations is severely affected by the removal of the older fish.

FIG. 44.9 Age structure in Pacific rockfish populations in fished and unfished waters. Harvesting larger and older individuals reduces the population's capacity

for growth, jeopardizing commercial stocks. *Data from S. A. Berkeley, M. A. Hixon, R. J. Larson, and M. S. Love, 2004, "Fisheries Sustainability via Protection of Age Structure and Spatial Distribution of Fish Populations," Fisheries 29(8):23–32.*

## Survivorship curves record changes in survival probability over an organism's life-span.

The age structure of a population reflects death rates as well as birth rates. **Demography** is the study of the size, structure, and distribution of populations over time, including changes in populations in response to birth and death rates, aging, and migration. The demography of the invasive Lime Swallowtail butterfly has been studied in Southeast Asia, where it is native. This investigation may be helpful in predicting the population dynamics of this species in coming years as it spreads from Hispaniola across the Americas.

The factors that cause insect mortality commonly differ from one life stage to the next, and knowing their effects can help us understand the physical and biological influences on population growth. **Fig. 44.10** shows the different dangers in each stage of the Lime Swallowtail's life. Each butterfly lays 30 or more eggs, but only a fraction of the eggs survive; most are lost to parasitism, drying out, falling from leaves, or predation by ants or other insects. The larvae have many defenses against predators, among them camouflage and chemical toxins, but they still fall prey to wasps, as well as to lizards and other animals. Thus, the faster they develop into adults, the more likely they are to

escape discovery by their enemies. The pupae, which are large and immobile, are perhaps the most vulnerable stage in the Lime Swallowtail life cycle, and pupae are often highly parasitized by a particular kind of wasp.

FIG. 44.10 Lime Swallowtail life cycle and natural enemies. The factors that cause insect mortality commonly differ from one life stage to the next.

**Fig. 44.11** presents data on the duration of each stage in the Lime Swallowtail life cycle and the numbers killed in that stage. The individual eggs that begin our study form a **cohort**, a group defined as the individuals born at a given time, and we can trace their survival as they age. The information about how many individuals of a cohort are alive at different points in time can be summarized in a life table, from which an ecologist can identify patterns of survival in a population.

The proportion of individuals from the initial cohort that survive to each successive stage of the life cycle is called survivorship. When survivorship curves for the Lime Swallowtail are plotted through time, they show an ever-declining fraction of the starting number of eggs (Fig. 44.11).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 44.11 Life table and survivorship curve for a population of Lime Swallowtail butterflies. (a) A life table summarizes the number of individuals alive in each cohort of a population and can be represented graphically by (b) a survivorship curve, which plots the proportion of the original cohort alive at the end of each stage or time period. Data from M. Pathak, and P. Q. Rivsi, 2002, "Age Specific Life Tables of *Papilio demoleus* on Different Hosts," *Annals of Plant Protection Sciences* 10(2):375–376.

We can see in the life table and the survivorship curve for this example that survival is lowest among eggs (68% survive to the next stage) and pupae (only 45% survive to the next stage), which cannot move to escape harm. If we divide the number lost at each stage by the number of days at that stage, we see that the egg stage losses are 16 per day, the pupal stage losses are 6 per day. By contrast, the larval stage losses are only 0.6 per day. Given these data, there is strong selective pressure to decrease the length of each stage, especially those stages most vulnerable to mortality. Nevertheless, if we remember that each adult female can lay 30 or more eggs, only a very few eggs need to survive to the adult egg-laying stage to ensure the growth of the population. In warm climates such as the Caribbean, these butterflies may reproduce eight or nine times in a year. Most of their eggs will not survive to become adults. If they did, available resources would soon be depleted.

## Patterns of survivorship vary among organisms.

Populations differ in the ages at which they experience the most mortality. In some species, many offspring are produced, but high mortality early in life means that few survive to reproductive age. In other species, mortality is highest in older individuals. In still other species, mortality occurs with equal frequency at all ages. [Fig. 44.12](#) illustrates the three principal types of survivorship curve—Type I, Type II, and Type III— which correspond to three different patterns of mortality: whether most mortality occurs late in life, is even throughout life, or is concentrated early in life, respectively.

FIG. 44.12 Survivorship curves. A Type I curve shows most mortality late in life; a Type II curve shows even mortality throughout life; a Type III curve shows most mortality early in life.

Human populations in affluent countries experience most mortality late in life, so they typically show a Type I survivorship curve (Fig. 44.12). Other large animals, such as elephants and whales, show similar survivorship curves. In contrast, birds and many small mammals commonly experience consistent levels of mortality throughout life, which can be graphed as a declining straight line. These animals, for which the probability of death does not change much through the life cycle, exhibit a Type II survivorship curve (Fig. 44.12). Finally, organisms like butterflies show high mortality at the earliest stages of their life cycles, resulting in a sharply declining survivorship curve that levels off (Fig. 44.12). This pattern is characteristic of a Type III survivorship curve, which is typical of

small herbaceous plants, small animals such as mice or minnows, insects such as the Lime Swallowtail, and other organisms that grow fast and produce a large number of seeds, eggs, or offspring.

## Reproductive patterns reflect the predictability of a species' environment.

In the preceding sections, we discussed population size and growth curves, and we outlined age structure and survivorship. These topics converge when we consider patterns of reproduction. Some species produce large numbers of offspring but provide few resources for their support. Such species are described as ***r*-strategists** ([Chapter 40](#)). In contrast, other species produce relatively few young but invest considerable resources in their support. These are termed ***K*-strategists**. How do these concepts relate to the intrinsic rate of increase  $r$  and carrying capacity  $K$  in population growth?

In general, species that live in unpredictable environments produce many young. When the environment is full of predators watching for vulnerable prey, such as gulls that watch for young turtles on a beach, or when resources are patchily distributed and abundant for only a short time, the chances of a young organism surviving to adulthood are low. Laying an egg, then, is like buying a lottery ticket: there is a limited chance of success. It is more advantageous to buy many tickets cheaply (that is, to have many offspring and make little parental investment in any of them) than to pay a lot for one ticket. Thus, salmon and other fish produce many thousands of young, each with an

extremely small chance of survival.

As we saw earlier, organisms like insects and plants that display Type III survivor curves also experience high mortality in the first stages of life. Because their reproductive success depends on the small chance that a few of their young will survive the hazards they encounter, parents produce many offspring and invest relatively little in any of them. We refer to species like the fish we just discussed as *r*-strategists because they reproduce at rates approaching  $r_{\max}$ , the maximum intrinsic rate of increase.

In contrast, species living where resources are predictable often produce a lower number of offspring and invest their reproductive resources in just a few, often larger and better-cared-for, offspring. These offspring are better protected from predators, able to compete with others when they are young, and more likely to survive to adulthood. Animals such as humans and bears, which have a Type I survivorship curve, produce only a few young and are *K*-strategists because their population densities commonly lie near the carrying capacity *K*.

These two strategies reflect an evolutionary trade-off. A reproductive individual has access to a finite amount of resources and can invest in either many inexpensive young or a few well-provisioned offspring. Depending on the combination of physiology and environment, natural selection in a given set of circumstances may favor one strategy over the other. However, *r*- and *K*-strategists represent the opposite ends of a continuum in reproductive pattern.

Many species lie between these extremes.

## The life history of an organism shows trade-offs among physiological functions.

As noted earlier, population growth can be limited by resource availability. How an organism makes use of the resources that are available can also affect population growth. Each individual must devote some of its total food and energy intake to growth, some to the maintenance of cells and tissues, and some to reproduction. This allocation is very much like a household budget, in which incoming resources are divided among the day-to-day expenses of acquiring food and paying for housing and transportation, meeting present and future medical and educational expenses, and savings held in reserve for emergencies. When one category goes up in cost—it requires more money, or more resources—another must come down.

In nature, individual organisms strike a balance in how they allocate resources to the basic needs of growth, maintenance, and reproduction. This balance has evolved to minimize energy loss while retaining the flexibility to use resources in different ways depending on environmental circumstances. These kinds of trade-offs evolve through natural selection and are the rule in ecology, explaining in part why species tend to produce either many small offspring or a few large ones.

The typical pattern of resource investment in each stage of a given

species' lifetime is its [life history](#). The amount of energy available for growth, maintenance, and reproduction vary over an individual's lifetime. Plants, for example, make trade-offs between defense and reproduction. When herbivores are around, plants that invest resources in defenses like poisons or thorns have an advantage over plants that do not invest in such defenses. These well-defended plants make a greater contribution to the next generation than poorly defended plants. In contrast, when herbivores are absent, well-defended plants are commonly at a competitive disadvantage compared with poorly defended plants. Individuals that do not invest in defenses can allocate more resources to reproduction. Such trade-offs in plant defense are especially important in nutrient-poor soils, where the cost of replacing valuable tissues lost to herbivores is higher than in nutrient-rich soils ([Chapter 30](#)).

The availability of nutrients and other resources may vary from place to place as well as over time, whether in different seasons or in different years. To take advantage of different conditions in their environment, the life history of many species includes some degree of control over their allocation of resources. Galápagos Lava Lizards, for example, show considerable flexibility in allocating resources of fat and protein that can be used for building eggs. As is the case for many other animals, availability of resources such as insects for food in the Lava Lizards' habitat varies from year to year due to variation in rainfall. This variation in resources determines how much energy is available for both growth and reproduction.

In dry years, the lizards show a physiological trade-off between the

number of eggs produced and the average size of each egg. Larger eggs require more resources to build, leaving less for additional eggs, and larger eggs hatch into larger offspring that are better able to fend for themselves. If the environment carries a high predation risk, however, then laying more eggs scattered in different places may be a better strategy than laying a few larger eggs in one place. Lizards may not reproduce at all if they are stressed by lack of resources for their other physiological needs, such as growth and development. Does this flexibility make these lizards *K*-strategists or *r*-strategists? The answer is neither. Which strategy is optimal depends on the nature of the risks faced by the Lava Lizards' young.

The key point is that food and other resources are typically limiting factors. The various ways in which animals and plants allocate such resources to growth and reproduction are rooted in their physiology, and their physiological traits are, themselves, evolved traits. Thus, ecology both reflects and determines how organisms function in nature.

#### Self-Assessment Questions

8. Draw a graph showing the age structure of a population that is growing rapidly and a graph of a population that is stable.
9. Plot a survivorship curve for a species with high rates of predation early in life and one for a species with high mortality late in life. Name the type of survivorship curve displayed in each graph.
10. How do *r* and *K* strategies relate to the predictability of the environment? In which kinds of environment is each strategist

more successful?

11. What is a trade-off in physiological functions? Give an example.

## 44.4 METAPOPULATION DYNAMICS

Up to this point, we have focused for the most part on single populations: how they are characterized, how they change in size over time, and what the distributions of ages are within them. In this section, we consider how multiple populations of a single species influence one another. In nature, the populations of many, if not most, species are unevenly distributed across the landscape. Deer occur only where there are forest patches of suitable size; milkweeds grow only in open fields; and ducks need to be near water. As a consequence of these preferences, local populations are usually separated from one another in space and are connected only occasionally by individuals that migrate between habitat patches. Moreover, some habitat areas that could, in principle, support populations of a given species are unoccupied, as invasive species, such as the Lime Swallowtail in Hispaniola, illustrate. How does this kind of distribution influence the dynamics—that is, the change in abundances through time—of populations in nature?

**A metapopulation is a group of populations linked by immigrants.**

Groves of trees, separated from other groves by fields, are patches of habitat for the birds, insects, and fungi that rely on them for food and shelter. Similarly, humans are patches of habitat for infectious viruses and certain bacteria; coral reefs are patches for fish; and mountaintops are patches for mountain goats and other high-altitude species. For

birds such as nuthatches or insects such as bark beetles, crossing between groves of trees is a risky business: predators abound and the possibility looms of not finding another suitable grove. Similarly, populations of reef corals are often separated by open waters full of predators. In effect, all of these habitats are islands separated by uninhabitable territory. We can define a patch as a bit of habitat that is separated from other bits of habitat by an inhospitable environment that may be difficult or risky for individuals to cross.

The nuthatches that occupy a particular tree grove interact with one another more frequently than they do individuals of other tree groves, and each group is considered a local population. Occasionally, a few migrants move from grove to grove, enabling gene flow between local populations. We can think of local populations of nuthatches in separate tree groves as parts of a larger, more inclusive group called a metapopulation. A **metapopulation** is a large population made up of smaller populations linked by occasional movements of individuals among them (**Fig. 44.13**).

populations connected by occasional immigrants, illustrated here by populations of nuthatches in groves of trees.

To understand the dynamics of populations, we must consider not only the birth and death of individuals, but also the colonization and extinction of local populations. Local populations within a metapopulation have independent fates and commonly become extinct because of their relatively small sizes. In general, small populations become extinct more often than large populations because they are more susceptible to random factors that increase mortality, such as extreme weather, natural disasters, or predation. For example, a nest of predators can eliminate a prey species locally. Or, if population density falls too low in a small local population because of disease or lack of resources, the survivors may not be able to find each other for mating. Nevertheless, as long as some of the local populations remain—that is, if all individuals do not all become extinct at the same time—these populations can recolonize old habitats or find new habitat patches, thus ensuring survival of the metapopulation.

Experiments with patches of moss growing on boulders show that the size and connectedness of the patches of moss affect the probability that species of arthropods inhabiting the moss will become extinct ([Fig. 44.14](#)). Researchers cut large patches of moss into several small fragments and sampled the number of insect species in each patch over time. As expected, isolated patches experienced decreases in species diversity, as much as 40% in one year; some species became extinct. However, when nearly isolated moss patches were left with a narrow corridor of moss connecting them, the rate of extinction was lower.

Even small corridors of suitable habitat can allow species to move between patches of habitat and prevent extinction, or serve to reintroduce species that become locally extinct.

Studies of metapopulations not only help us understand the dynamics of populations, but also have relevance to conservation biology ([Chapter 48](#)). For example, researchers have monitored nine forest patches near Manaus, Brazil, for more than 30 years as part of the Biological Dynamics of Forest Fragments Project, one of the

largest and longest-running ecological studies ever undertaken ([Fig. 44.15](#)). The researchers learned that fragmentation strongly affects forest biodiversity, providing clues to the design of effective refuges. Species survival depends on both the health of local populations and the ability of individuals to colonize new habitat patches. As the simple experiment in [Fig. 44.14](#) with mosses shows, corridors that connect endangered populations can dramatically increase the probability that a species will survive. However, corridors are important only to species that use them to cross barriers between patches. For species such as ferns, which produce spores that are able to float between patches on breezes, corridors may not be as important as they are to patch colonization. Dispersal ability differs among species, strongly influencing their capacity to colonize distant patches.

## CASE 8 CONSERVING BIODIVERSITY: RAINFOREST AND CORAL REEF HOTSPOTS

### How do populations colonize islands?

Islands represent extremes in habitat patchiness for colonizing species: organisms that live on a mainland must successfully cross a barrier of water to establish a new population on an island. For this reason, ecologists commonly use the term “island” to refer to any habitat patch that is surrounded by a substantial expanse of inhospitable environment. While this definition certainly includes parcels of land surrounded by water (what we usually think of as islands), it can also apply to a body of water surrounded by land, an expanse of forest surrounded by grasslands, or a mountaintop alpine field surrounded by lower-elevation forests.

*Anolis* lizards provide a classic and dramatic example of evolutionary diversification on the island of Hispaniola, where many dozens of closely related species coexist. Phylogenies suggest that *Anolis* lizards colonized Hispaniola in five or six separate events, but the dozens of species present today indicate that the populations diversified markedly after colonization. For flightless animals such as lizards, the ocean that surrounds Hispaniola is a barrier that prevents easy crossing, yet the island is clearly not unreachable. The distance of Hispaniola from other Caribbean islands and from the mainland is such that lizards and frogs and other small flightless animals have some chance of reaching it, perhaps by riding natural rafts of vegetation set adrift following mainland storms.

When the first lizards landed on the island, there may have been few natural predators and/or an abundance of small prey, allowing the population to grow rapidly. At the same time, Hispaniola featured unique types of habitats not available on the mainland, allowing the lizards to diversify over time into new species by adaptive radiation ([Fig. 44.16](#); [Chapter 21](#)).

FIG. 44.16 *Anolis* lizards in Hispaniola. The lizards arrived as colonists from elsewhere in the Caribbean and subsequently diversified to produce a variety of species.

Not all species are equally able to colonize a new island. For example, as you might expect, flying animals such as bats and birds more frequently arrive on oceanic islands than nonflying animals such as rodents, lizards, and frogs. However, the nonflying animals that do colonize islands successfully more often evolve into multiple new species. If the new, closely related species do not themselves colonize another area, they will be found nowhere else in the world; these are called endemic species. Endemic species are particularly vulnerable to invasive species, such as the Lime Swallowtail of Hispaniola.

Islands are natural laboratories for studies of evolution, ecology, and conservation biology. On islands, we can study how populations grow after the initial colonization event, and then how populations adapt to their new environment, which can be quite different from the mainland where they originated. We can also look at how different species interact with one another, the subject of the next chapter. Finally, in a world increasingly marked by habitat fragmentation caused by human activities, studies of islands are playing an important role in conservation biology ([Chapter 48](#)) by helping us better understand the impacts of fragmentation.

#### Self-Assessment Questions

12. What is the difference between a population and a

metapopulation?

13. Why are corridors important to the health of local populations?
14. List three examples of a habitat island. What makes each an island?

## CORE CONCEPTS SUMMARY

**44.1 POPULATIONS AND THEIR PROPERTIES:** A population consists of all the individuals of a given species that live and reproduce in a particular place.

Population size is the number of individuals at a particular time and place. [page 1002](#)

A population is characterized by its size, range, and density. [page 1002](#)

Population range is the total area in which a population lives. [page 1002](#)

Population density is the population size divided by its range. [page 1003](#)

Population size can be estimated by sampling and mark-and-recapture techniques. [page 1003](#)

**44.2 POPULATION GROWTH AND DECLINE:** Population size can increase or decrease over time.

Population size is determined by births, deaths, immigration, and emigration. [page 1005](#)

The population growth rate is the change in population size over time and is commonly expressed as the per capita growth rate, the rate of growth (or decline) per individual. [page 1005](#)

Populations grow continuously when life cycles are not synchronized, and discretely when organisms reproduce seasonally

so that population size changes at one step in each generation. [page 1006](#)

Exponential growth is characterized by a constant per capita growth rate, so that the population grows in proportion to the number of individuals. [page 1006](#)

Population density often limits population growth because of decreasing resources. This limit defines the carrying capacity ( $K$ ) of the environment. [page 1007](#)

The growth of natural populations is often logistic, producing an S-shaped curve in which growth is exponential at first, but then tapers off as population size approaches the carrying capacity of the environment. [page 1007](#)

Population density can be limited by density-dependent factors, such as competition for resources and predation, and by density-independent factors, such as drought and fire. [page 1008](#)

**44.3 AGE-STRUCTURED POPULATION GROWTH:** The age structure of a population helps ecologists understand past changes and predict future changes in population size.

The age structure of a population is the number of individuals of each age group and is often depicted as a histogram. [page 1009](#)

A growing population is characterized by a pyramid-shaped age distribution, with the youngest classes more abundant than older classes, whereas a stable population shows an even distribution of age classes. [page 1009](#)

Survivorship is the proportion of individuals from an initial cohort that survives to each successive age or stage of the life cycle. [page 1010](#)

Type I, Type II, and Type III survivorship curves correspond to mortality that occurs predominantly late in life, is even throughout life, or is concentrated early in life, respectively. [page 1011](#)

*r*-Strategists are organisms that live in unpredictable environments and produce many young, but invest relatively little in each offspring. [page 1012](#)

*K*-Strategists live where resources are predictable; they produce few young but invest heavily in each offspring. [page 1012](#)

The life history of an organism is the evolved pattern of resource investment in each stage of a given species' lifetime. [page 1012](#)

Organisms often exhibit trade-offs between reproduction and other physiological functions. [page 1012](#)

**44.4 METAPOPOPULATION DYNAMICS:** The dynamics of populations are influenced by the colonization and extinction of smaller, interconnected populations that make up a metapopulation.

The size of local populations (patches) and the degree of connectedness between patches determines in part whether a given patch will persist. [page 1014](#)

An ecological island may be a true island surrounded by water or any habitat "island" surrounded by uninhabitable areas. [page 1015](#)

## CHAPTER 45 Species Interactions and Communities

Charles J. Smith

---

### CORE CONCEPTS

**45.1 THE NICHE:** The niche encompasses the physical habitat and

ecological role of a species.

**45.2 ANTAGONISTIC INTERACTIONS:** Competition, predation, parasitism, and herbivory are interactions in which at least one species is harmed.

**45.3 MUTUALISTIC INTERACTIONS:** Mutualisms are interactions in which both species benefit.

**45.4 COMMUNITIES:** Communities are composed of local populations of multiple species that may interact with one another.

---

The chocolate tree, *Theobroma cacao*, known simply as cacao, is native to tropical America, where the environment is consistently warm and humid. Physical environment alone, however, does not determine where cacao lives. Cacao reproduction, and ultimately its geographic range, is limited by the requirement that tiny flies called midges pollinate the plants ([Fig. 45.1](#)). The midges' eggs and young need deep shade and a thick layer of moist rotting vegetation that forms either from the natural fall of leaves onto the forest floor or from banana plants intentionally left to decay in cacao plantations. Because of the needs of the midges, cacao cannot reproduce—at least not without human help—in areas that experience full sun or on clean ground. The natural distribution of cacao plants, therefore, depends on interactions with both the physical environment and other species.

Sources: a. Exotica im/AGE Fotostock; b. Brian V. Brown.

FIG. 45.1 A mutually beneficial interaction between two species. Development of (a) seed-rich cacao fruits depends on pollination of the cacao flower by (b) midges.

The reliance of chocolate trees on midges is not unusual. Every species interacts with other species in ways that affect growth and reproduction. These other species may be the insects that help a plant pollinate its flowers or ones that eat its leaves. They may be a fungus that helps a tree gain nutrients or another that attacks it. They may be other species that compete for resources, predators and pathogens that reduce population size, prey species that provide a specialized food resource, or microbes that provide or consume nutrients while living inside their hosts ([Case 5 The Human Microbiome](#)). Associations among species, whether positive or negative, form a complex web of interactions in which species influence the population size and distribution of other species, whether they are partners, enemies, or food. In this chapter, we explore where and how species live and how they interact with one another in a community.

## 45.1 THE NICHE

Why do species live where they do? As discussed in [Chapter 44](#), a population persists only in places where its members can tolerate the physical environment. Plants, for example, are sensitive to rainfall, temperature, and nutrient levels in the soil. The habitat occupied by a species usually contains other species, and the distribution of each species reflect interactions with the other species, as the example of cacao illustrates. Competition between species can occur when different species use the same resources in the same place. Distinct species can coexist within shared habitat only if they use different resources, if they are active at different times, or if the local populations of one or both species have so few individuals that resources do not serve to limit their survival and reproduction. In other cases, such as cacao, species persist only when other species that benefit their growth or reproduction are also present.

### The niche is a species' place in nature.

The combination of a species' physical habitat and its ecological role in that habitat defines a species' [niche](#). The meaning of this term has changed over the years. Nearly a century ago, the American ecologist Joseph Grinnell defined the niche as the sum of the habitat requirements needed for a species' survival and reproduction. Later, ecologist Charles Elton redefined the niche as the role a species plays in a community, shifting the emphasis from the habitat to the species itself. By the middle of the twentieth century, ecologist G. Evelyn Hutchinson had combined these ideas, popularizing the concept of the niche as a multidimensional habitat that allows a species to practice its

way of life.

The niche is determined by physical (abiotic) factors such as climate and soil chemistry, as well as by biological (biotic) factors based on interactions with other species. Although species are commonly associated with a specific habitat, the terms “niche” and “habitat” are not interchangeable. Niches have a dual nature: they reflect both where organisms occur and what they do there. Furthermore, niches encompass the ways that organisms respond to, and also affect, the resources and other species found in the habitat.

## The realized niche of a species is more restricted than its fundamental niche.

The **fundamental niche** of a species includes the full range of climate conditions and food resources that permit the individuals in a species to live. In nature, however, many species do not occupy all the habitats permitted by their physiology because of interactions with other species, such as competition and predation, that can limit the range actually occupied. The actual range of habitats occupied by a species is its **realized niche**.

For example, Red-Winged Blackbirds (*Agelaius phoeniceus*) nest in marshes (**Fig. 45.2**). Their survival is most successful when they nest over deep water that provides protection from predators. In the western United States, Yellow-Headed Blackbirds (*Xanthocephalus xanthocephalus*) compete for territory with Red-Winged Blackbirds. In this region, the larger Yellow-Headed Blackbirds occupy the deep water parts of the marshes, while the Red-Winged Blackbirds nest at

the water's edge. In this example, the entire marsh is the fundamental niche for Red-Winged Blackbirds ([Fig. 45.2a](#)). By contrast, the shallow water sites are the realized niche for the Red-Winged Blackbirds, where they co-occur with Yellow-Headed Blackbirds ([Fig. 45.2b](#)).

FIG. 45.2 Fundamental and realized niches. (a) The fundamental niche includes all the habitat potentially available to a population. (b) The realized niche is the subset of that habitat actually occupied by the population.

Some of the best evidence that organisms can live beyond the ranges they actually occupy comes from studies of invasive species ([Chapter 48](#)). For example, cane toads were introduced into Australia in 1935 and now occupy a wider range of habitats than they do in their native South America. Similarly, many familiar European weedy plants are much more widespread in North America than they are in Europe, hinting at the limits imposed by competitors and predators in their native ranges. Invasive species show us that the realized niche is often much smaller than the fundamental niche.

# Niches are shaped by evolutionary history.

The niches of nearly all species are narrow in at least one way, and often in several ways. For example, among woodland birds, warblers hunt insects on leaves, thrushes seek insects in soil, and woodpeckers find insects that live inside the wood of trees. These specializations may be explained at least in part by the niches of the ancestors from which these different woodland birds evolved. The tendency of species to retain aspects of their ancestral niches, and therefore for closely related species to resemble each other in niches, is called **phylogenetic niche conservatism**. While the conservatism of morphological traits has long been appreciated and studied, study of the importance of niche conservatism is a relatively new focus in evolutionary biology and speaks to our increasing awareness of the strong influence of evolutionary history in shaping ecological niches of organisms.

For example, the ecological niches of birds often remain relatively constant even as new species form, with the result that closely related species are similar in their ways of life, including the kinds of nests they build and the kinds of food they eat. Nearly all sandpipers have long bills they use to probe wet sandy beaches for the tiny animals they consume; different swallow species all hunt insects as they fly over fields, rivers, and ponds; and different species of woodpecker feed on insects living inside the wood of tree trunks and branches (**Fig. 45.3**).

Photography/Getty Images.

**FIG. 45.3 Phylogenetic niche conservatism.** Semipalmated, White-Rumped, and Western Sandpipers run along the water line on beaches in search of places to probe for tiny invertebrates buried in the sand. Tree, Barn, and Rough-Winged Swallows have long wings and broad bills that help catch flying insects. Downy, Hairy, and Pileated Woodpeckers drill holes in trees to reach insects.

---

The evolutionary ancestors of sandpipers, swallows, and woodpecker species were adapted for their ways of finding food. Food gathering is enabled by the long legs and bills of sandpipers that allow them to probe along long sandy beaches. Similarly, the long wings and broad mouths of swallows are particularly well adapted for catching flying insects. Woodpeckers have stiff tailfeathers that allow them to brace vertically on trees and use their chisel-like bills to bore holes that they probe in search of insects with their extraordinarily long, barbed tongues. These examples illustrate that closely related species (in this case, different species of sandpipers, swallows, and woodpeckers) share similar niches (feeding on insects on beaches, in the air, and in wood, respectively), supporting the concept of phylogenetic niche conservatism.

#### Self-Assessment Questions

1. What defines the niche of a species?
2. Choose an organism, such as an oak tree, and explain which types of parameters define its niche.

## 45.2 ANTAGONISTIC INTERACTIONS

Comparing the realized and fundamental niches of Red-Winged Blackbirds makes it clear that interactions with other species play key roles in the distribution and abundance of populations (see [Fig. 45.2](#)). Virtually every organism interacts with other species: think of plants and their pollinators or predators and their prey. These interactions often narrow the geographic distributions of species within the larger boundaries of their physical requirements, and help shape their realized niches.

All interactions involve costs (often in resources) and benefits (usually increases in reproduction). Some interactions are direct, where species physically interact (such as plants and their pollinators). Others are indirect, where species influence one another through competition for a shared resource, such as food. In many interactions, the benefits are one-sided: one organism actually consumes another or successfully competes with it for food or some other resource. In this section, we focus on [antagonisms](#), interactions in which at least one participant loses more than it gains.

### Limited resources foster competition.

Whenever there are fewer resources than individuals seeking them, competition can arise. [Competition](#) is an interaction in which the use of a mutually needed resource by one individual or group of individuals lowers the availability of that resource to another individual or group. For example, different species of sea anemones compete for

space in rocky shallows and male dung beetles compete with each other for animal droppings. In many animal species, males compete with each other for female mates.

Recall from [Chapter 44](#) that in many populations the tension between the intrinsic rate of increase and the environmental carrying capacity results in **[intraspecific competition](#)**, competition among individuals of a single species. The increase in intraspecific competition that accompanies increased population density is a major reason why population growth slows as the population approaches the environment's carrying capacity. Competition among individuals of different species, called **[interspecific competition](#)**, is also common.

Whether competition occurs among individuals of one species or two, it is generally a lose–lose situation: each side loses access to resources or spends energy it would not expend in the absence of the other. Indeed, Darwin recognized that the “struggle for existence,” as he called it, is a primary driver of natural selection, leading to the evolution of traits that aid survival and reproduction by reducing competition in one way or another.

## Species compete for resources other than food.

Food is the resource we most often think of as the limiting factor for population growth and reproduction. Many species, though, just require a place to stand, so to speak, or suitable conditions for a nest. Barnacle and mussel larvae compete for a place to attach on submerged rocks. The food these organisms consume, tiny plankton, is almost

always abundant. Thus, the food factor is not as likely to limit population growth for these species as attachment space is.

Similarly, plants compete for space in fields and forests so they can collect sunlight and obtain water and nutrients from the soil. Of course, sunlight cannot be used up, but room to collect sunlight on the ground below can be filled. Nesting sites for birds that lay their eggs in tree hollows or on cliff faces can also be strongly limited by the availability of space, as can the settling of corals on reef surfaces ([Fig. 45.4](#)).

Sources: a. Courtesy of Jim Maddox, Galloway, NJ;  
b. Franco Banfi/Getty Images.

FIG. 45.4 Competition for space. (a) Herons, egrets, and cormorants compete for nest sites in wetland trees. (b) Corals compete for space on reef surfaces.

Competitive exclusion prevents two species from occupying the same niche at the same time.

In general, when two species have overlapping niches (if, for example,

they share a physical habitat and overlap strongly in resource use), one will either become extinct in that place or change its niche. Coyotes and foxes eat the same small prey, but when they meet, a coyote wastes energy by chasing the fox, and the fox loses energy by running away from the coyote. In regions where foxes and coyotes can potentially share a habitat, the foxes avoid interactions with the larger coyotes by leaving the area, placing their dens in locations where coyotes do not roam.

The idea that two species cannot occupy the exact same niche at the same time is called **competitive exclusion**. Although the general idea is discussed in Darwin's *On the Origin of Species*, this principle is often attributed to the Russian biologist Georgii Gause. A consequence of competitive exclusion can be as simple as one species moving its territory when the other is present, as in the example of foxes and coyotes. A similar outcome occurs when Red-Winged and Yellow-Headed Blackbirds occupy the same marsh. Competitive exclusion is one way in which a fundamental niche can be reduced to a smaller realized niche.

More dramatically, competitive exclusion can lead to the local extinction of one of the two species. Squirrels provide a well-known example (**Fig. 45.5**). For millennia, European Red Squirrels (*Sciurus vulgaris*, different from the American Red Squirrel discussed in **Chapter 44**) thrived in woodland habitats throughout the British Isles. In 1876, however, the American Grey Squirrel (*Sciurus carolinensis*) was introduced to Great Britain and spread rapidly. Grey and Red Squirrels have similar dietary preferences, but the larger Grey Squirrels

are better at gathering these resources. For this reason, as Grey Squirrels expanded, Red Squirrels declined to near extinction, excluded by their competitors.

Sources: a. Sarah Peters/Getty Images; b. Zen Rial/Getty Images.

**FIG. 45.5 Competitive exclusion.** European Red Squirrels (a) and American Grey Squirrels (b) share the same niche, and the Grey Squirrels outcompete the Red Squirrels where they co-occur.

While Grey Squirrels excluded Red Squirrels in Great Britain, nine closely related squirrel species live together in the tropical forests of Malaysia. They are able to coexist because the different species move through distinct areas of the forest, prefer different foods, and are active at different hours of the day. All of these traits were likely shaped by competition in the past. **Resource partitioning**, the division of resources by different species living in the same habitat, can minimize competition, allowing two or more species to coexist. Competitive exclusion is what keeps species that depend on the same resource from living at the same place at the same time, and resource partitioning is what allows similar species to coexist.

Even if two species overlap substantially in resource use, competitive exclusion may not always take place. It is more likely to occur when the population sizes of both species are large enough to encounter each other or reduce the resources available. As discussed later in the chapter, predation and parasitism can keep population sizes low.

## CASE 8 CONSERVING BIODIVERSITY: RAINFOREST AND CORAL REEF HOTSPOTS

### Can competition drive species diversification?

In [Chapter 44](#), we discussed the *Anolis* lizards on the island of Hispaniola and other islands of the Caribbean. Many closely related species of *Anolis* lizards live in similar areas and they all feed on insects and other invertebrates (see [Fig. 44.16](#)). How do they coexist?

Within their fundamental niche of tropical forests, different *Anolis* species differ in how and where they search for prey. Lizards with long legs run on the ground, while those with shorter legs and long tails climb on vegetation. Still others are large and robust and live in the high canopies of trees. Altogether, *Anolis* lizards have evolved at least six different feeding strategies with corresponding morphological traits ([Fig. 45.6](#)). In other words, they exhibit resource partitioning, allowing them to coexist in one place.

Source: (a and b) Eladio M. Fernandez.

FIG. 45.6 Adaptations of *Anolis* lizards. (a) *Anolis* species that feed on twigs have short limbs and a prehensile tail that they use to support themselves when they sleep; (b) those that feed on trunks have long limbs.

In many cases, resource partitioning reflects an evolutionary history in which competition for similar resources promoted the use of different niches by different groups, and eventually the diversification of species in this group. That is, competitive exclusion, played out over time, resulted in divergence in habitat use and feeding strategies, and ultimately speciation. The result is that the overlap between closely related groups is minimized. Among animals, resource partitioning usually entails behavioral shifts (and eventually often divergence in morphology) that enable different groups of individuals to use resources beyond those that the two groups share. For example, if two groups of finches normally feed on the same type of seed, resource partitioning may result in the groups accumulating physiological differences that allow each to feed more effectively on a different size of seed ([Chapter 21](#)).

**Predation, parasitism, and herbivory are interactions in which one species**

## benefits at the expense of another.

In contrast to competition, some interactions benefit one participant and harm the other. **Predation** is a type of interaction in which one organism, a predator, consumes another, its prey. In this interaction, the predator benefits at the expense of the prey. Early experiments by Georgii Gause showed that a simple system with one predator population and one prey population is inherently unstable. In such a scenario, the predator will overexploit the prey, driving it to extinction, and then become extinct itself.

In 1958, the American scientist Carl Huffaker demonstrated that if the prey had refuges where some individuals could escape from predators, the prey species could persist while predator populations declined. Through time, the prey population would recover. Population density would then rise to a point where predators would again expand and cause prey abundance to decline—and then decline again themselves (**Fig. 45.7**). Huffaker showed that predators and prey cycle repeatedly through periods of increasing and then decreasing density, as predators track their prey and some prey escape predation. A long-term, stable oscillation pattern can be achieved when prey are able to find temporary escape in refuges. In natural environments, predators may switch to other more common prey species when a particular prey becomes scarce, allowing prey populations time to recover.

HOW DO WE KNOW?

FIG. 45.7

Can predators and prey coexist stably in certain

# environments?

## BACKGROUND

In the 1950s, it was not clear whether predators and prey could and exist in the same habitat indefinitely or whether both groups of species would become extinct as predators consumed all available prey. The results of experiments up to that time gave no concrete conclusions, and ecologists knew of examples of predators introduced to islands that hunted their prey to extinction.

## HYPOTHESIS

Ecologist Carl Huffaker hypothesized that predators and prey could stably coexist if temporary refuges were available for the prey.

## EXPERIMENT

Huffaker studied two kinds of mites: one that eats orange peels, and another that preys on the orange peel-eating mite. Huffaker put two sets of oranges on a table and separated them with barriers of petroleum jelly, essentially making each orange its own habitat patch ([Fig. 45.7a](#)). He added toothpicks to one set of oranges so that the peel-eating mites could let out silk and float over the petroleum jelly barriers and, at least temporarily, escape predation.

## RESULTS

In the setup in which prey could not escape, a single cycle of increase and

decline was observed (graphed in [Fig. 45.7b](#)): the size of the prey population (red line) increased but was closely tracked by rising populations of the predator (blue line), and eventually both declined to extinction.

In the environments where toothpicks were provided, the orange-feeding mites climbed the toothpicks and fled on the silken threads they produced, escaping predators and reaching oranges without mites. These populations of predators and prey went through three cycles of increase and decline (graphed in [Fig. 45.7c](#)), and cycles would probably have continued if oranges continued to be supplied.

## CONCLUSION

Predator–prey systems can be stable if there are sufficient areas available where prey can escape predators, at least temporarily.

SOURCE Information from Huffaker, C. B. 1958. “Experimental Studies on Predation:

Predation can affect population dynamics beyond just those of the predator and its prey. For example, predators can limit the population sizes of their prey to the extent that competitive exclusion does not occur between the prey and a competing population.

For example, in ponds throughout the southern United States, tadpoles of the large Southern Toad, the Eastern Spadefoot, and the tiny Spring Peeper all depend on the same food source; that is, they all graze on algae. In the presence of the two larger species’ tadpoles, Spring Peeper tadpoles compete poorly for food ([Fig. 45.8](#)). As a result, they have low survival rates, and those individuals that do make it to maturity are often undersized because as tadpoles they did not have access to adequate nutrition. In the presence of a predatory Red-Spotted Newt, however, the tables are turned. The newt prefers to eat the larger tadpole species, and its voraciousness prevents the larger species from becoming sufficiently abundant to outcompete the smaller Spring Peeper tadpoles. In these situations, the Spring Peeper tadpoles have the highest survival rates. With competition for food reduced, the small tadpoles grow to their maximal body size, and become the most abundant tadpole species in the ponds.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 45.8 Effect of predators on the outcome of competition. Newt predators in ponds prefer to eat bigger tadpoles that compete well for food, enabling smaller tadpoles that are poorer competitors to survive to adulthood. *Data from P. J. Morin, 1981, "Predatory Salamanders Reverse Outcome of Competition Among Three Species of Anuran Tadpoles," Science 212:1284–1286.*

Parasitism is another interaction in which one participant benefits at the expense of another. [Parasites](#) live in close association with another species, gaining nutrition by consuming their hosts' tissues. Unlike predators, parasites rarely kill their hosts, but they can reduce the host's fitness and ability to reproduce or increase the host's susceptibility to harsh environmental conditions by tapping its resources. In this way, parasites can limit the population size of their host, keeping numbers well below the carrying capacity of the environment.

An extreme example of parasitism is the fungus that infects the American chestnut, a tree once dominant in eastern North American forests. This fungus attacks the vascular system of young chestnut trees, which usually succumb when they reach 2 to 3 m in height, before reaching reproductive maturity. Today, there are only a few

isolated patches of large chestnut trees that have escaped the fungus in Vermont and a handful of other places. As chestnut populations have declined, populations of oak, beech, and other trees that grow in the same forest have increased.

**Herbivory**, the consumption of plant parts, benefits herbivorous animals by providing nutrients, and harms plants by directly affecting the products of photosynthesis. Plants are generally not as nutritious for animals as other animals are, so herbivorous animals must eat greater amounts of plant material to obtain the nutrients they need for survival and reproduction. As we saw in [Chapter 30](#), plants are not passive victims of herbivores; most are well defended with chemical or physical deterrents to herbivory.

#### Self-Assessment Questions

3. What is the difference between competitive exclusion and resource partitioning?
4. How can predators influence competition and affect the niches of other species?
5. What do competition, predation, parasitism, and herbivory all have in common?

## 45.3 MUTUALISTIC INTERACTIONS

As our chapter-opening example of cacao and midges shows, some interactions benefit both participants, though usually each participant's benefits are associated with some costs. When the benefits for each participant outweigh their costs, the interaction is a [mutualism](#).

Typical benefits include access to nutrients, shelter from predators or weather, and direct help in reproduction. Ultimately, all benefits are measured by natural selection in terms of reproductive output. Some typical costs include the proteins, fats, and carbohydrates that are invested in building structures such as flowers that attract pollinators or specialized tissues that house bacteria or algae. Costs can also take the form of energy-consuming activities such as the transport of pollen or seeds or the loss of food resources consumed by a partner.

**Mutualisms are interactions between species that benefit both participants.**

The midges in the chapter-opening example obtain the benefit of food from the cacao blossoms at the cost of pollen transport between flowers. For its part, the chocolate tree obtains the benefit of pollination at the cost of producing the sugars and amino acids in the flowers' nectar.

The nitrogen-fixing bacteria that live in nodules on the roots of soybeans ([Chapters 24](#) and [27](#)) provide another illuminating example of a mutualism. The bacteria occur naturally in the soil and are attracted by molecular signals to the soy plant roots, where they take

up residence in nodules produced by the plant. The bacteria provide their host plant with nitrogen in a biologically useful form, and the plant provides the bacteria with food and a stable environment. In response to signals from the bacteria, the plant builds the bacteria's home, the nodules, out of root tissue. The cost involved in this construction is outweighed by the benefit of enhanced access to nitrogen, which is measured in greater growth and reproductive output for the plant. In the interaction between plant and bacteria, both sides win.

Despite both partners in a mutualism benefiting from the interaction, it is important to remember that each side is acting in its own self-interest and bears costs that are weighed against benefits in terms of growth and reproduction. Associations that, overall, are beneficial to one partner are often also beneficial to the other partner and, therefore, more often represented in the next generation. For example, nitrogen-fixing bacteria are ubiquitous. Likewise, their principal hosts, members of the plant family to which beans belong, are unrivaled in their diversity of species, dominating tropical forests all over the world. Nitrogen-fixing bacteria are equally important in the sandy shallows of tropical seas, where they form associations with vast beds of sea grasses, which in turn serve as nurseries for tropical reef fish.

In other words, mutualisms are subject to natural selection, just like any other adaptation ([Chapter 20](#)), and are at the heart of some of the most important biological interactions on Earth.

## Mutualisms may evolve increasing interdependence.

Close interactions between species, either antagonisms or mutualisms, that have evolved over long periods of time are called [symbioses](#) (singular, [symbiosis](#)). One of the best-studied symbiotic mutualisms involves aphids (and their insect relatives) and closely associated bacteria. The insects suck plant sap for food, and the bacteria live in tissues that develop within the insects adjacent to their digestive system. The insects provide a home for the bacteria at some physiological cost, but also gain an important benefit from their residence: plant sap contains relatively few nutrients, and the bacteria provide their hosts with essential amino acids. The bacteria benefit from a stable and favorable environment at the cost of some nutrients supplied to the aphids. The aphids pass the bacteria from mother to daughter in egg cells, guaranteeing that offspring have bacteria. When the interaction between species drives reciprocal adaptations in both participants, there is a possibility for long-term coevolution because the descendants of each side are associated with each other, just as were past generations. Any mutations that arise can affect both members of the partnership, because neither aphids nor bacteria are found without the other.

DNA evidence suggests that aphids and their bacteria have been associated for 100 million years or more, and that the bacterial genomes have been gradually losing genes they would need for life outside the insects ([Fig. 45.9](#)). In fact, some bacterial genes have been acquired by the insects. We saw a similar process of coevolution in

[Chapter 24](#) in the example of mitochondria and chloroplasts, which is probably nature's most dramatic example of a coevolved mutualism.

#### HOW DO WE KNOW?

### FIG. 45.9

## Have aphids and their symbiotic bacteria coevolved?

#### BACKGROUND

Aphids are small insects that are common pests of garden plants. Specialized cells in the aphids harbor populations of the bacterium *Buchnera*, which provide their aphid hosts with amino acids essential for growth. Mother aphids pass the bacteria through their eggs to their daughters.

#### HYPOTHESIS

Aphids and *Buchnera* bacteria have coevolved for millions of years.

#### EXPERIMENT

American evolutionary ecologist Nancy Moran sequenced the DNA of the *Buchnera* bacteria and their host aphids to establish the phylogenetic relationships of aphid species and their symbionts. Moran reconstructed the phylogeny of both groups and compared their relationships. She reasoned that if the two phylogenies matched each other, the hypothesis of coevolution is supported.

#### RESULTS

The phylogenetic trees of aphids and their associated bacteria match perfectly, just as if the bacteria were a gene of the aphids instead of a separate organism. This matching of phylogenetic trees is seen both among aphid species in different genera and for aphid populations within a single species. A DNA-based molecular clock ([Chapter 20](#)) further

shows that aphids, and the insects related to them, have all coevolved with these bacteria over nearly 200 million years.

## CONCLUSION

A single group of *Buchnera* has been passed down through generations of its aphid hosts for nearly 200 million years. Host–symbiont systems can be stable over long time intervals and show long-term coevolution.

## FOLLOW-UP WORK

Researchers are studying the changes in the genomes of bacteria living inside aphids to see how they lost the genes necessary for living independently of their aphid hosts.

SOURCE Moran, N. A., et al. 1993. “A Molecular Clock in Endosymbiotic Bacteria Is Calibrated Using the Insect Hosts.” *Proceedings of the Royal Society. London, Series B*, 253:167–171.

While some mutualisms involve close interactions between specific species, others are less particular. For example, sweet-tasting fruits evolved in many flowering plants, attracting mammals and birds that

disperse their seeds, but not in response to any particular bird or mammal species. Similarly, flowers evolved in response to insect pollinators such as bees and flies, whose own adaptations for visiting flowers evolved in response to flower availability. General associations such as these can be beneficial, especially when the population of one partner undergoes declines. For example, *Freycinetia arborea*, a vine found only in the Hawaiian Islands, is pollinated exclusively by birds introduced from Japan in 1929. How was *F. arborea* pollinated before the twentieth century? Pollen grains on the pelts of extinct Hawaiian bird species preserved in museum collections show that the vine was once pollinated by birds that are no longer found in Hawaii. The vines persist because they were able to form a mutualism with the newly introduced Japanese species.

## Digestive symbioses recycle plant material.

In [Case 5 The Human Microbiome](#), we saw that diverse microorganisms in the human digestive tract provide important services to our own well-being. Humans are not alone in hosting microbial symbionts; most animals have microbiomes. All herbivorous animals studied to date, from cows and sheep to ants, beetles, and termites, are able to feed on plant tissues only with the help of microbial symbionts. Much of Earth's biomass consists of wood and other plant tissues rich in cellulose and lignin. Few organisms have the ability to digest these molecules, but some microorganisms, mainly bacteria and fungi, can. When these microorganisms reside in an animal gut, such as the rumen or large intestine of a cow, they enable

their host to benefit from plant tissues that the animal itself cannot break down. In this way, both host and symbiont benefit from the association.

Not all plant-digesting symbionts live within the digestive tracts of their hosts. Consider leaf-cutting ants. Colonies of these ants in a Central American forest can consume as much as 14% of the leaves of nearby trees, hauling each leaf in pieces down into their subterranean nests. A single colony of leaf-cutting ants can consume as many kilograms of leaves per hectare as an herbivore the size of a sheep over the same amount of time. The ants do not feed on the leaves directly, but rather use them to feed gardens of fungi that the ants tend carefully ([Fig. 45.10](#)). The fungi, in turn, serve as food for the ant colony. The fungi benefit from being fed, and the ants benefit from the nutrients that the fungi provide.

Sources: a. Redmond Durrell/Alamy; b. Martin Dohrn/naturepl.com.

**FIG. 45.10 Plant-digesting symbioses.** Leaf-cutter ants (a) feed leaf fragments to gardens of fungi (b), which digest the leaves and ultimately become food for the ants.

These insect–fungi symbioses can be thought of as a form of agriculture that, like human agriculture, has a large impact on the

biosphere through their efficient breakdown of plant materials. Insect–fungus mutualisms are certainly dramatic, but they are more the rule than the exception: nearly all eukaryotes depend on microbial symbionts with which they have coevolved ([Chapter 25](#) and [Case 5: The Human Microbiome](#)).

In some cases, animal–bacterial mutualisms have been implicated in resource partitioning and speciation, providing another link between ecology and evolution. Snails of the genus *Alviniconcha* occur widely along hydrothermal ridge systems in the western Pacific Ocean, gaining nutrition from chemoautotrophic bacteria within their tissues. The types and amounts of gases and ions emanating from the ridge vary along the ridges, as do the species of snails. Three closely related snail species are each found in association with distinct bacterial symbionts. Each group of bacterial symbionts facilitates growth under a different range of ridge chemistries. Resource partitioning and speciation are evidently based not solely on either the snails or their bacterial symbionts, but rather on the close mutualistic association of snail and bacterium.

## Mutualisms may be obligate or facultative.

When one or both sides of a mutualism cannot survive without the other, the association is said to be **obligate**. The association of aphids and bacteria is obligatory for both sides: bacteria cannot live without the shelter the aphids provide, and aphids cannot live without the nutrients provided by the bacteria.

Many other associations are not so tightly intertwined, such that one or both participants can survive without the other. These interactions are termed [facultative](#). For the midges that pollinate cacao, the association is facultative because the midges have other sources of food, including other flowers, in the wet forests they inhabit. For cacao, however, the relationship is obligate because bees and other insects do not usually pollinate them. Thus, their reproduction is more or less dependent on visits by midges.

Many obligate mutualisms are thought to have begun as facultative relationships that became reinforced over time by natural selection. For example, the mutation that originally made a cacao flower sprout from the tree trunk close to the ground rather than high out on a branch made the flower easier for low-flying midges to pollinate while decreasing the chances of bees discovering and pollinating the flowers. If midges were consistently more reliable pollinators than bees, the mutation would have been selected and then spread throughout the population of cacao ([Chapter 20](#)).

## In some interactions, one partner is unaffected by the interaction.

In addition to interactions that benefit both partners and those in which at least one partner is harmed, there are interactions in which one partner benefits and there is no apparent effect on the other. These interactions are called [commensalisms](#). For example, Gray Whales in the Pacific Ocean are commonly covered with barnacles. The barnacles benefit from the association, obtaining both a substrate for growth and a free ride through waters rich in planktonic food. By comparison, the

presence or absence of barnacles doesn't seem to affect the whales one way or the other.

Some ecologists also recognize another class of interaction, called amensalism, in which one species in an interacting pair is harmed with no apparent effect on the other. For example, as they forage for food, elephants in African forests and woodlands commonly destroy trees. This behavior has a harmful effect on birds and insects living in the trees, not to mention the trees themselves, without apparently benefiting or harming the elephant populations. Similarly, wild pigs destroy plants as they plow up acres of soil in forests in their search for roots and small subterranean animals. The spectrum of costs and benefits associated with interactions among organisms is summarized in [Table 45.1](#).

**TABLE 45.1 Major Types of Species Interactions**

| INTERACTION | EFFECT ON EACH SPECIES | EXAMPLE                                                                                                         |
|-------------|------------------------|-----------------------------------------------------------------------------------------------------------------|
| Competition | -/-                    | A grass and a wildflower: Each species loses the water, nutrients, and access to sunlight that the other takes. |
| Predation   | +/-                    | Arctic Foxes and lemmings: Foxes benefit from eating lemmings; lemmings lose opportunities to reproduce.        |
| Herbivory   | +/-                    | Bison and grass: Bison benefit from eating grass; grass loses biomass that is eaten.                            |
| Parasitism  | +/-                    | Tapeworms and humans: Tapeworms benefit from absorbing nutrients in human intestine; humans lose nutrients.     |

|              |       |                                                                                                       |
|--------------|-------|-------------------------------------------------------------------------------------------------------|
| Mutualism    | $+/+$ | Flowers and bees: Flowers gain pollination; bees gain nectar and some pollen.                         |
| Commensalism | $+/0$ | Egrets and cattle: Egrets benefit from insects stirred up by cattle; cattle are unaffected by egrets. |

## Facilitation occurs when one species indirectly benefits another.

In the mutualisms and commensalisms we have considered, species affect each other's fitness through direct interactions. Species can also benefit through indirect interactions. For example, trees may alter the amount of sunlight that reaches the forest floor, creating conditions that benefit particular understory plants. Similarly, kelp forests in the oceans can create suitable habitat for other species. When one species creates an environment that helps another, the interaction is called **facilitation**. Facilitation benefits one species, with the other at least not harmed, so it can include both mutualisms and commensalisms.

This type of interaction can be more complex, as, for example, when two different species attack a third. Both fungi and beetles attack pine tree phloem, and the attack of each benefits the other. Bark beetles facilitate fungi that attack pine trees by providing entryways through their tunnels into the tree, while fungi facilitate bark beetles by lowering the amount of resinous defenses the pines produce. Like insects, bacteria and other pathogens usually attack only one particular type of host tissue, such as the gastrointestinal, respiratory, nervous, or circulatory system. Severe infections can sometimes render the hosts more susceptible to infection by other pathogens.

## The costs and benefits of species interactions can change over time.

Associations are not fixed: they can change over time. A mutualism can, in some cases, become antagonistic if one of the partners “cheats” by imposing a larger cost than benefit on the other. In fact, mutualisms that are loose associations among changing partners can become one sided rather quickly. For example, many plants have evolved tubular flowers that guide bees past their anthers or stigma on the way to the nectar at the base. Navigating this route takes just a little more time for the bees, which try to visit as many flowers as possible. Some bees have short-circuited this plant mechanism by nipping the flower base from the outside and then drinking the nectar without pollinating the flower. Most plants have enough successful pollination to ensure seed production, but losses from cheating can still be costly.

Some interactions begin as a benefit to one species, with no benefit or cost to the other species. For example, cattle egrets follow water buffalo to pick up the insects stirred up by the buffalo as they pass. The egrets gain food, but the buffalo are not affected either way—an example of commensalism ([Fig. 45.11](#)). However, cattle–egret commensalism can become mutualism over time if the egrets give early warnings of nearby predators such as lions or eat insects like tsetse flies that carry diseases harmful to the buffalo.

Source: Biosphoto/Gérard Lacz.

**FIG. 45.11 Changing costs and benefits.** Egrets feed on insects stirred up by water buffalo, which are usually not affected by the egrets—a commensalism. If, however, the egrets spot lions and the poor-sighted buffalo take warning, the relationship becomes a mutualism.

#### Self-Assessment Questions

6. What are some of the costs and benefits to an apple tree and to the honeybee that pollinates it? Which kind of interaction is this?
7. Give an example of an obligate mutualism. Why is it considered obligate?

## 45.4 COMMUNITIES

We have been discussing how species interact and how these interactions can shape the distributions of populations, limiting distributions in one way or another. Now we look collectively at all the species that occur together in the same place. How, and to what extent, do species interact? What are the properties of these interacting sets of species?

### Species that live in the same place make up communities.

A **community** is the set of all populations of two or more different species found in a given place at a particular time. Populations in a community, whether a salt marsh, mountaintop, or desert, are connected by their various interactions as well as by their physical location. The populations in a local community share the same rainfall, climate, and soil, and often encounter one another physically as they grow, reproduce, and die. Some provide food or shelter for others, and all end up being recycled by the many small decomposers in the soil. We often characterize communities by the principal plants and animals they harbor, such as the cacti and lizards of deserts, the tiny, rock-loving mosses and marmots of a mountaintop, or the grasses and mosquitoes of the coastal salt marsh. Indeed, communities often seem quite distinctive to us and easily recognized. At first glance, it would even appear that the plants and animals and fungi that live in one kind of place might be competing for the same local resources.

When we look at the details of where particular species occur,

almost no two species have exactly the same geographic distribution. Consider the bogs of northern New England, as shown in [Fig. 45.12](#). This community is made up of Black Spruce, Bog Club Moss, and other bog-loving species of plants. They all occur in this area because of their mutual preference for the water-saturated, acidic, sandy soils found in northern bogs. But when we look more closely, we find that these different species of plants have only partially overlapping geographic ranges. Black Spruce populations occur from New England north through Canada, while Bog Club Moss populations occur as far south as Virginia. Even in one location, such as Victory Bog in northern Vermont, the Black Spruce and Bog Club Moss are not distributed in exactly the same way across the wet bog and surrounding woods. Nevertheless, we focus on the assemblage of species that occur in a particular place to discuss their interactions with each other.

*Source: Erin Paul Donovan/Alamy.*

Fig. 45.12. A bog community. This community in northern New England consists of bog-loving species of plants, such as Black Spruce and Bog Club Moss.

The activities of different populations in a community vary in time

as well as space. For example, flies are active during the day, pollinating flowers that open in the morning. Likewise, predators of the flies, such as dragonflies and birds, are active during the day. In contrast, moths are active at night, as are the spiders and bats that prey on moths. Similarly, in coastal marine communities, oysters, crabs, and many other animals follow the daily rise and fall of tides. And, of course, the activities of many species change seasonally in responses to sunlight, temperature, and rainfall. The protein-rich insects that birds prey on to feed their young are most abundant in the spring, and fruits and seeds rich in the oils that migratory birds need to supply fat reserves are mostly available in late summer and fall.

---

## CASE 8 CONSERVING BIODIVERSITY: RAINFOREST AND CORAL REEF HOTSPOTS

### How is biodiversity measured?

A key feature of any community is its **biodiversity**, or biological diversity. Biodiversity is often taken to mean the number of species, but we can also think of it more broadly and at many levels, including the variety of genetic sequences, cell types, metabolisms, species, life histories, phylogenetic groups, and communities. We can also consider biodiversity for a particular place, such as a single tropical rainforest on the island of Hispaniola, or the whole island of Hispaniola, or the entire planet.

Biodiversity is usually first measured by counting the number of species present in a particular area, known as the species richness.

Because of limitations in time and expertise, scientists often focus on a subset of the taxonomic groups present. One approach is to start with the number of plant species. In terrestrial environments, the number of plant species is often a good predictor of total species diversity. For example, there are approximately four times as many animal species as plant species known on Earth. Therefore, scientists estimate the numbers of animal species by multiplying the number of plant species by 4. These animal species include arthropods and other small animals that live on or near the plants, birds and other vertebrates that prey on the insects and plants, and larger predators that prey on these birds and other vertebrates.

Another aspect of biodiversity is the relative proportions of individual species in a community, known as species evenness. Consider two communities of 100 individuals distributed across 10 different species of plants. The number of individuals of each species can differ greatly between the two communities. The first community might have 91 individuals of a single plant species and one individual each of 9 other plant species, while the second community might have 10 individuals of each of the 10 species of plants. The two communities have the same number of species, or species richness, but the second community is more even.

This idea of differences in evenness among communities can be measured and used to compare communities. Species evenness is an important measure because a community that is dominated by a single species may be more vulnerable to pathogens or unusual environmental conditions than a community in which every species is equally

abundant. Of course, when determining evenness, the samples must be taken in the same way in the two places to avoid possible biases in sampling one community more intensely than another. Such measures of evenness, therefore, are most feasible and appropriate for local communities that can be sampled in a repeatable, consistent way in different places.

When we are comparing the biodiversity of regions or countries, however, we usually have only the most basic information on the total numbers of species, and for most kinds of organisms, we don't even have that. For most communities on the planet, the richness of their flowering plant species is among the best-known elements of biodiversity, rivaled only by knowledge of the birds or mammals. In contrast, the number of species of the main plant pollinators, consumers, and decomposers, and the insects and fungi in communities around the world, is poorly known. On the island of Hispaniola, for example, nearly every flowering plant species, approximately 6000 in all, is known (and so are the birds and mammals). Because scientists estimate that there are about two to three times as many kinds of insects as flowering plants at any given place on earth, the number of insect species on Hispaniola will likely total 12,000 to 18,000 once all have been identified. Indeed, each year new studies of different insect groups are published that report a doubling or tripling of the known species. For example, recent intensive studies of fireflies on Hispaniola reported a new total of 69 species, up from the 17 previously known.

Tropical islands such as Hispaniola, Hawaii, and the Galápagos are also missing elements of biodiversity because certain species have not

been able to migrate there from the nearest mainland. For example, only a few of the many South American frog and lizard groups are found on Hispaniola, and only large iguanas made it to the Galápagos Islands, which are even farther away from the mainland. Thus, the ability of organisms to disperse from one place to another influences biological diversity by limiting the kinds of immigrants.

## Species influence each other in a complex web of interactions.

The interactions among all the populations in a given habitat define the nature of that community. In habitats with many different predator and prey species, identifying the ways that each species affects others can be challenging. For this reason, much research on how predators and prey influence community structure has been carried out in the Arctic, where communities tend to have relatively few species.

One well-studied community is on Bylot Island in the Canadian territory of Nunavut. There, lemmings and Snow Geese are the main herbivores, eating grasses and other low plants that grow on the island. The main predators of lemmings and snow geese are Arctic Foxes and Snowy owls. Lemmings, foxes, Owls, geese, and plants are linked by a set of interactions illustrated in [Fig. 45.13](#). Lemming populations rise and fall every 4 years or so. When lemming populations decline, foxes turn to other prey, including Snow Geese. The population density of Snow Geese, therefore, is indirectly influenced by the population density of lemmings. When the foxes focus on the Snow Geese as a food source, the now harder-to-find lemmings escape, allowing lemming populations to increase again. Snowy Owls chase the foxes

away, which in turn indirectly benefits snow geese, which are preyed upon by foxes when lemming populations are low.

## Keystone species have disproportionate effects on communities.

While all or nearly all species in a given place have some effect on one another, the integrity of a community may depend on a single species.

This situation can occur when one species influences the interactions of species in the community downstream of its own, or when the species modifies its physical environment, as beavers do when they make ponds. Pivotal populations are called **keystone species** because they support a community in much the same way that an architectural keystone supports an arch. Although all species contribute to the structure of a community, a keystone species affects other members of the community in ways that are disproportionate to its abundance or biomass.

A classic experiment by American zoologist Robert Paine in the 1960s gave birth to the concept of keystone species. Along the northwestern coast of the United States, mussels adhere to rocks in the intertidal zone, where they coexist with about two dozen other species of invertebrate animals and seaweeds. Mussel populations are regulated by their principal predator, a sea star called *Pisaster ochraceus*. When Paine removed the sea star from experimental plots, mussel populations exploded, outcompeting other animals and seaweeds for space and so eliminating the other animals and plants from the rocky shoreline. Control plots in which the sea star remained present showed no such change. From these results, Paine concluded that the activities of the predatory sea star had a singularly strong influence on the diversity and distribution of other populations in the rocky intertidal community. *Pisaster ochraceus* is a keystone species.

Another experiment, this time unintended, drives home the point. Along the west coast of the United States and Canada, giant kelp grow more than 50 m tall, providing a home for a remarkable diversity of

fish and invertebrates ([Fig. 45.14](#)). The kelp community depends strongly on a single predator: the sea otter. Sea otters prey on sea urchins, which graze on the rootlike holdfasts that anchor kelp to the seafloor. When the otters were removed by overhunting decades ago, sea urchin abundance soared and the kelp nearly disappeared, along with many other populations that live in kelp forests. Now, in areas where otters are protected, they again keep urchin populations in check, enabling the kelp to return, and along with it, diverse fish and animal species.

Keystone species called ecosystem engineers actively shape the

physical environment, creating habitat for others. The classic example is beavers, which produce ponds by damming streams in forests, creating habitat that would not otherwise exist ([Fig. 45.15](#)).

Hippopotamuses provide another only recently recognized example of this role. In East Africa, hippos loll about in rivers and lakes during the day, but venture onto the land at night to feed on grasses and other low-lying plants. The hippos return to the water before the sun rises and—importantly—defecate in their watery home. In this way, hippos transfer a substantial amount of nutrients from land to river, and these nutrients support a community that is more abundant and diverse than would be possible in the absence of hippos.

FIG. 45.15 An ecosystem architect's effect on the environment. This satellite image shows the world's largest beaver dam in Alberta, Canada, which has flooded the surrounding area, creating a new habitat.

## Disturbance can modify community composition.

Earlier, we discussed how predation, herbivory, and parasitism can reduce the effects of competition ([section 45.2](#)). Severe physical impacts on a habitat, such as those caused by storms, earthquakes, or road building, can also dramatically lower the abundances of some species. For example, fire may remove the grasses and trees in a woodland, with the species that depend on them, such as deer and birds, then disappearing. Such events are known as disturbances, and they have effects on populations of interacting species that are independent of their densities, which we discussed in [Chapter 44](#). Disturbances often affect multiple species in the same community, thereby exerting a strong influence over community composition. We usually think of disturbances as abiotic, but the line is not so clear when we consider road building by humans, for example, or dam building by beavers.

The impact of severe weather in forests demonstrates how disturbance can affect a community. When wind takes down tall trees in a forest, it also takes away the shade that had prevented some species from establishing new seedlings. Fires are frequent sources of disturbance in regions with a seasonally dry climate, such as parts of western North America and southwestern Australia. Like storms, fires remove existing plants and animals, opening up habitat for recolonization. Some species have adapted to frequent fires. For example, several pine species have evolved thick bark and high branches, traits that help protect them from fire. Other pines, which

have evolved cones that open only in the wake of fire, have adapted to use the habitat space opened up in the aftermath of the fire and the nutrients that dead plant matter releases into the soil.

Noting the influence of storms on community composition in forests and coral reefs, American ecologist Joseph Connell proposed in the 1970s that the diversity of species in a given community reflects, at least in part, the frequency and intensity of disturbance. If disturbance is intense, few species can tolerate the physical conditions of the habitat and diversity is low. By comparison, if disturbance is rare or weak, competition may take over and only a few, stronger, competitors may remain in the community. Species diversity tends to be highest when disturbance is frequent or intense enough to inhibit competition, but not so strong as to limit the number of species that can tolerate the environment.

## Succession describes the community response to new habitats or disturbance.

Following disturbance or the appearance of a new habitat, a community goes through a series of changes. These changes involve a predictable sequence of colonizations by species that transform the community, in what can appear to be a linear process of maturation. Each species modifies the habitat by affecting the environment or changing the community structure, creating opportunities for other kinds of species to colonize. The pace of this transformation may be rapid, occurring over a few decades, or it may be much slower,

depending on the environment.

This process of species replacing each other in time in a predictable sequence is called **succession** (Fig. 45.16). Ecologists sometimes differentiate between the colonization of a new and previously uninhabited area (such as land exposed by a retreating glacier, an important factor following the last ice age, and again today), known as primary succession, and the reestablishment of communities following disturbance, known as secondary succession. Whether succession is primary or secondary, the succession of species reflects the adaptations of each species to the changes in sunlight, soil, water, and space that occur as the first organisms arrive, mature, and die. These organisms influence their habitat in both life and death, whether aquatic or terrestrial.

FIG. 45.16 Succession. In new habitats or following disturbance, species colonize and transform the habitat in a predictable sequence that reflects the adaptations of participating species.

Succession over thousands of years can turn bare rock into forest.

Lichens are often the first organisms to colonize the bare rock newly formed by cooling lava or exposed by landslides. Initially, only a few mites and other tiny invertebrates may live in the lichen. As the stones weather, and microorganisms feed on the lichen and on one another, they form particles of soil that accumulate in cracks and crevices. Eventually, small plants, such as sedges and grasses, take root, and the growing plant community begins to gain height and diversity as other plants establish themselves.

Soon, larger insects, spiders, and other invertebrates join the community, as well as the first small mammals and birds. Many of these early colonizing species are *r*-strategists ([Chapter 44](#)), growing and reproducing quickly, and spreading their young far and wide. Birds carry the seeds of shrubs and other plants in their droppings, and the gradually deepening soil eventually permits the establishment of shrubs that in turn provide habitats for larger mammals and birds, and perhaps snakes and salamanders.

The first sun-loving trees, such as birches and pines, appear next, providing shade for the seedlings of later colonizing trees such as oaks and maples. In many forests, stable, long-lived *K*-strategists ([Chapter 44](#)) make up a final stage in the succession, forming a mature assembly commonly called a climax community. A [climax community](#) is one in which there is little further change in species composition.

The Pin Cherry, a resident of New England forests, illustrates how the life histories of individual species can contribute to succession. If you walk through a forest in New Hampshire, you will see oak trees

and beeches, pine and hemlock. A mature forest may contain few or no Pin Cherry trees. However, if you examine seeds lying dormant within the forest soil, you will see numerous Pin Cherry seeds. How did they get there?

Years earlier, disturbance from a storm or fire opened up the forest floor in these areas. Pin Cherries established themselves in the now-sunlit soils, growing from seeds left in the droppings of birds that had consumed the cherries elsewhere. The seedlings of Pin Cherries grow well in full sunlight, so the trees grew rapidly to reproductive maturity. Pin Cherries are considered *r*-strategists because they thrive in unpredictable openings in the forest, with few competitors, and reproduce early in life. Eventually, though, Pin Cherries and other pioneering species such as birches are shaded out by *K*-strategists such as oaks and beeches.

Once a forest canopy is established, Pin Cherries disappear because their seeds do not germinate in the shade, although the seeds remain on the forest floor. In contrast, oak seedlings prosper in shade. Over time, oaks and other shade-loving species come to dominate this patch of forest, forming a climax community that other tree seedlings cannot enter. They will continue to dominate it until the next disturbance, when the removal of mature trees will once more expose the forest floor to bright sunlight, literally giving Pin Cherries another day in the sun.

Each stage of plant succession is accompanied by changes in the animals (and fungi) associated with them and the habitat they create.

The pioneering Pin Cherry is colonized quickly by tent caterpillars that cannot feed on the later climax species of oaks or beeches. Later, acorns and beech nuts support rodents such as squirrels and mice, as well as nut weevils, and the large trunks of these trees provide homes for woodpeckers and other species that cannot nest in small Pin Cherry trees. Underground, the fungi associated with the roots of these different trees also undergo succession in parallel, as do the insects that feed on them. Entire assemblages of species turn over as sunlight and other physical factors change along with the succession of species that depend on them and each other.

## Island biogeography explains species diversity on habitat islands.

Islands allow us to examine patterns of ecological succession as well as the number of species (the species richness) in a particular area.

Species diversity of an island reflects both the rate at which new species arrive on the island and the rate at which species already on the island become extinct ([Fig. 45.17](#)). As species arrive on an initially uninhabited island, the colonization rate is high because there are no predators yet and the small number of colonists means that there is little competition for resources. Over time, as more species arrive and successfully establish populations on the island, the rate of colonization slows because competition and predation increase, making successful colonization of newly arrived species more difficult. At this point, there is also a smaller number of species left in the pool of potential colonists. In contrast, the extinction rate increases as newly arrived species compete.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 45.17 Island species diversity, a balance of colonization and extinction.

At some point, a balance is achieved between the arrival of new species and the loss of species by extinction. At this point, diversity is said to be at equilibrium ([Fig. 45.17](#)). This does not mean that no new species will colonize the island, but instead that the establishment of a new colonist species will be matched by the extinction of one already in place. There is generally turnover in species composition through time.

The [theory of island biogeography](#), articulated in 1967 by the American biologists Robert MacArthur and Edward O. Wilson, states that the number of species that can occupy an island depends on two factors ([Fig. 45.18](#)). The first factor is the size of the island. Because of their size, larger islands receive more colonists than smaller ones.

Furthermore, larger islands can support more species than smaller ones can. For these reasons, the equilibrium number of species for larger islands is greater than that for smaller islands ([Fig. 45.18a](#)). The second factor is the distance of the island from a source of colonists. More distant islands have lower rates of colonization, reducing the number of species at equilibrium ([Fig. 45.18b](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 45.18 Effect of (a) island size and (b) distance from source populations on the equilibrium number of species on an island.

Wilson and his student Daniel Simberloff tested the theory of island biogeography in a novel way. Working among small mangrove islands off the Florida Keys, they used short-term insecticides to remove all the arthropods living on individual islands. Over the next few years, the researchers followed ecological succession as new arthropod populations established themselves on the islands. They found that the species diversity of islands differing in size and distance from shore corresponded to those predicted by the theory. Larger and closer islands had more successful colonists, whereas smaller and more distant islands had fewer colonists.

**Fig. 45.19** shows the relationship between island size and species number. Similar relationships between island size and equilibrium species diversity have been observed repeatedly in various locations. The relationship is described mathematically as a **species–area relationship**:

$$S = cA^x$$

where  $S$  is the number of species at equilibrium,  $c$  is a mathematical constant that depends on the species in question,  $A$  is the habitat area, and  $x$  is an experimentally determined exponent that relates island size ( $A$ ) to the number of species ( $S$ ) on the island and is between 0.1 and 0.4. The observation that the value of  $x$  falls in this narrow range indicates not only that larger islands support more species than smaller ones, but also that there is a quantitative, consistent relationship between island size and species number.

FIG. 45.19 Island size and number of species. The diversity of amphibian and reptile species on Caribbean islands fits the predictions of island biogeography theory. Source: After R. H. MacArthur and E. O. Wilson, 1967, *The Theory of Island Biogeography*, Princeton, NJ: Princeton University Press.

This mathematical formula translates into a useful back-of-the-envelope relationship: a ten-fold increase in island size results in a doubling of species diversity. Perhaps more relevant for conservation, a 90% reduction of habitat area results in a 50% loss of species diversity if no other factors are taken into account. The species–area relationship applies to habitat islands as well as true islands, and it holds broadly for areas as large as continents. This relationship has many applications in conservation biology. For example, it is used to determine how large a protected area must be to support some species and how close reserves must be to one another to ensure the movement of at least some individuals between them.

Many oceanic islands, such as Hawaii and the Galápagos, are

volcanic in origin, so they began with no organisms at all. Their histories provide models both for habitat islands and for ecological succession. We follow changes over time in an aquatic and terrestrial habitat to summarize key concepts about population growth, species interactions, and communities in [Fig. 45.20](#). We also introduce ways in which humans affect these processes, a topic that we revisit in [Chapter 48](#).

## Self-Assessment Questions

8. Lemmings affect many other species in the Bylot Island community. Why are lemmings not considered a keystone species?
9. What are three factors that help determine the species

composition of a community?

10. How can a physical disturbance, such as a drought, affect community composition?
11. What is meant by “ecological succession”? Give an example.
12. Which factors determine the diversity of species on a habitat island? What is the relevance of these factors in managing the habitat of an endangered species?

## CORE CONCEPTS SUMMARY

**45.1 THE NICHE:** The niche encompasses the physical habitat and ecological role of a species.

The niche reflects the biological and nonbiological factors that determine where an organism lives and how it functions. [page 1019](#)

The fundamental niche is the full range of physical conditions and food resources that permit an organism to live. [page 1020](#)

The realized niche is the actual range of habitats where an organism lives. It is often smaller than the fundamental niche because of competition, predation, and other interactions between species. [page 1020](#)

Many closely related species have broadly similar niches as a result of their shared evolutionary history. [page 1021](#)

**45.2 ANTAGONISTIC INTERACTIONS:** Competition, predation, parasitism, and herbivory are interactions in which at least one species is harmed.

Competition is a form of interaction in which two individuals of the same or different species use the same limited resource. [page 1022](#)

Intraspecific competition is competition between individuals of a single species; interspecific competition is competition between individuals of different species. [page 1022](#)

Individuals can compete for food, space, mates, or other resources. [page 1022](#)

Competitive exclusion prevents two species from occupying the same niche at the same time. [page 1022](#)

Over time, competitive exclusion can lead to resource partitioning, in which two species evolve in such a way that they occupy different niches. [page 1023](#)

Predation, parasitism, and herbivory are interactions in which one species benefits and one is harmed. [page 1024](#)

**45.3 MUTUALISTIC INTERACTIONS:** Mutualisms are interactions in which both species benefit.

In mutualism, the benefits to both species outweigh the costs of participation. [page 1026](#)

Mutualisms can be obligate, meaning that they are required for survival or reproduction, or facultative, meaning that they are not required. [page 1029](#)

Obligate mutualisms can strongly influence the evolution of both partners, whose lineages may remain associated through their respective joint speciation and diversification. [page 1029](#)

Interactions in which one species benefits and the other is unaffected are commensalisms. [page 1029](#)

Facilitation is a type of indirect interaction where one species creates a suitable habitat for another. [page 1030](#)

Species interactions can change over time. For example, partners can become parasites. [page 1030](#)

**45.4 COMMUNITIES:** Communities are composed of local populations of multiple species that may interact with each other.

An ecological community consists of all the organisms living in one place at a given time. [page 1031](#)

Biodiversity, or biological diversity, includes the diversity of genetic sequences, cell types, metabolisms, species, life histories, phylogenetic groups, and communities. [page 1032](#)

Biodiversity is often measured by the number of species present in a given area. [page 1032](#)

Populations of consumers and producers may affect each other directly through the act of consumption or indirectly by influencing competition and other kinds of interactions. [page 1032](#)

Keystone species have a large influence on the composition of a community disproportionate to their numbers. [page 1033](#)

Physical disturbances, such as a storm or drought, can reshape communities. [page 1034](#)

Succession is the predictable order of species colonization and replacement in a new or newly disturbed patch of habitat. [page 1035](#)

Species diversity on habitat islands reflects both the rate at which new species arrive and the rate at which colonist species become extinct. [page 1036](#)

The theory of island biogeography proposes that the number of

species that can occupy an island depends on the size of the island and its distance from the mainland. [page 1036](#)

# CHAPTER 46 Ecosystem Ecology

Andre Gallant/Getty Images

---

## CORE CONCEPTS

**46.1 THE SHORT-TERM CARBON CYCLE:** Photosynthesis and respiration are the key biochemical pathways for the biological, or short-term, carbon cycle.

**46.2 THE LONG-TERM CARBON CYCLE:** Physical processes govern the carbon cycle on longer timescales.

**46.3 FOOD WEBS AND TROPHIC PYRAMIDS:** Species interactions cycle carbon and transfer energy through ecosystems.

**46.4 OTHER BIOGEOCHEMICAL CYCLES:** Nitrogen and

phosphorus also cycle through ecosystems.

#### **46.5 THE ECOLOGICAL FRAMEWORK OF BIODIVERSITY:**

Biogeochemical cycles help us understand the evolution of biological diversity.

---

In previous chapters, we have seen how the functional characteristics of different species link them together in ecological interactions. Species compete with one another, prey on each other, and respond in varying ways to disturbance. All of these interactions help to shape communities, the associations of species that live together at a given time in a given place. But populations do not interact only with other populations; they also interact with their physical environment in intimate ways. An **ecosystem** consists of the organisms in a community and their physical environment, with each influencing the other through time. Ecosystem ecology, then, explores the processes that link the physical and biological Earth, both the ways that physical environments shape communities and the ways that organisms affect the physical environment. Biogeochemical cycles, the pathways by which biologically important elements move back and forth between Earth and life, provide a fundamental illustration of ecosystems at work.

## 46.1 THE SHORT-TERM CARBON CYCLE

Let's imagine that we could tag a carbon atom at its moment of origin and then follow its odyssey through time and space. Formed in a nuclear blast furnace deep within an ancient star and then ejected into space as the star exploded in death, our atom was eventually swept up with other materials to form the Earth, a small planet orbiting the newer star we now call the sun. Volcanoes introduced our carbon atom into the early atmosphere as carbon dioxide ( $\text{CO}_2$ ). Slowly, over millions of years, this  $\text{CO}_2$  reacted chemically with water and rocks, transferring the carbon to limestone that accumulated on the seafloor. Here, our atom sat for many millions of years, until earthquakes, erosion, or other geologic activities returned it to the atmosphere as, once again,  $\text{CO}_2$ . Slowly but surely, geologic processes on the early Earth cycled carbon from atmosphere to rocks, and back again.

Sometime between 4 and 3.5 billion years ago, our carbon atom began to cycle more rapidly—much more rapidly. Communities of interacting microorganisms began to cycle carbon through metabolism, with photosynthetic microorganisms converting  $\text{CO}_2$  into organic molecules, and respiring microorganisms returning  $\text{CO}_2$  to the environment. To this day, the biological carbon cycle endlessly propels our atomic wayfarer from atmosphere and oceans to cells and back again, while the slow burial of organic matter and limestone in sedimentary rocks continues to bring carbon atoms to the solid Earth, returning them to the atmosphere only slowly, on geologic timescales.

The [carbon cycle](#) is the intricately linked network of biological and physical processes that shuttles carbon among rocks, soil, oceans, air, and organisms. Why focus on carbon? Because the carbon cycle provides an organizing principle for understanding life on Earth. The chemistry of life is, in no small part, the chemistry of carbon. When we discuss primary producers and consumers, predators and prey, or decomposers, we are really talking about how carbon moves from one species to another, and between organisms and their surrounding environment. Photosynthetic organisms convert the energy of the sun to chemical energy in carbon molecules, and consumers gain energy by eating those molecules. Thus, the carbon cycle also traces the transfer of energy through ecosystems. In short, the cycling of carbon and other biologically important elements underpins both the efficient functioning of ecosystems and their persistence over an immense span of time. The carbon cycle, therefore, focuses our attention on the ways that physical and biological processes together determine the properties of ecosystems. In addition, it provides a basis for assessing the role that humans play in our environmental present and future.

## The Keeling curve records changing levels of carbon dioxide in the atmosphere over time.

In 1958, American chemist Charles David Keeling began a novel program to monitor the atmosphere. At the time he began his study, scientists had only a vague notion of how CO<sub>2</sub> behaves in air. Many thought that the CO<sub>2</sub> concentration might vary unpredictably from time to time, and from place to place. Keeling decided to find out if, in fact,

it did.

From five towers set high on Mauna Loa in Hawaii, 3400 m above sea level, Keeling sampled the atmosphere every hour and measured its composition with an infrared gas analyzer. Within the first few years of his project, a pattern of seasonal oscillation became apparent: CO<sub>2</sub> concentration in the air reached its annual high point in spring, but then declined by about 6 parts per million (ppm, by volume) to a minimum in early fall ([Fig. 46.1](#)). Such regular variation was unexpected: what could be causing it?

CO<sub>2</sub> concentrations over half a century, measured from an observatory at Mauna Loa, Hawaii. *Data from Dr. Pieter Tans, NOAA/ESRL ([www.esrl.noaa.gov/gmd/ccgg/trends/](http://www.esrl.noaa.gov/gmd/ccgg/trends/)) and Dr. Ralph Keeling, Scripps Institution of Oceanography ([scrippsco2.ucsd.edu/](http://scrippsco2.ucsd.edu/)).*

Perhaps the pattern was local, the researchers thought. Airplane traffic to Hawaii peaked in winter, and maybe that was affecting the air around Mauna Loa. As measurements continued through a number of years, however, the pattern persisted, even as trends in air traffic changed. Moreover, monitoring stations in many other parts of the globe gave similar results. Knowing that the Mauna Loa measurements are representative of the atmosphere as a whole allows us to appreciate what an annual variation of 6 ppm really means. With calendar-like regularity, approximately 47 billion metric tons of CO<sub>2</sub> enters and leaves the atmosphere annually—that's 13 billion metric tons of the element carbon (the rest of the mass is oxygen). To explain such a pattern, we must consider processes that affect the planet as a whole.

A second pattern is evident in [Fig. 46.1](#). Summertime removal of CO<sub>2</sub> from the atmosphere does not quite balance winter increase, with the result that the amount of CO<sub>2</sub> in the atmosphere on any given date is greater than it was a year earlier. Atmospheric CO<sub>2</sub> levels have increased steadily through the period of monitoring. For example, in 1958 the maximum monthly value recorded for CO<sub>2</sub> was 317 ppm; in April 2018 the CO<sub>2</sub> level reached 410 ppm. This is an increase of about 30%, and the rise does not appear poised to slow or stop any time soon.

What causes atmospheric CO<sub>2</sub> to vary through the year and over a timescale of decades? To answer this question, we need to ask which

processes introduce CO<sub>2</sub> into the atmosphere and which processes remove it. Carbon dioxide is added to the atmosphere by (1) geologic inputs, mainly from volcanoes and mid-ocean ridges, where CO<sub>2</sub> is emitted as new seafloor forms; (2) biological inputs, especially respiration; and (3) human activities, including deforestation and the burning of fossil fuels.

Processes that remove CO<sub>2</sub> from the atmosphere include (1) geologic removal, especially by chemical weathering, in which CO<sub>2</sub> in rainwater reacts with exposed rocks, and (2) biological removal, mainly through photosynthesis, in which CO<sub>2</sub> is turned into organic molecules used for growth and reproduction. As we will see in the next section, geologic processes play key roles in the carbon cycle on timescales of centuries and longer. Only biology, however, can account for the annual rhythm of the Keeling curve.

## Photosynthesis and respiration are key processes in short-term carbon cycling.

To grow, all organisms require both carbon and energy. As we saw in [Chapter 8](#), photosynthetic organisms use energy from the sun to form ATP and NADPH, which reduce CO<sub>2</sub> to carbohydrates. As photosynthesis pulls CO<sub>2</sub> out of the atmosphere (or water, for aquatic organisms), the carbon is transferred to carbohydrates in the Calvin cycle, and oxygen is given off as a by-product. The overall chemical reaction is shown here:

It is estimated that photosynthetic organisms remove approximately 210 billion metric tons of carbon (in nearly 770 billion metric tons of CO<sub>2</sub>) from the atmosphere each year, with land plants removing approximately half of this mass and phytoplankton and seaweeds in the oceans removing the rest. This annual photosynthetic removal of CO<sub>2</sub> equals approximately 25% of the total CO<sub>2</sub> in the atmosphere. In the absence of processes that restore CO<sub>2</sub> to the atmosphere, high rates of photosynthesis would use up the atmospheric reservoir of CO<sub>2</sub> in just a few years. But the Keeling curve tells us that atmospheric CO<sub>2</sub> is not decreasing rapidly; instead, it is rising. Moreover, the geologic record indicates that photosynthesis has fueled ecosystems for billions of years without causing catastrophic CO<sub>2</sub> depletion.

Which processes return CO<sub>2</sub> to the atmosphere, balancing photosynthetic removal? In [Chapter 7](#), we discussed aerobic respiration. Humans and many other organisms gain both the energy and carbon needed for growth from organic molecules (that is, by consuming food). As explained in [Chapter 7](#), aerobic respiration uses oxygen to oxidize organic molecules to CO<sub>2</sub>, converting chemical energy in the organic molecules to ATP for use in cellular processes. Aerobic respiration can be summarized by this chemical equation:

Plants respire, too, thereby converting the chemical energy in carbohydrates into useful work. On the present-day Earth, the amount of CO<sub>2</sub> returned annually to the atmosphere by aerobic respiration and related processes is about equal to the amount that plants and algae remove by photosynthesis. That is why photosynthesis does not deplete

the CO<sub>2</sub> in air.

As we discussed in [Chapter 8](#), the equations for oxygenic photosynthesis and aerobic respiration mirror each other. Photosynthesis continually converts CO<sub>2</sub> to organic molecules, using energy from the sun, and respiration harvests the chemical energy stored in organic molecules, releasing CO<sub>2</sub> and water in the process. Photosynthesis and aerobic respiration are complementary metabolic pathways: each uses the products of the other and generates a new supply of substrates for its complement. Anoxygenic photosynthesis and anaerobic respiration also form complementary metabolisms. The result is a cycle, called the short-term, or biological, carbon cycle ([Fig. 46.2](#)).

The regular oscillation of CO<sub>2</sub> reflects the seasonality of photosynthesis in the Northern Hemisphere.

Now that we have identified the major processes in the short-term (days to decades) carbon cycle, we can examine what makes atmospheric CO<sub>2</sub> level oscillate seasonally. Except in a narrow band around the equator, photosynthesis is seasonal: it occurs at higher rates in the summer and at lower rates in the winter, when many plants go dormant and deciduous trees shed their leaves. Respiration, in contrast, remains more or less constant through the year.

Even a quick look at the globe shows that land is distributed asymmetrically, with more land—and hence more plants—in the Northern Hemisphere than in the Southern Hemisphere. For this reason, global atmospheric CO<sub>2</sub> declines through the northern summer, when rates of photosynthesis are highest relative to respiration, and then increases through fall and winter, when the ratio of photosynthesis to respiration is reversed. The result is the seasonal oscillation of atmospheric CO<sub>2</sub> levels documented by Keeling.

## Human activities play an important role in the modern carbon cycle.

Now let's consider the second major pattern evident in the Keeling curve. Although CO<sub>2</sub> levels oscillate on an annual basis, the overall pattern is one of sustained increase. During the 1960s, the observed increase was less than 1 ppm each year. In contrast, in 2016, atmospheric CO<sub>2</sub> increased by 3 ppm. The current level of atmospheric CO<sub>2</sub> is 30% higher than it was 60 years ago. Why has CO<sub>2</sub> input into the atmosphere outstripped removal for the past half century? Should we consider this pattern unusual?

Answering the second question helps us to address the first. The question of whether it is unusual for atmospheric CO<sub>2</sub> to increase 30% in 60 years can be answered only if we can compare the Keeling curve with longer records of atmospheric CO<sub>2</sub> levels. Before Keeling began his monitoring, researchers had not systematically collected air samples. Fortunately, however, nature did it for us.

When glacial ice forms, it traps tiny bubbles of air. Each year, snowfall gives rise to a new layer of ice, and as layers accumulate through time, their bubbles preserve a history of the atmosphere. The graph in [Fig. 46.3](#) shows the amount of CO<sub>2</sub> in air bubbles trapped in Antarctic ice that has accumulated over the past 1000 years. Ice samples show that CO<sub>2</sub> levels actually began to increase slowly in the 1800s, the time of major transformations in mining, manufacturing, and transportation we call the Industrial Revolution. Before that period, atmospheric CO<sub>2</sub> levels had varied little since the Middle Ages, staying at 270–280 ppm for centuries on end. On a 1000-year timescale, then, big changes in CO<sub>2</sub> abundance happened only over the last 200 years. Atmospheric CO<sub>2</sub> inputs and outputs were approximately in balance until the Industrial Revolution.

#### HOW DO WE KNOW?

### FIG. 46.3

How much CO<sub>2</sub> was in the atmosphere 1000 years ago?

#### BACKGROUND

Direct measurements of the atmosphere show that CO<sub>2</sub> has increased by

nearly 30% over the past 60 years. Is this pattern representative of atmospheric change over the past millennium, or is the pattern recorded by the Keeling and his successors unusual?

#### OBSERVATION

Scientists recognized that the snow that accumulates on glaciers to form new layers of ice is initially full of small spaces that are in contact with the air. Through time, as snow changes to ice, these spaces become sealed off from the surrounding environment and form bubbles, preserving a sample of air at the time of ice formation. Cores drilled through glacial ice, then, provide an opportunity to view the Keeling curve within a longer framework of time.

Ice core drilled from a glacier in Antarctica

Viewed under the microscope, glacial ice contains small bubbles that trap samples of air.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

Photo sources: (left) Courtesy of Ted Scambos and Rob Bauer, National Snow and Ice Data Center, University of Colorado, Boulder; (right) Courtesy of Vin Morgan.

#### MEASUREMENTS

By identifying chemical indicators that vary on an annual basis in successive layers of ice, scientists were able to assign ages to ice samples taken from cores drilled through the Law Dome, a large ice dome in Antarctica. The youngest ice samples overlap in age with the first part of the Keeling data, providing a check that air samples trapped in ice have

CO<sub>2</sub> concentrations similar to those in air measured directly over the same interval.

## CONCLUSIONS

Before the Industrial Revolution, atmospheric CO<sub>2</sub> levels had varied little over 1000 years, generally ranging between 270 and 280 ppm. From this, scientists have concluded that current changes in atmospheric CO<sub>2</sub> are unusual on the timescale of the past millennium.

SOURCE Etheridge, D. M., et al. 1996. "Natural and Anthropogenic Changes in Atmospheric CO<sub>2</sub> over the Last 1000 Years from Air in Antarctic Ice and Firn." *Journal of Geophysical Research* 101:4115–4128.

[Fig. 46.3](#) shows that there is a **correlation** between the increasing CO<sub>2</sub> content of the atmosphere and human activities. A correlation simply indicates that two events or processes occur together. But can we actually demonstrate that humans have played a role in recent atmospheric change? By itself, correlation does not establish **causation**, a relationship in which one event leads to another. We

might propose instead that recent CO<sub>2</sub> increase reflects natural processes and matches the period of industrialization just by coincidence.

## Carbon isotopes show that much of the CO<sub>2</sub> added to air over the past half century comes from burning fossil fuels.

We can test the hypothesis that human activities have contributed to the increases in atmospheric CO<sub>2</sub> measured at Mauna Loa and in ice cores by making careful measurements of a chemical detail: the isotopic composition of atmospheric CO<sub>2</sub>. As discussed in [Chapter 2](#), many elements have several isotopes, atoms of the element that vary in atomic mass because they have different numbers of neutrons. Carbon has three isotopes: <sup>12</sup>C (with six neutrons, accounting for about 99% of all carbon atoms), <sup>13</sup>C (with seven neutrons, accounting for most of the remaining 1%), and the rare <sup>14</sup>C (with eight neutrons, about one part per trillion of atmospheric carbon).

More than 40 years ago, the Austrian-born chemist Hans Suess began to measure the relative abundances of the three isotopes of carbon in atmospheric CO<sub>2</sub>, a program that continues today. He observed that the proportion of <sup>13</sup>C in atmospheric CO<sub>2</sub> has declined as the total amount of CO<sub>2</sub> has increased ([Fig. 46.4](#)). This subtle change in isotopic composition has occurred because the CO<sub>2</sub> now being added to the atmosphere has less <sup>13</sup>C than the CO<sub>2</sub> already in the air.

## FIG. 46.4

What is the major source of the CO<sub>2</sub> that has accumulated in Earth's atmosphere over the past two centuries?

### BACKGROUND

Chemical analyses show that CO<sub>2</sub> levels in the current atmosphere are 46% higher than they were at the time of the American Revolution. This rise coincides with major advances in manufacturing and transportation, which are powered by the burning of fossil fuels. These coincidences in timing suggest that human activities are responsible for increasing CO<sub>2</sub> levels.

### HYPOTHESIS

The burning of fossil fuels, a development central to the emergence of modern industrial societies, has been the principal cause of the measured increase of CO<sub>2</sub> in the atmosphere.

### EXPERIMENT AND RESULTS

Hans Suess measured the abundance of the two stable isotopes of carbon, <sup>13</sup>C and <sup>12</sup>C, in air samples and demonstrated that the amount of <sup>13</sup>C in atmospheric CO<sub>2</sub> has decreased relative to the amount of <sup>12</sup>C over the second half of the twentieth century. Additional measurements of coral skeletons and wood show that the ratio of <sup>13</sup>C to <sup>12</sup>C in air has been decreasing over the entire period during which atmospheric CO<sub>2</sub> levels have been increasing.

## DISCUSSION

The ratio of  $^{13}\text{C}$  to  $^{12}\text{C}$  in  $\text{CO}_2$  added to the atmosphere over the past 200 years is lower than that in  $\text{CO}_2$  that was already in the air 250 years ago. The ratio of  $^{13}\text{C}$  to  $^{12}\text{C}$  in  $\text{CO}_2$  emitted by volcanoes or other geologic processes is too high to account for these data. In contrast, organic matter formed by photosynthesis has just the right ratio of  $^{13}\text{C}$  to  $^{12}\text{C}$  to account for Suess's measurements. By itself, the changing abundance of  $^{13}\text{C}$  in the air could reflect the conversion of plant carbon to  $\text{CO}_2$  by burning, or it could reflect the burning of fossil fuels formed by the burial of plant and algal materials in the geologic past.

## FOLLOW-UP WORK

Further studies of  $^{14}\text{C}$ , the third, unstable isotope of C, also show a strong decrease in the abundance of  $^{14}\text{C}$  in atmospheric  $\text{CO}_2$  over time, relative to other isotopes. While the burning of vegetation to clear land for agriculture results in  $\text{CO}_2$  with the right ratio of  $^{13}\text{C}$  to  $^{12}\text{C}$ , modern vegetation has far too much  $^{14}\text{C}$  to account for the decrease in the  $^{14}\text{C}$  composition of air. Only fossil fuels have the right ratios of all three carbon isotopes— $^{12}\text{C}$ ,  $^{13}\text{C}$ , and  $^{14}\text{C}$ —to account for the pattern of isotopic change in atmospheric  $\text{CO}_2$  measured by Suess and others. In fact,  $^{14}\text{C}$

data from the high Rocky Mountains indicate that if fossil fuels were the principal source of added CO<sub>2</sub>, CO<sub>2</sub> levels should have increased by a little less than 2 ppm per year between 2004 and 2008—which is very close to the increase actually measured.

## CONCLUSION

Burning of fossil fuels by industrialized societies has been, and continues to be, a principal source of CO<sub>2</sub> buildup in Earth's atmosphere.

SOURCES Revelle, R., and H. E. Suess. 1957. "Carbon Dioxide Exchange between Atmosphere and Ocean and the Question of an Increase of Atmospheric CO<sub>2</sub> during the Past Decades." *Tellus* 9:18–27; Rubino, M., et al. 2013. "A Revised 1000Year Atmospheric δ<sup>13</sup>C-CO<sub>2</sub> record from Law Dome and South Pole, Antarctica." *Journal of Geophysical Research Atmospheres* 118:8482–8499; Turnbull, J. C., et al. 2007. "A New High Precision <sup>14</sup>CO<sub>2</sub> Time Series for North American Continental Air." *Journal of Geophysical Research: Atmospheres* 112(D11):D11310. doi: 10.1029/2006JD008184.

What does this change in isotopic composition tell us about the source of carbon in the atmosphere? In photosynthesis, enzymes preferentially incorporate CO<sub>2</sub> containing the lighter isotope <sup>12</sup>C into

biomolecules rather than CO<sub>2</sub> containing <sup>13</sup>C. Carbon in volcanic gases and dissolved in seawater has a different ratio of carbon isotopes. Only the isotope ratio contained in the organic matter of organisms matches the shift in carbon isotope ratios in Suess's measurements of the atmosphere. Therefore, processes that cause a net conversion of organic matter to CO<sub>2</sub>, such as burning of forests to clear land or fossil fuel combustion, must be adding CO<sub>2</sub> to the atmosphere.

Here's where the other isotope of carbon, <sup>14</sup>C, comes in. Measurements also show that the sources of added CO<sub>2</sub> are depleted in <sup>14</sup>C relative to the CO<sub>2</sub> already in the air. Modern organic matter contains too much <sup>14</sup>C to account for the observed pattern, but ancient organic matter—the coal, petroleum, and natural gas burned as fossil fuels—is isotopically just right. Chemical analyses, therefore, support the hypothesis that human activities cycle carbon in amounts high enough to affect the chemical composition of the atmosphere.

That atmospheric CO<sub>2</sub> is increasing is not a hypothesis; it is a measurement. That the burning of fossil fuels plays an important role in this increase is also unambiguously documented by chemical analyses. Current debate focuses not on these observations, but instead on the more difficult problem of understanding how increasing CO<sub>2</sub> will affect climate. We discuss this problem in [Chapter 48](#). For now, however, we can use some relevant numbers to reveal another important aspect of the carbon cycle.

As shown in the top graph in [Fig. 46.5](#), humans now add almost 9 billion metric tons of carbon to the atmosphere each year, nearly all of

it as  $\text{CO}_2$ . Much of this material comes from power plants, airplanes, ships, and automobiles, which oxidize ancient organic matter in the form of fossil fuels to  $\text{CO}_2$  on a grand scale. Other important inputs come from the conversion of forests to agriculture or pastureland. Clearing and burning forest trees also oxidizes organic carbon to  $\text{CO}_2$ .

FIG. 46.5 Carbon dioxide sources and sinks. Much of the  $\text{CO}_2$  introduced by humans into the atmosphere has not stayed there. About half of it has accumulated as dissolved inorganic carbon in the oceans or as new biomass on the continents. Data from J. G. Canadell, C. Le Quéré, M. R. Raupach, C. B. Field, E. T. Buitenhuis, P. Ciais, T. J. Conway, N. P. Gillett, R. A. Houghton, and G. Marland, 2007, "Contributions to Accelerating Atmospheric  $\text{CO}_2$  Growth from Economic Activity, Carbon Intensity, and Efficiency of Natural Sinks," *Proceedings of the National Academy of Sciences USA* 104:18866–18870.

Interestingly, if we compare our best estimates of human  $\text{CO}_2$

generation since 1958 (not including CO<sub>2</sub> added through respiration) with the measured increase in atmospheric CO<sub>2</sub>, we find that roughly half of the CO<sub>2</sub> released by human activities did not end up in the air. Where did it go? This has been a major question for years. It now appears that much of the “missing carbon” has been stored as inorganic carbon in the form of CO<sub>2</sub>, bicarbonate (HCO<sub>3</sub><sup>-</sup>), and carbonate (CO<sub>3</sub><sup>2-</sup>) ions dissolved in the oceans. Some has also been taken up by vegetation or stored in soils. The bottom graph in [Fig. 46.5](#) shows an estimate of the various places, or sinks, where human-produced CO<sub>2</sub> ends up. These observations indicate that Earth’s carbon cycle is more complicated than a simple exchange of carbon between photosynthesis and respiration. There are additional storehouses of carbon and additional processes that move carbon from one store to another, topics we discuss next.

#### Self-Assessment Questions

1. Why does the coupling of photosynthesis and respiration result in the cycling of carbon?
2. Draw and explain the curve representing the changing atmospheric levels of CO<sub>2</sub> over the course of a year.
3. Draw and explain the curve representing the changing atmospheric levels of CO<sub>2</sub> over the past 150 years.
4. The graph in [Fig. 46.3](#) suggests that human activities have influenced CO<sub>2</sub> levels in the atmosphere. What is one line of evidence that lends support to this hypothesis?

## 46.2 THE LONG-TERM CARBON CYCLE

Up to this point, we have considered only the short-term carbon cycle: exchanges over days, years, and decades driven by the biological processes of photosynthesis and respiration, and altered in recent times by human activities. Geologic evidence, however, tells us that on timescales of thousands to millions of years, CO<sub>2</sub> levels in air have changed even more dramatically. These longer-term changes mean that we must consider additional contributions to the carbon cycle: physical processes, including volcanism and climate change. Indeed, the complete carbon cycle links Earth's physical and biological processes, providing a foundation for understanding the interconnected histories of life and environment through our planet's long history.

### Records of atmospheric composition over 400,000 years show periodic shifts in CO<sub>2</sub> levels.

In the preceding section, we discussed evidence that before the Industrial Revolution, atmospheric CO<sub>2</sub> levels had not changed appreciably for 1000 years or more. Longer-term records, however, show that the CO<sub>2</sub> levels in air can change substantially through time. For example, at Vostok, high on the Antarctic ice sheet, glacial ice records more than 400,000 years of environmental history ([Fig. 46.6](#)). As shown in the upper graph of [Fig. 46.6a](#), the youngest samples at Vostok show about 285 ppm CO<sub>2</sub> in the atmosphere, consistent with direct measurements of air, including the first years of the Keeling

curve. By comparison, CO<sub>2</sub> levels were much lower 20,000 years ago—about 180 ppm. In fact, the Vostok ice core in its entirety shows that atmospheric CO<sub>2</sub> has oscillated between 285 ppm and 180 ppm for at least 400,000 years.

FIG. 46.6 Atmospheric CO<sub>2</sub> content over the past 400,000 years. (a) The graphs show measurements made from ice (lower graph) and air bubbles (upper graph) trapped in glacial ice at Vostok, Antarctica. (b) Twenty thousand years ago during Earth's most recent ice age, glacial ice (shown in white) covered much of North America and Europe, as well as mountain ranges such as the Andes and Himalayas. Sea ice (light blue) expanded markedly in both northern and southern oceans. *Data from P. Reakewicz, "Temperature and CO<sub>2</sub> Concentration in the Atmosphere over the Past 400,000 Years," from Vital Climate Graphics, UNEP/GRID-Arendal*

Maps & Graphics Library, JPG file, 2005,  
<http://www.grida.no/publications/vg/climate/page/3057.aspx>. Based on J. R. Petit  
*et al.*, 1999, “Climate and Atmospheric History of the Past 420,000 Years from the  
Vostok Ice Core, Antarctica,” *Nature* 399:429–436. Plate tectonic maps and  
continental drift animations: Last Glacial Maximum by C. R. Scotese, PALEOMAP  
Project.

The lower graph in [Fig. 46.6a](#) shows an estimate of surface temperature obtained by chemical analysis of oxygen isotopes in ice from the same glacier—specifically, how it differed from the average temperature in 1950. Over the last 400,000 years, Antarctic temperature has oscillated between peaks of a few degrees warmer than today and temperatures as much as 6°C to 8°C colder than the present. As discussed more fully in [Chapter 48](#), CO<sub>2</sub> is a potent greenhouse gas: it allows incoming solar radiation to reach Earth’s surface, but traps heat that is re-emitted from land and sea. Higher concentrations of CO<sub>2</sub> result in warmer temperatures. Therefore, it is not surprising that climate and atmospheric CO<sub>2</sub> levels changed in parallel over the past 400,000 years.

The two curves correlate closely with another phenomenon, the periodic growth and decay of continental ice sheets. Large glaciers expanded in the Northern and Southern Hemispheres a few million years ago, ushering in an ice age. Today, we live in an interglacial interval, when climate is relatively mild, but 20,000 years ago thick sheets of ice extended far enough away from the poles to cover the present site of Boston ([Fig. 46.6b](#)). The repeated climatic shifts recorded in ice cores reflect periodic variations in the amount and distribution of solar radiation on Earth’s surface, caused by oscillating

changes in Earth's orbit around the sun. Scientists continue to debate why atmospheric CO<sub>2</sub> oscillates in parallel with glacial expansion and retreat, but the proposed mechanisms commonly suggest interactions involving the ocean's capacity to store large amounts of inorganic carbon, especially during glacial times. Whatever the explanation, the historical record of the past 400,000 years shows that climate can and does change without any input from humans, something we must take into account when considering our climatic present and future ([Chapter 48](#)).

On still longer timescales, atmospheric levels of CO<sub>2</sub> have varied even more widely. The atmospheric record trapped in glacial ice extends back in time less than 1 million years. To estimate atmospheric CO<sub>2</sub> levels for earlier intervals of Earth history, we must rely on computer models and measurements of chemical or paleontological features of ancient rocks that are thought to reflect the levels of atmospheric CO<sub>2</sub> at their time of formation. Such indirect observations and analyses come with a large degree of uncertainty, but most Earth scientists accept at least the broad pattern of atmospheric history shown in [Fig. 46.7](#). On this timescale, atmospheric CO<sub>2</sub>, and hence climate, are determined in large part by geologic processes, especially the chemical weathering of continental rocks uplifted into mountains.

FIG. 46.7 Atmospheric CO<sub>2</sub> content for the past 541 million years. Models and indirect estimates from geological measurements suggest that CO<sub>2</sub> levels have varied substantially through Earth's history. Data from [Fig 3.4](#) in K. Wallmann and G. Aloisi, 2012, "The Global Carbon Cycle: Geological Processes," in *Fundamentals of Geobiology*, edited by A. H. Knoll, D. E. Canfield, and K. O. Konhauser, pp. 20–35, Chichester, UK: Wiley-Blackwell.

## Reservoirs and fluxes are key in long-term carbon cycling.

To understand the long-term carbon cycle better, we must look at how carbon is distributed among its various **reservoirs**, the places where carbon is found on the Earth. As shown in the purple boxes in [Fig. 46.8](#), reservoirs of carbon include organisms, the atmosphere, soil, the oceans, and sedimentary rocks. Both biological and geologic processes cycle carbon back and forth among these pools.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Photo source: Fotosearch Stock Images

FIG. 46.8 Movement of carbon between reservoirs. The numbers for each reservoir are gigatons of carbon (GtC), and those for fluxes are gigatons of carbon per year. (1 gigaton = 1 billion metric tons.) Data from P. Rekacewicz, "The Carbon Cycle," from *Vital Climate Graphics*, UNEP/GRID-Arendal Maps & Graphics Library, JPG file, 2005, [http://www.grida.no/graphicslib/detail/the-carbon-cycle\\_a224](http://www.grida.no/graphicslib/detail/the-carbon-cycle_a224).

How much carbon is stored in each of Earth's major reservoirs? If we add up all the carbon contained in the total mass of organisms living on land, that amount of carbon is just a bit smaller than the amount of carbon stored as CO<sub>2</sub> in the atmosphere. Soil, by comparison, stores as much carbon as do land organisms and the atmosphere combined, mostly as slowly decaying organic compounds. In the oceans, the amount of carbon contained in living organisms is actually very small. Much more resides as inorganic carbon dissolved

in the water—most of it in the deep oceans as  $\text{CO}_2$  and bicarbonate and carbonate ions.

The biggest carbon reservoir of all lies beneath our feet, within sediments and sedimentary rocks. Calcium carbonate minerals ( $\text{CaCO}_3$ ), which form limestone, and organic matter preserved in sedimentary rocks dwarf all other carbon reservoirs combined by three orders of magnitude. Coal, petroleum, and natural gas make up only a small part of the organic matter stored in sedimentary rocks, but as we have seen, releasing the carbon in this reservoir by combustion plays an important role in the modern carbon cycle.

**Fluxes** are the rates at which carbon flows from one reservoir to another. In addition to the biological processes of photosynthesis and respiration described earlier, physical processes add and remove  $\text{CO}_2$  from the atmosphere. Volcanoes and mid-ocean ridges forming new seafloor release an estimated 0.1 billion metric tons of carbon (as  $\text{CO}_2$ ) into the atmosphere each year. More  $\text{CO}_2$ , approximately 0.05 billion metric tons of carbon per year, is released by the slow oxidation of coal, oil, and other ancient organic material in sedimentary rocks exposed at the Earth's surface. In nature, bacteria and fungi accomplish most of this oxidation by respiring old organic molecules. By burning fossil fuels, humans accelerate this process dramatically, increasing by a hundredfold the rate at which sedimentary organic carbon is oxidized.

Approximately 0.43 billion metric tons of  $\text{CO}_2$  are removed from the atmosphere each year by chemical reactions involving air, water,

and exposed rocks, a process called chemical weathering. Ions released during this weathering eventually precipitate as  $\text{CaCO}_3$  in the oceans, contributing to the large sedimentary reservoir of carbon.

One final set of geological processes completes the long-term carbon cycle. Earth's crust is constantly in motion, propelled by heat within the Earth's interior. Plate tectonics is the name given to this dynamic movement of our planet's outer layer. Plate tectonics provides geology's best explanation for the formation of mountains and ocean basins, and it plays an important role in the long-term carbon cycle. New crust that forms the seafloor and the sediments that accumulate on top of it are returned to the mantle by subduction, in which one plate sinks beneath another.  $\text{CaCO}_3$  and organic carbon deposited as part of those sediments return to the mantle in this way, eventually to be recycled to the surface as  $\text{CO}_2$  emitted from volcanoes and at mid-ocean ridges where new seafloor forms. [Fig. 46.9](#) shows the physical processes at work in Earth's long-term carbon cycle.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 46.9 Geological processes that drive the long-term carbon cycle. Numbers are estimates for annual fluxes of carbon in gigatons (GtC). Red boxes and arrows indicate processes that move CO<sub>2</sub> from geologic reservoirs into the atmosphere. Blue boxes and arrows indicate processes that move CO<sub>2</sub> from the atmosphere into geologic reservoirs. Data from J. Gaillardet and A. Galy, 2008, "Himalaya—Carbon Sink or Source?" *Science* 320:1728, doi:10.1126/science.1159279.

In essence, carbon moves from the atmosphere to sediments, where it can be stored for millions of years before returning to the surface environment through physical processes of volcanism and seafloor

formation. The sensitivity of different reservoirs to change depends on the relative sizes of the reservoir and of the amount of movement of material into and out of it. When fluxes are large relative to the size of the reservoir, reservoir size can change rapidly. In particular, the amount of carbon stored as CO<sub>2</sub> in air is not that much larger than the annual fluxes into and out of the atmosphere. For this reason, atmospheric CO<sub>2</sub> abundance can be influenced by a number of processes at work in the carbon cycle.

#### Self-Assessment Questions

5. Draw and explain the curve representing changing atmospheric levels of CO<sub>2</sub> over the last 400,000 years.
6. How do geologic processes participate in the long-term carbon cycle?
7. If plate tectonic processes form a chain of high mountains, would you expect atmospheric CO<sub>2</sub> to increase or decrease?
8. Rates of respiration are known to vary positively with temperature. As increasing CO<sub>2</sub> causes temperatures at the Earth's surface to rise, would changing rates of respiration tend to exacerbate or dampen this rise?

## 46.3 FOOD WEBS AND TROPHIC PYRAMIDS

So far, we have outlined the biological and physical pathways that cycle carbon through Earth's surface environments. The cycling of carbon and other elements depends on and reflects interactions among species as well. Moreover, the physical and biological components of ecosystems are linked by the processes that cycle carbon and other elements and transfer energy through the system.

### Food webs trace carbon and other elements through communities and ecosystems.

As you sit quietly by a woodland pond, the carbon cycle is at work all around you. In the forest, plants generate carbohydrates as they photosynthesize, and algae and photosynthetic bacteria do the same in the pond. In [Chapter 6](#), we called photosynthetic organisms autotrophs (“self feeders”) because they synthesize the organic molecules needed for growth and reproduction from CO<sub>2</sub>. Ecologists commonly refer to these organisms as **primary producers**, reflecting the fact that they fix inorganic carbon into organic molecules that feed other organisms in the community.

An insect grazes on leaves, and ducks feed on both insects and algae. Ducks and insects obtain the carbon they need for growth and reproduction from the foods they eat, and they also gain energy by respiring food molecules. In [Chapter 6](#), we called such organisms

heterotrophs (“other feeders”); ecologists refer to them as [consumers](#). All the animals in both pond and forest are consumers. Beneath our feet, similar interactions play out on a microscopic scale, especially among the fungi, protists, and bacteria that consume the dead remains of other organisms.

[Primary consumers](#) consume primary producers. As we saw in [Chapter 45](#), this kind of interaction is used to classify consumers as herbivores or grazers, whether they are eating plants on land or algae in aquatic environments. Primary consumers transfer carbon and energy drawn by the primary producers from the environment to a second biological reservoir and, through respiration, return some of the carbon to surrounding air or water.

[Secondary consumers](#), in turn, are predators or scavengers that feed on primary consumers. These organisms may provide food for still other consumers, generating successive tiers of organisms that feed upon one another. Like primary consumers, secondary consumers continue the transfer of carbon and energy from reservoir to reservoir, eating the primary consumers and returning some of the carbon stored in that reservoir to the environment through respiration.

Eventually, having passed from one consumer to another, the carbon originally fixed by photosynthesis is returned to the atmosphere by the respiration of fungi, bacteria, and other [decomposers](#) that break down dead tissues. The same is true of other biologically important elements such as nitrogen and phosphorus (discussed in the next section).

The transfer of carbon and energy from one organism to another

forms a food chain. Because most heterotrophs within a community can consume or be consumed by a number of other species, biologists often prefer to speak of **food webs**, a term that provides a better sense of the complexity of biological interactions within the carbon cycle (**Fig. 46.10**). Food webs define the interactions among organisms in ponds, forests, and many other habitats and trace the passage of carbon atoms through the biological carbon cycle. Put another way, biogeochemical cycles underpin the ecological structure of biological communities.

**FIG. 46.10** A food web. A food web traces the cycling of carbon and other elements from the environment through a succession of organisms and back to the environment. Energy is transferred from primary producers to consumers, eventually to be dissipated through work and the production of heat.

An organism's typical place in a food web is its **trophic level**. The

first trophic level consists of primary producers; consumers occupy the levels above the first trophic level. At the second trophic level are primary consumers; they comprise the herbivores, organisms that eat plants or other primary producers. Secondary consumers are found at the third trophic level and potentially higher levels as well. Top or apex consumers, which have few, if any, natural predators, occupy the highest trophic level. Parasites exploit all levels of the system, obtaining carbon and other nutrients from primary producers and consumers alike. Finally, the all-important decomposers and detritivores include fungi, bacteria, protists, and certain animals. Decomposers feed on the dead cells or bodies of other organisms, and detritivores do much the same, consuming partially decomposed plants or animals in soil or sediment, as well as organic compounds in feces. These organisms both provide food for microbe-eating consumers and return carbon dioxide and other inorganic compounds to the environment, completing the cycle of elements through the ecosystem.

## Energy as well as carbon is transferred through ecosystems.

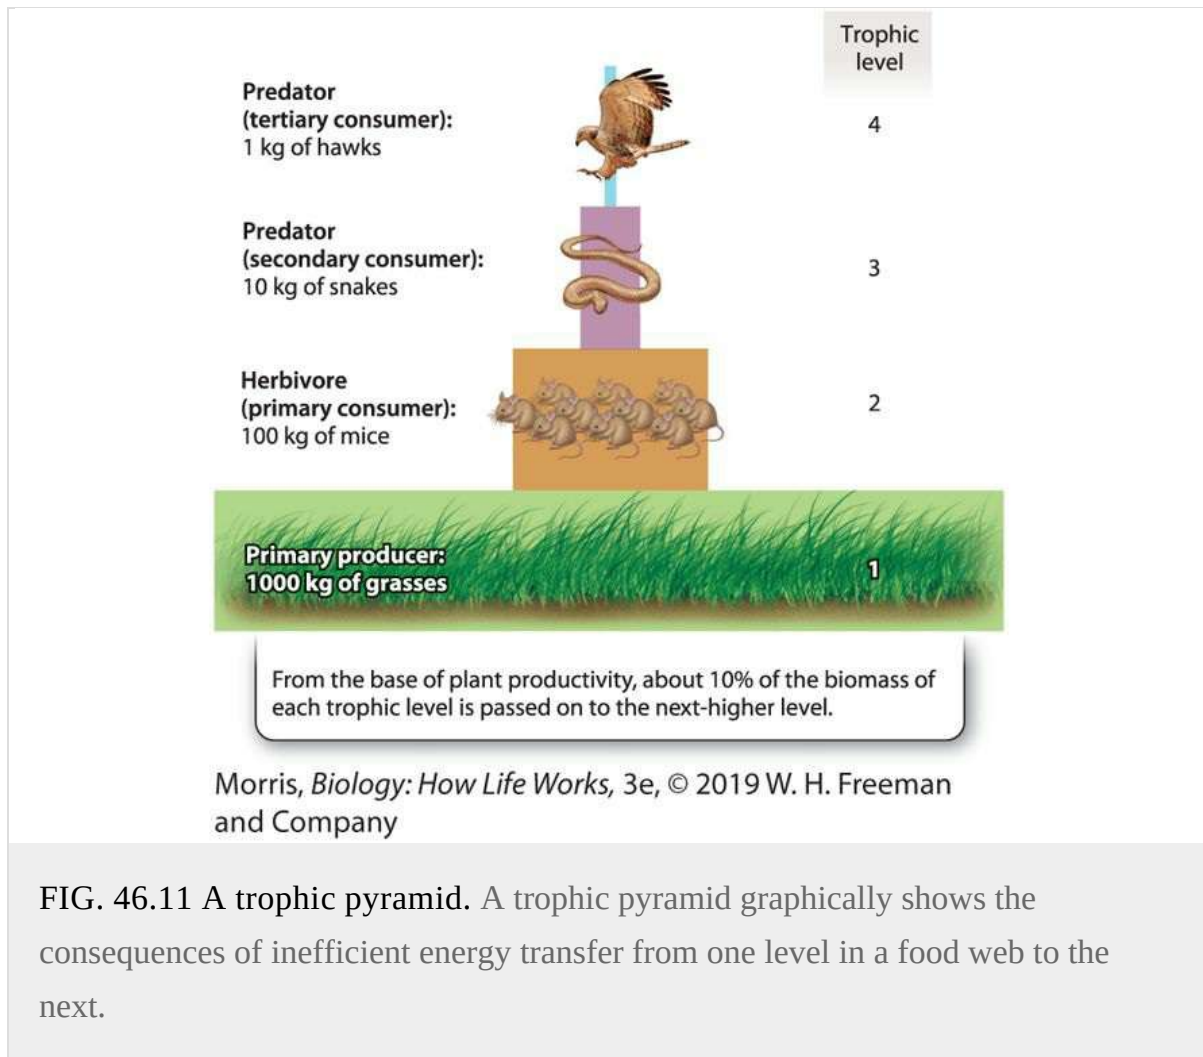

As the organisms in food webs move carbon and other elements from one organism to another, they also transfer energy. Carbon and energy are closely intertwined in food webs for the simple reason that the energy sources for consumers are the carbon-rich organic molecules in the organisms they eat. Unlike carbon, energy does not cycle through an ecosystem, so new energy must continually be harvested from the environment to sustain the community. In essentially all ecosystems where sunlight is available, photosynthesis is necessary for the species

interactions that define a community and ecosystem. Plants, algae, and photosynthetic bacteria capture energy from the sun and use it to synthesize energy-rich organic molecules. Where sunlight is absent, especially in the vast depths of ocean, bacteria and archaeons drive primary production through chemical reactions.

As plants capture energy from sunlight and carbon from the atmosphere, they build chemical bonds that store energy in carbohydrates. The organisms that consume these organic molecules store some of the energy in other molecules such as fat and starch, but they also use much of their food energy to do work (such as moving, growing, or reproducing) or generate heat. When carbon is released during respiration by consumers, it can be reincorporated into organisms by photosynthesis; in contrast, energy expended as heat or work cannot be captured again by other organisms. Therefore, while carbon and other elements are recycled in ecosystems, energy transfer is unidirectional.

Because organisms at one trophic level rarely consume all the resources at the level beneath them, and because energy is lost through wastes, work, and heat dissipation, only approximately 10% of the energy available at one trophic level in an ecosystem is incorporated into the next level. The consequences of this inefficient transfer of energy through food webs can be illustrated by a [trophic pyramid \(Fig. 46.11\)](#), which shows the biomass supported at each level by the biomass and energy available in the level beneath it. For example, 1000 kg of grass and herb biomass will support approximately 100 kg of mice (a little more than 3000 animals), and that, in turn, will support

10 kg of small predators like snakes. At the apex of the pyramid, we find a single kilogram of hawk or owl tissue. As the trophic pyramid suggests, primary production exerts a powerful influence over the rest of the community. To get more foxes and eagles, an ecosystem would need more photosynthesis.

On land, trophic pyramids generally have a wide base and a narrow apex. In aquatic habitats, however, trophic webs may be inverted, at least with respect to biomass. Planktonic algae at the base of the pyramid are tiny and may have high rates of primary production, resulting in high rates of energy generation but low total biomass. The

herbivores that consume these algae and the predators that eat them in turn are successively larger, are longer lived, and forage for food over a larger area. This trend can result in increasing biomass as we move upward through the pyramid, leading to its inverted shape. But note that while the trophic pyramids for aquatic communities may be inverted with respect to biomass, they are not inverted with respect to energy: because of energy loss through inefficient feeding, work, and heat dissipation, communities always require more energy to be available at lower trophic levels to support higher ones.

In summary, the complementary metabolic processes of photosynthesis and respiration cycle carbon and transfer energy through terrestrial and aquatic ecosystems ([Fig. 46.12](#)). On land, primary production is dominated by a single group of photosynthetic organisms, vascular plants such as the tree illustrated in [Fig. 46.12a](#). In the oceans, many groups of algae and cyanobacteria convert carbon dioxide to organic molecules ([Fig. 46.12b](#)). And in the dark waters of the deep sea, primary production by chemoautotrophic Bacteria and Archaea can contribute in important ways to the carbon cycle. Consumers, from animals to bacteria, live on organic matter originally generated by primary producers. Plants and animals may be the most conspicuous components of the biological carbon cycle, but it is the microorganisms—fungi, bacteria, and archaeons—that complete the cycle, generating CO<sub>2</sub> by respiration or fermentation from organic materials that leak into soils, sediments, and deep seawaters.

FIG. 46.12 The biological carbon cycle. Carbon cycles, both (a) terrestrial and (b) marine, link metabolism and ecology into functioning ecosystems.

Complementary metabolic processes also cycle nitrogen, phosphorus, and other elements required for life, as we discuss in the next section. By continually recycling materials, biogeochemical

cycles, which involve both biological and physical processes, sustain life over long intervals. In their absence, life could hardly have persisted for 4 billion years.

#### Self-Assessment Questions

9. How does a food web that diagrams the movement of carbon through an ecosystem also show how energy is transferred from one organism to the next?
10. Biomass generally declines substantially as we move upward from one trophic level to the next in a trophic pyramid. This pattern was discussed in this section in terms of energy loss from one level to the next, but carbon must be lost as well. What happens to it?
11. Describe how herbivores can affect the abundances of organisms at higher and lower trophic levels.

## 46.4 OTHER BIOGEOCHEMICAL CYCLES

Until now, we have focused on carbon, and for good reason. Carbon atoms form the backbone of most molecules in cells other than water, and carbon compounds such as fatty acids and sugars are the principal means through which energy is transferred from consumed to consumer. However, other nutrients, such as nitrogen (N) and phosphorus (P), are critical for building amino acids and nucleic acids that play key roles in the synthesis of proteins, DNA, and RNA, among other organic molecules important for the growth, maintenance, and reproduction of all species. Thus, as organisms cycle carbon through ecosystems, they also cycle nitrogen, phosphorus, and other elements. The primary producers that fix  $\text{CO}_2$  into carbohydrates also take up nitrogen and phosphorus from the environment, and use them to synthesize amino acids, nucleic acids, and membranes. Consumers depend on primary producers not only for their supply of carbon and energy, but also for the nitrogen and phosphorus they need to synthesize their own organic molecules. Along the way in these biogeochemical cycles, metabolic wastes, including excess nitrogen and phosphorus, as well as carbon dioxide, are passed back to the environment through excretion and gas exchange.

For this reason, the long-term maintenance and functioning of ecosystems require that organisms actively cycle not only carbon, but also other elements critical for life. In the following discussion, we focus on the nitrogen and phosphorus cycles.

# The nitrogen cycle is closely linked to the carbon cycle.

**Fig. 46.13** illustrates the same terrestrial ecosystem as shown in **Fig. 46.12a**, but highlights the cycling of nitrogen. The primary producers, consumers, and decomposers linked in the carbon cycle also cycle nitrogen. Indeed, the biological carbon and nitrogen cycles are closely connected by both ecology and metabolism.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

**FIG. 46.13** The nitrogen cycle. The nitrogen cycle also links metabolism and ecology, governing the availability of nitrogen for primary producers and thereby exerting a strong influence on the biological carbon cycle.

Primary producers need nitrogen as well as carbon. While they fix  $CO_2$  into organic molecules by photosynthesis or chemosynthesis, primary producers generally obtain the nitrogen they require by taking up biologically usable nitrogen found as nitrate ( $NO_3^-$ ) or ammonia ( $NH_3$ ) in soil or water, a process called **assimilation**. Primary consumers obtain nitrogen from the primary producers they consume,

just as they obtain carbon from these organisms. Through such consumption, both nitrogen and carbon travel across food webs. Decomposers return nitrogen to the environment as ammonia, a process termed **ammonification**.

As shown in [Fig. 46.13](#), a number of bacteria and archaeons use nitrate or ammonia to generate energy, releasing nitrogen gas ( $\text{N}_2$ ) to the atmosphere. These processes include denitrification (a form of anaerobic respiration in which nitrate, rather than oxygen, serves as the terminal electron acceptor), nitrification (a chemoautotrophic process that uses energy gained from the oxidation of ammonia or nitrite,  $\text{NO}_2^-$ , by oxygen), and anammox (a form of chemoautotrophy, with energy gleaned from the reaction of ammonia and nitrite) ([Chapter 24](#)). Because of these processes, the amount of biologically usable nitrogen in communities would decline through time to very low levels were it not for **nitrogen fixation**, the process by which some bacteria and archaeons reduce nitrogen gas ( $\text{N}_2$ ) to biologically usable ammonia ([Chapter 24](#)). Nitrogen fixation, then, is the process by which nitrogen enters food webs.

In the oceans, nitrogen cycling works much as outlined in the preceding paragraph: microorganisms fix  $\text{N}_2$ , decomposers return biologically usable nitrogen compounds to the water, primary producers assimilate this nitrogen, and consumers cycle nitrogen even as they move carbon and energy through ecosystems. Eventually, as on land, microbes convert biologically usable nitrogen compounds back to  $\text{N}_2$ .

The continual generation of biologically usable nitrogen compounds by nitrogen-fixing bacteria is fundamental not only to the nitrogen cycle but also to the carbon cycle, as it supplies critical nutrients for the primary producers at the base of an ecosystem's trophic pyramid and food web. As discussed in [Chapter 48](#), humans now fix a great deal of nitrogen through industrial processes, altering the balance of nutrients in many ecosystems.

## Phosphorus cycles through ecosystems, supporting primary production.

Like nitrogen, phosphorus is a key element needed for growth; this nutrient is incorporated into the nucleic acids and membranes found in all organisms as well as into ATP, the universal currency of life. The phosphorus cycle, however, is quite different from the nitrogen cycle. Whereas nitrogen is found largely in the atmosphere, phosphorus is mostly present in rocks. In addition, although nitrogen and phosphorus are both assimilated by primary producers, phosphorus does not provide electron donors or electron acceptors for energy metabolism. It simply enters the food web as phosphate ions ( $\text{PO}_4^{3-}$ ) released from rocks by chemical weathering; is taken up, or assimilated, by primary producers; and then is transferred from one organism to another through cycles of consumption and decomposition, eventually returning to its geological reservoir by accumulation in sediments ([Fig. 46.14](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 46.14 The phosphorus cycle. Phosphorus, another key nutrient, is weathered from rocks and eventually returns to its geological reservoir through deposition in sediments. Before it does, organisms repeatedly cycle phosphorus through ecosystems.

In the long term, phosphorus-containing sediments will be uplifted by tectonic processes to form mountains, making the phosphorus available again for release by chemical weathering. As is the case for nitrogen, humans have greatly accelerated phosphorus cycling through the mining of phosphate ores for fertilizer ([Chapter 48](#)).

### Self-Assessment Questions

12. Describe two ways that the biological nitrogen cycle interacts with the biological carbon cycle.
13. What are two ways in which the nitrogen and phosphorus cycles differ?

## 46.5 THE ECOLOGICAL FRAMEWORK OF BIODIVERSITY

Among the most remarkable features of life is its astonishing diversity. In previous chapters, we have discussed biological diversity, or biodiversity, in terms of the remarkable variety of form and function displayed across the tree of life. Here, we revisit biodiversity within the framework of ecology. While biodiversity is the product of evolution, it is shaped and sustained by ecological interactions among organisms and between organisms and the physical environment.

### Biological diversity reflects the many ways that organisms participate in biogeochemical cycles.

An estimated 500,000 species of photosynthetic organisms lie at the base of trophic pyramids in all but a few deep-sea and subterranean ecosystems. In terms of nutrient metabolism and their function in an ecosystem's food web, all these species do pretty much the same thing. Why, then, is there such a diversity of photosynthetic organisms? Why don't just a few species dominate the world's photosynthesis?

The example of a forest pond helps to make the basis of photosynthetic diversity clear. In the forest community, the leaves of several different tree species form a photosynthetic canopy above the forest floor. Below, shrubs grow, making use of light not absorbed by the leaves above them. And below the shrubs are grasses, herbs, ferns,

and mosses that can grow in the reduced light levels of the forest floor. In the nearby pond, a few species of aquatic plants line the water's edge, but beyond that algae and photosynthetic bacteria dominate photosynthesis, with some species anchored to the pond bottom and others floating in the water column.

Within even a single ecosystem, then, the different photosynthetic species that transfer carbon atoms from CO<sub>2</sub> to organic molecules subdivide the forest on the basis of light, water, and nutrient availability—that is, they occupy distinct niches ([Chapter 45](#)). On a larger scale, climate and physical features (mountains, valleys, rivers, lakes) vary tremendously from one region to another, and these features also help explain how primary producers can build and maintain diversity even though they all perform the same basic function in ecosystems. In the forests of New England, the tree species that thrive in wet regions differ from those found on well-drained hillsides. In southern California, seasonally dry woodlands support yet another set of plant species. In general, plants of varying size, shape, and physiology inhabit physically and biologically distinct environments, and the same is true of photosynthetic organisms in lakes and oceans.

Thus, the immense diversity of photosynthetic organisms found today does not reflect differences in how energy-rich molecules are produced for a community of organisms (although some of that occurs; see [Chapter 24](#)) so much as it does structural and physiological adaptations. These adaptations allow the effective gathering of light, nutrients, and—critical to life on land—water, in widely varying local

environments. Natural selection, acting on local populations, links the diversity of photosynthetic organisms to the carbon cycle.

If half a million species function as primary producers, an estimated 10 million species help to transfer energy and cycle carbon and other elements onward through food webs. These include plants, algae, and bacteria that respire as well as conduct photosynthesis, and animals, fungi, and microorganisms that obtain their carbon, nitrogen, phosphorus, and energy from organic compounds in photosynthetic organisms or the consumers that eat them. These organisms are essential to the completion of the short-term carbon cycle, returning carbon atoms to the environment as CO<sub>2</sub>.

Heterotrophic bacteria, amoebas, and humans may use essentially the same biochemical pathway to respire organic molecules, but they differ markedly in how they feed and, therefore, in what they can eat. Bacteria (and also fungi) absorb molecules from their environment, but amoebas and many other eukaryotic microorganisms can capture and ingest cells—they are capable of predation. Animals capture prey as well, but commonly feed on organisms far too large for an amoeba to eat. As photosynthetic organisms have adapted structurally and physiologically to local environments across the globe, consumers have adapted by means of locomotion, mouth and limb specialization, perception, and behavior to obtain their food.

**Biological diversity can influence primary production and therefore the**

## biological carbon cycle.

The biodiversity of a given region reflects its level of primary productivity. We have seen that predators' population sizes depend on the population sizes of their prey, which in turn depend on what those prey consume, going all the way down the trophic pyramid to primary production. Greater primary production also means that a greater variety of plants of different sizes and kinds can coexist, which in turn supports a greater variety of herbivorous animals. While this pattern suggests that high productivity can foster high diversity, recent experiments show that the reverse may also be true: biodiversity may itself play an important role in the productivity of ecosystems ([Fig. 46.15](#)). This role reflects the many different ways that different plants and animals may use the resources provided by soil, water, and sunlight in a particular place. Because no species is adapted for all functions in a given set of conditions, a diverse collection of species with different adaptations will collectively be more productive than a single species.

### HOW DO WE KNOW?

#### FIG. 46.15

### Does species diversity promote primary productivity?

#### BACKGROUND

The different plant species found in a community have combinations of leaves, stems, and roots that tap different sources of water and nutrients in the soil and capture light at different levels of sun and shade. Do the differences among plant species result in higher levels of primary

production than would be possible with fewer species?

#### HYPOTHESIS

Plant diversity promotes primary production within a community.

#### EXPERIMENT

Ecologist David Tilman conducted a long-term experiment in Minnesota, seeding each of 11 plots with 1, 2, 4, or 16 grassland species. He controlled each plot's amount of nutrients, water, and carbon dioxide, and also manipulated the plots' exposure to herbivory and disturbance by fire. The primary production of each plot was measured annually for up to 23 years.

#### RESULTS

The graph shows that the addition of nitrogen fertilizer [quantified as kilograms of nitrogen (kg of N) per hectare (ha)] increased primary production significantly, and additional water, higher CO<sub>2</sub>, herbivory, and disturbance also resulted in at least a modest increase in productivity. The difference in primary production between high-diversity (16 species) and low-diversity (1, 2, or 4 species) plots was at least as great as the largest additions of fertilizer—and much greater than any of the other treatments.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

## CONCLUSION

The hypothesis was supported: in the grassland community under study, species diversity promoted primary production.

## FOLLOW-UP WORK

Researchers continue to study the ecosystem effects of species diversity. Steadily accumulating data show the importance of conserving the species diversity found in nature.

SOURCE Tilman, D., P. B. Reich, and F. Isbell. 2012. "Biodiversity Impacts Ecosystem Productivity as Much as Resources, Disturbance, or Herbivory." *Proceedings of the National Academy of Sciences USA*, 109:10394–10397.

# Biogeochemical cycles weave together biological evolution and

# environmental change through Earth history.

As we have seen, the short-term carbon cycle and associated biological cycles of nitrogen, phosphorus, and other elements provide a framework for understanding ecology. It is the long-term cycles of carbon and other elements, however, that establish the context of evolution and environmental change through Earth's history.

The world did not always support the biological diversity we see today. Indeed, 2 billion years ago, the carbon cycle included mostly photosynthetic bacteria and microbial heterotrophs because there were no plants or animals ([Fig. 46.16](#)). Subsequently, algae gained an ecological foothold as nutrients became more widely available. Single-celled eukaryotic heterotrophs expanded their reach by gathering food in ways not possible for bacteria, ingesting cells and other types of particulate food. With the evolution of multicellularity, animals and seaweeds added further complexity to carbon cycling in the sea. Eventually, some aquatic green algae evolved the capacity to live on land, and animals soon followed, building the carbon cycle on land and thereby generating unprecedented levels of diversity on our planet.

Source: Albert Aanensen/naturepl.com

FIG. 46.16 Microbial communities in hot springs in New Zealand. This environment and others that few eukaryotes tolerate provide a glimpse of how the carbon cycle worked before plants and animals evolved.

The history of life is one of accumulating variety and complexity, based mostly on the great biological components of the carbon cycle: photosynthesis and respiration. Indeed, the carbon cycle did more than provide a framework for accumulating diversity: it changed the very nature of Earth's surface environments in ways that enabled new types of organism to evolve.

When life began, Earth's atmosphere and oceans contained little or no oxygen gas. How did our present oxygen-rich environment come to be? The key lies in the formulas for photosynthesis and respiration, shown in [Fig. 46.2](#). Photosynthesis and respiration cycle not only carbon, but oxygen (and water) as well. For this reason, the history of atmospheric oxygen is closely tied to the workings of the carbon cycle through time. When oxygen production by photosynthesis and oxygen consumption by respiration are in balance, oxygen levels do not change. However, organic carbon generated by photosynthesis can be

buried in sediments, thereby avoiding its usual return to the environment through respiration. Some of the  $O_2$  also generated by primary producers can then accumulate in the atmosphere and oceans. The geologic history of oxygen, shown in [Fig. 46.17](#), results from the interactions through time between the carbon and other biogeochemical cycles with plate tectonics. Not until Earth was 2 billion years old did the photosynthetic production of  $O_2$  come to exceed oxygen consumption owing to reduced gases and minerals, as well as by respiring organisms. And only about 580 million years ago did increasing nutrient levels result in an atmosphere much like our own. Our oxygen-rich world is a latecomer in Earth history, but its emergence was key to the diversity of animals that require high levels of  $O_2$  to live.

---

But life does not just respond passively to changing environments: it can also drive environmental change through time. For example, in [Fig. 46.7](#), notice the large drop in the line representing atmospheric CO<sub>2</sub> in the mid-Paleozoic Era, 400–350 million years ago. This sharp decline is thought to reflect the evolution of a new player in the carbon cycle: woody plants. The evolution of trees increased the size of the carbon reservoir on land and ushered in an important new mechanism for removing carbon from the air and ultimately transferring it to sedimentary rocks. That mechanism was the burial of plant material on land, forming peat and, eventually, coal.

In the current century, a single animal species is influencing the carbon cycle in new ways: humans. As noted in our discussion of the Keeling curve, we are adding CO<sub>2</sub> to the atmosphere at a high rate, warming Earth's surface by the greenhouse effect. The consequences of human activities for Earth and its living organisms are discussed more fully in [Chapter 48](#). For now, just bear in mind that modern humans are not simply observers of the carbon cycle; we are major participants in it.

[Fig. 46.18](#) summarizes the global flow of carbon and energy through ecosystems, including their interactions with the nitrogen and phosphorus cycles and human impacts.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 46.18 VISUAL SYNTHESIS: Flow of Matter and Energy Through Ecosystems Integrating concepts from [Chapters 45–48](#)

### Self-Assessment Questions

14. If photosynthetic organisms all gain carbon and energy in much the same way, how do diverse photoautotrophs persist in ecosystems?
15. How can plant diversity influence rates of primary production in terrestrial ecosystems?
16. Compare and contrast a modern marine food web with food webs that existed two billion years ago.

## CORE CONCEPTS SUMMARY

**46.1 THE SHORT-TERM CARBON CYCLE:** Photosynthesis and respiration are the key biochemical pathways of the biological, or short-term, carbon cycle.

Keeling's program to monitor CO<sub>2</sub> levels in the atmosphere revealed two patterns: (1) CO<sub>2</sub> levels oscillate on a yearly basis and (2) CO<sub>2</sub> levels have increased annually to the present day since measurements began. [page 1044](#)

The first pattern (seasonal oscillation) can be explained by the global imbalance between photosynthesis and respiration in the summer and in the winter months. [page 1045](#)

The second pattern (annual increase) can be extended further back in time by measuring the composition of air trapped in gas bubbles within polar ice. These measurements indicate that CO<sub>2</sub> levels in the atmosphere remained steady for more than a thousand years, but then started to increase in the mid-1800s, during the Industrial Revolution. [page 1045](#)

The ratio of different isotopes of carbon in the atmosphere indicates that most of the carbon added to the atmosphere in recent decades comes from human activities, particularly the burning of fossil fuels. [page 1046](#)

**46.2 THE LONG-TERM CARBON CYCLE:** Physical processes govern the carbon cycle on longer timescales.

Physical processes, which act at slower rates and over longer

timescales, are the major drivers of the long-term carbon cycle.

[page 1048](#)

Over the last 400,000 years, CO<sub>2</sub> levels in the atmosphere have gone through periodic shifts that coincide with repeated cycles of glaciation. [page 1050](#)

CO<sub>2</sub> levels in the atmosphere 500 million years ago may have been as much as 15 to 20 times higher than present-day levels ([Fig. 46.7](#)). [page 1050](#)

In following carbon through its cycle, it is important to consider where carbon is stored (reservoirs) and the rates at which it is added to or removed from these stores (fluxes). [page 1051](#)

Important reservoirs of carbon include organisms, the atmosphere, soils, the oceans, and sedimentary rocks. Sedimentary rocks are by far the largest carbon reservoir. [page 1051](#)

Physical processes that remove CO<sub>2</sub> from the atmosphere include the weathering of rocks; processes that add CO<sub>2</sub> to the atmosphere include volcanoes and the oxidation of ancient organic matter in sedimentary rocks. [page 1051](#)

The slow leakage of organic matter from biological communities to sediments accumulating on the seafloor links the short-term carbon cycle populated by organisms to the long-term carbon cycle driven by the Earth. [page 1051](#)

Over time spans of hundreds of millions of years, movements of Earth's tectonic plates become major influences on the carbon

cycle. [page 1051](#)

**46.3 FOOD WEBS AND TROPHIC PERIODS:** Species interactions cycle carbon and transfer energy through ecosystems.

An ecosystem is the community and the physical habitat in which the organisms live. [page 1053](#)

Photosynthetic and other autotrophic organisms are primary producers, converting CO<sub>2</sub> into organic molecules. [page 1053](#)

Heterotrophic organisms that eat primary producers are called primary consumers. [page 1053](#)

Heterotrophs that prey on grazers are called secondary consumers. [page 1053](#)

Primary producers gain energy, carbon, nitrogen, phosphorus, and other elements from the environment. Consumers gain all of these resources from their food. [page 1053](#)

Interacting networks of species, linked by predator–prey interactions, are called food webs. [page 1053](#)

Trophic pyramids show that losses of energy and carbon from one level in a food web to the next result in ever decreasing biomass at higher trophic levels. [page 1055](#)

Because of energy lost to heat, work, and the inefficiencies of consumers, each trophic level in an ecosystem generally has approximately 10% of the biomass found at the next-lower level. [page 1055](#)

Carbon cycles through ecosystems, but energy is used and dissipated. [page 1055](#)

#### **46.4 OTHER BIOGEOCHEMICAL CYCLES:** Nitrogen and phosphorus also cycle through ecosystems.

Nitrogen in the atmosphere is fixed by bacteria and archaeons, and then cycles through primary consumers, consumers, and decomposers; thus, the nitrogen cycle is closely linked to the carbon cycle. [page 1057](#)

Phosphorus is found mostly in rocks, enters the food web as phosphate ion by chemical weathering, and cycles through ecosystems, supporting primary production. [page 1058](#)

#### **46.5 THE ECOLOGICAL FRAMEWORK OF BIODIVERSITY:** Biogeochemical cycles help us understand the evolution of biological diversity.

Primary producers are well adapted to obtaining sunlight, water, and nutrients in different environments. [page 1059](#)

Primary and secondary consumers are adapted to obtaining different sources and sizes of food. [page 1059](#)

The evolution of life on Earth can be considered a long history during which organisms have evolved different ways of obtaining energy and carbon from their environment. [page 1059](#)

The interactions between biological and geologic processes at work in the carbon cycle are also responsible for Earth's oxygen-rich atmosphere and oceans. [page 1060](#)

## CHAPTER 47 Climate and Biomes

Mike Hill/Getty Images

---

### CORE CONCEPTS

**47.1 CLIMATE:** Solar radiation, wind and ocean currents, and topography determine the distribution of major climatic zones on Earth.

**47.2 BIOMES:** Biomes are broad, ecologically uniform areas whose characteristic species reflect regional climate.

**47.3 GLOBAL PATTERNS:** Global patterns of primary production and biodiversity reflect climate, nutrient availability, and evolutionary history.

---

Watching a movie or video, you often don't need a map to figure out

where the action is taking place. Cactus and scraggly shrubs suggest the deserts of Mexico or the American Southwest; dense stands of low-growing conifers bring to mind central Canada or Siberia. The deciduous forests of eastern North America and Europe are equally distinctive, as are prairies and tropical rainforests. Plants conspicuously show that biological communities vary from place to place, reflecting the adaptations to local conditions of temperature, rainfall, and nutrient availability of the species that live there. If we take the time to survey the animals in these diverse communities, we will find that they are distinctive as well.

**Biomes** are broad geographic areas with similar communities. Climate exerts a major influence on the nature and distribution of biomes on land and in the sea. Before we consider this interaction between Earth and life, however, we must first ask what climate is and why it varies from place to place.

## 47.1 CLIMATE

Climate can be thought of as long-term average weather. In Boston, any given day in March may be warm or cold, dry or rainy, or even snowy. Nevertheless, records compiled over decades show that, on average, March days in Boston vary from about 42°F (5°C) at the beginning of the month to 47°F (9°C) at its end. March brings an average of 4.3 inches (110 mm) of precipitation in Boston, at least some of it typically snow. Montreal is colder and snowier in March; Phoenix is much warmer and drier.

What controls this broadly predictable distribution of average weather across the planet? Climate in Boston, and around the world, is determined by solar radiation, global patterns of wind and ocean circulation, and Earth's varying topography.

**The principal control on Earth's surface temperature is the angle at which solar radiation strikes the surface.**

In our solar system, Earth stands out as the planet with life. Our nearest neighbors, Venus and Mars, are, respectively, too hot for liquid water to persist and too cold. Earth is the Goldilocks planet: just the right distance from the sun so that, in conjunction with the greenhouse effect of the atmosphere, solar radiation maintains surface temperatures that can keep water in its liquid form. As we look across Earth, we see that climate varies markedly from one region to another. This variation

reflects the relationship between Earth and the sun, modified by the physical features of Earth and the circulation of air and seawater.

**Fig. 47.1** shows how mean annual temperature is distributed across Earth's surface. Earth is hot near the equator (the red colors in [Fig. 47.1](#)) and cold at the poles (blue and purple). This temperature distribution results from incoming solar radiation. Sunlight strikes the equatorial regions directly, but at higher latitudes (closer to the poles), the curvature of the Earth means that its surface is oriented at an angle to incoming radiation. To see what a difference this makes, shine a flashlight directly on a sheet of paper placed perpendicular to the beam of light. Now, tilt the paper at 45 degrees to the light. You'll notice that the same amount of light (and, therefore, the same amount of energy) is distributed over a larger area. On Earth, the amount of solar energy striking a given area in the tropics is about twice that found near the poles, so tropical regions are warmer than polar regions.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 47.1 Solar radiation and surface temperature. The angle at which solar radiation strikes our planet's curved surface is the primary determinant of Earth's surface temperatures.

At higher latitudes, temperature is not only lower, but also exhibits greater variation throughout the year. Seasonality reflects a second feature of Earth as a planet: Earth's axis of rotation is not oriented perpendicular to incoming sunlight but rather tilts at an angle of 23.5 degrees ([Fig. 47.2](#)). Because of this tilt, solar radiation strikes North America and Europe more directly in July than it does in January—and so these areas are warmer in summer and colder in winter. At the extreme, above the Arctic Circle, incoming solar radiation can be absent for days to months during the winter. A similar pattern of

seasonality characterizes the Southern Hemisphere, but winter is in July and summer is in January. These patterns of temperature variation through the year go a long way toward explaining the geographic distribution of biomes across the globe.

**Topography**—that is, the physical features of Earth's surface—also contributes to global temperature patterns. Even at low latitudes, mountaintops can have glaciers, reflecting the fact that temperature declines with increasing elevation. In general, temperature drops about 3.6°F for every 1000 feet in elevation (6.5°C per kilometer). For this reason, climate and biomes on mountains change as elevation increases, mirroring the spatial pattern observed from lower to higher

latitudes.

## Heat is transported toward the poles by wind and ocean currents.

To further understand how temperature is distributed across the Earth, we need to think about another set of processes: those that transport heat energy from the equator toward the poles. Evidence that heat moves from low latitudes to high can be found in the distribution of temperatures at the Earth's surface. Temperatures at the equator are actually a bit cooler than we might predict based solely on how directly solar radiation strikes Earth at that latitude; the poles, in turn, are somewhat warmer than a diagram of solar radiation like [Fig. 47.1](#) would predict. To reconcile these predicted and measured temperatures, we need to consider how heat is transported from low to high latitudes. This heat transport is carried out by wind and ocean currents.

The gas molecules that make up air are constantly in motion. When they are heated, they move faster, and (unless confined) the volume of the air expands. For this reason, warm air is less dense than colder air and, therefore, rises through the atmosphere. Not surprisingly, the rise of warm air is particularly strong at the equator ([Fig. 47.3](#)). As shown in the inset in [Fig. 47.3](#), air cools as it rises. Once it reaches an altitude of 10 to 15 km above Earth's surface, the air no longer continues to rise but instead spreads toward the poles, continuing to cool as it goes. Eventually, at about 23 to 30 degrees north and south latitude, the cooling air becomes dense enough to sink back to the surface. This air continues to move along Earth's surface: some of it moves toward a

pole, while the rest moves back toward the equator. In either case, the air warms again as it moves across Earth's surface, rising once more at the equator or at about 60 degrees north and south latitude. Thus, as shown in [Fig. 47.3](#), Earth's lower atmosphere is organized into cells of rising and falling air masses. The cells that flank the equator are called Hadley cells after George Hadley, who in 1735 proposed this pattern of circulation as an explanation for the trade winds so important to ships sailing from Europe to the Americas.

FIG. 47.3 Wind currents. The rise of warm air through the atmosphere and the descent of colder air govern patterns of prevailing winds, transporting heat from the equator toward the poles.

As warm air expands upward, cool air moves in to replace it. We experience this movement as wind. As sailors have known for thousands of years, the prevailing direction of the wind differs from one latitude to another. Prevailing winds reflect those atmospheric cells of rising and falling air. Warm air moves toward the equator in some

cells and away from the equator in others, with a net transport of heat occurring from the equator to the poles. The winds don't move strictly in a north or south direction; instead, prevailing wind direction has a strong east–west component (as, for example, with the westerlies and trade winds shown in [Fig. 47.3](#)). To understand this, we have to consider one additional aspect of our planet: its rotation about an axis.

Earth rotates in a counterclockwise direction, moving from west to east. In the course of one daily rotation, a spot at the equator moves through a distance equivalent to our planet's circumference—nearly 25,000 miles, or 40,000 km. Points at higher latitudes travel a shorter distance in a single rotation; the distance traveled eventually is zero at the poles. So, in a period of 24 hours, a point at the equator has traveled farther than a point at higher latitude; that is, the point at the equator moves more quickly than the point closer to the poles. As the cooling air moves north and south from the equator as shown in [Fig. 47.3](#), the land beneath it rotates to the east, but at a slower speed than the land at the equator. Because of this, winds moving north or south appear to deflect to the right in the Northern Hemisphere and to the left in the Southern Hemisphere ([Fig. 47.4](#)). This phenomenon is called the **[Coriolis effect](#)**; in conjunction with the cells of rising and descending air masses, it explains the pattern of prevailing winds illustrated in [Fig. 47.3](#).

FIG. 47.4 The Coriolis effect. Because of Earth's counterclockwise rotation about its axis, winds in the Northern Hemisphere deflect to the right; those in the Southern Hemisphere deflect to the left.

Winds, in turn, push on water in the oceans, directing surface currents as shown in [Fig. 47.5](#). Water can carry much more heat than air can carry, so ocean currents transport a great deal of heat toward the poles. For example, the ocean current known as the Gulf Stream (and its northeasterly extension, the North Atlantic Drift) transports warm water north along the eastern margin of North America and then east toward Europe. The heat it carries helps to keep northwestern Europe much warmer than land at equivalent latitudes in North America. Thus, subtropical plants that thrive in gardens of coastal Scotland would be unthinkable in Newfoundland, Canada, which lies at approximately the

same latitude.

FIG. 47.5 Ocean currents. Prevailing ocean currents reflect the winds that drive the circulation of water at the ocean's surface and transport a large amount of heat from the equator toward the poles.

Just as colder air sinks below warmer and less dense air, cold dense waters sink beneath less dense water masses. At high latitudes, surface waters cool enough to sink beneath warmer, less dense waters, sinking to the deep ocean where they begin to move slowly toward the equator. The result is a complex three-dimensional circulation of water through Earth's oceans that plays an important role in regional climates.

In sum, wind and water transfer heat from the equator toward the poles, modifying the direct effects of solar radiation. Together, these processes result in the temperature distribution observed across the planet, explaining why palm trees that cannot tolerate freezing are confined to low latitudes, while deciduous trees that lose their leaves every fall occur mostly in the seasonal climates found at mid-latitudes.

However, if you drive due west from New York to northern California, you will pass sequentially through deciduous forest, grass-dominated prairies, and stands of conifers on mountains. Clearly, there is more to the distribution of biomes than temperature alone.

## Global circulation patterns determine patterns of rainfall, but topography also matters.

To fully understand the features and distribution of biomes around Earth, we must introduce one more physical principle: warm air can carry more water vapor than cold air can carry. Armed with this insight as well as the observation from the previous section that on a global scale, heat is transferred from the equator to the poles in cells of rising and falling air, we return to the global circulation of air. Especially at the equator, warm air carries a great deal of water vapor, but, as it rises and the air cools, the amount of water vapor the air can carry decreases. As a result, the vapor condenses, and it rains. Conversely, the air descending at about 23 to 30 degrees latitude north and south warms as it sinks; thus it takes up water vapor rather than releasing it, leading to aridity ([Fig. 47.6](#)). Zones of high annual rainfall (polar and subtropical highs in [Fig. 47.6](#)) and low annual rainfall (subpolar lows and ITCZ equatorial low) follow this broad pattern of rising and descending masses, with the highest rainfall occurring near the equator and the lowest rainfall between 23 and 30 degrees latitude north and south.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 47.6 Global rainfall patterns. The rise and fall of air masses govern the global distribution of rainfall.

Regional precipitation (rain or snow) patterns are actually more complicated than this simple picture would suggest, as seen in the precipitation map for Washington state ([Fig. 47.7](#)). From the coast eastward into the Cascade Mountains, Washington and neighboring British Columbia are wet all year long, supporting magnificent conifer forests. However, east of the Cascades and the Coast Mountains that extend to the north, the land is dry. As this observation suggests, the mountains themselves impose a regional pattern of rainfall. This effect, called a rain shadow, reflects the same general principles of rising and descending air masses. As shown in [Fig. 47.7](#), as wet air moves from the ocean up into the mountains, it cools, releasing its moisture as precipitation. Moving past the mountains, air masses descend, warming as they go and taking up water vapor. For this reason, lands in the rain

shadow of the mountains are arid.

In general, regional climate reflects the interactions among solar radiation, global patterns of circulation, and Earth's varying topography. Biomes, in turn, reflect these variations in climate.

#### Self-Assessment Questions

1. Explain how incoming solar radiation exerts a direct influence on the distribution of temperature across Earth's surface.
2. How would climates be different if Earth's axis of rotation were perpendicular to incoming solar radiation rather than tilted at 23.5 degrees?
3. Why are equatorial latitudes generally wet, but land masses at about the 23 to 30 degrees north and south latitudes generally dry?
4. Why are the sides of tall mountains that face oncoming wind generally wetter than their opposite slopes?

## 47.2 BIOMES

Most of us are familiar with the dense canopies of tropical rainforests and the rolling grasslands of prairies. Likewise, we know that coral reefs occur in tropical to subtropical waters. As we noted at the beginning of the chapter, we can recognize these and other biomes based on their characteristic communities. On land, the most conspicuous feature of any biome is its vegetation, which reflects the evolutionary adaptation of plant form and physiology to climate. But how close is this relationship between biome and climate?

In 1884, Wladimir Köppen published a global climate map that, with relatively few changes, is still used today. You might wonder just how much information was available to Köppen about temperature and rainfall in, for example, the Amazon rainforest or central Asian steppes. The answer: not much. In fact, Köppen's diagram actually charts global vegetation; the reason it works so well as a climate map is that plant form strongly correlates with global patterns of temperature and rainfall ([Fig. 47.8](#)). In designating major climate zones according to their characteristic vegetation, Köppen mapped out Earth's terrestrial biomes.

FIG. 47.8 Global distribution of terrestrial biomes. Distributions of terrestrial biomes around the world reflect regional climates. *Data Source: D. M. Olson et al., 2001, "Terrestrial Ecoregions of the World: New Map of Life on Earth," Bioscience 51:933–938.*

## Terrestrial biomes reflect the distribution of climate.

In [Chapter 27](#), we saw that plants perform a physiological balancing act, opening their stomata to allow carbon dioxide into leaves, but losing water vapor through transpiration (evaporation from leaves) as a result. [Evapotranspiration](#) is the sum of evaporation directly from soils and water bodies plus the amount transpired by plants ([Fig. 47.9](#)). In many ecological communities, transpiration returns a large amount of water vapor to the atmosphere. For example, a single acre of corn can transpire 3000–4000 gallons (10,000–15,000 L) of water per day.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 47.9. Evapotranspiration. The supply (precipitation and groundwater flow) and demand (evapotranspiration) for water determine the nature of vegetation in terrestrial biomes.

As we've seen, temperature varies with latitude and altitude, as do humidity and wind. Temperature, humidity, and wind all determine the rate at which evapotranspiration removes water from plants and soils. The water within plants is replenished mostly by roots that take up water from soil. This water, in turn, must be replenished by precipitation and ground water flow. As a consequence, rates of transpiration by plants reflect both rate of photosynthesis and the availability of soil and ground water. Where water resources are limited, transpiration is limited as well. Plants conserve water by

closing their stomata, which restricts intake of carbon dioxide and photosynthesis.

In deserts, which have low annual precipitation, the moisture in soils evaporates rapidly. Therefore, to conserve water, desert plants must keep transpiration (and therefore photosynthetic rate) to a minimum. The plants' ability to store water in their tissues provides a defense against drought, so succulents—plants such as cactus, which store water in their stems—are common. At the other extreme, rainforests experience high rates of precipitation, which permit nearly unlimited transpiration (and therefore high photosynthetic rates). The result is wet forests with high biomass. Intermediate levels of water availability and evapotranspiration characterize the temperate zones that encompass much of the United States, Europe, and parts of eastern Asia, as well as mid-altitudes, below the highest mountain peaks but well above the coastline. Both latitude and altitude influence evapotranspiration through their effects on temperature and precipitation, and the combined effects of these factors are reflected in the distribution of biomes around the world ([Fig. 47.10](#)).

FIG. 47.10 Evapotranspiration, precipitation, and terrestrial biomes.

Precipitation and the potential for evapotranspiration change with latitude and altitude. The ratio between precipitation and evapotranspiration acts as a primary determinant of vegetation type. *Data from International Water Management Institute Global Monthly Dataset. Relationship of biomes to precipitation and temperature from J. R. Mather and G. A. Yoshioka, 1968, "The Role of Climate in*

*the Distribution of Vegetation,” Annals of the Association of American Geographers, 58(1):29–41.*

In similar biomes on different continents, dominant plants generally look much the same, but commonly they are not closely related. Plants have independently evolved adaptations to particular climatic regimes by convergence ([Chapter 22](#)). For example, the cacti that grow in deserts of western North America look very similar to plants in arid regions of Africa, but the African plants belong to an entirely different family ([Fig. 47.11](#)). Convergent evolution is also seen in the trees of rainforests in different regions of the world. Distantly related trees have evolved leaves with long tips that allow excess water to drip away, a reddish color in new leaves that protects them from intense sunlight, and roots with high buttresses that support tall trees atop thin soil.

**FIG. 47.11** Convergence of plant form. (a) Cacti in the deserts of North America and (b) euphorb plants in Africa look similar because they are both adapted to conserve and store water, but they are not closely related.

In terrestrial biomes, vascular plants dominate primary production,

although mosses, lichens, algae, and cyanobacteria contribute as well. Plants also provide a physical structure for biomes, with high canopies in wet temperate forests and tropical forests, but shorter vegetation where water or nutrients are scarce, or where the growing season (the part of the year when temperature and precipitation permit plant growth) is short.

Primary consumers include a variety of animals. These consumers have adaptations that facilitate feeding on specific plant resources, and—like the plants they eat—consumers commonly show evidence of convergent evolution. In many environments, mammals and insects are the principal herbivores, grazing on leaves, fruits, seeds, and stems. Insects and vertebrates also play major roles as secondary consumers. Predatory insects in various terrestrial biomes include hornets, the praying mantis, and larval ant lions that trap their prey in small sandy pits. Terrestrial biomes are often characterized by the carnivorous vertebrates that live there, which include some of the most charismatic of all animals—for example, lions, tigers, and wolves. In all terrestrial biomes, despite the activities of consumers, detritus from both plants and animals ends up on the ground and may accumulate in soil.

Decomposers, especially fungi, protists, and bacteria, feed on this detritus, returning CO<sub>2</sub> to the atmosphere through respiration and returning nutrients to the soil. Still more protists and animals feed on these decomposers, populating a detritus-based food web within the soil. Soil animals include tiny nematodes ([Chapter 42](#)) as well as larger earthworms that eat both detritus and decomposers, ventilating the soil as they tunnel in search of food.

FIG. 47.12 Common land biomes.

## Tundra

Tundra is the coldest biome, and short days in winter limit the growing season. Tundra occurs close to the North Pole, above 65° N. The South Pole is largely surrounded by the ice and seas of Antarctica, so there is very little area with plants. The climate diagram from Barrow, Alaska, shows that in tundra biomes, both temperatures and precipitation are low, with highs for both occurring during the summer. Although precipitation is low, rates of evaporation are also low. Because drainage is commonly poor, the ground is usually waterlogged and permanent ice occurs below a few centimeters of soil. Primary producers are mostly mosses, lichens, herbs, and low shrubs. Grasses and sedges occur in drier places, as do other flowering plants. Plant diversity is low, and most plants are small. Caribou are conspicuous grazers, but other primary consumers, including musk oxen, rabbits, birds, and insects, occur as well. Wolves and foxes are key predators. Fungi and bacteria decompose organic detritus, but low temperatures and waterlogged soils limit rates of respiration.

## Alpine

The Alpine biome is similar to tundra but lacks permanent ice below the soil, and the temperatures vary more widely. Alpine areas occur throughout the world, often at approximately 10,000 feet (3000 m) at lower latitudes, but always just below the elevation where snow cover persists throughout the year. Because of their altitude, they are windy, cold places. The thin atmosphere provides only limited protection from UV radiation, so many alpine plants are low and slow growing. Grasses are abundant, as are herbs that can provide spectacular wildflower displays during the short growing season. Alpine grazers include mountain goats, llamas, yaks, and marmots, as well as seasonally active insects. Predators include wolves and cats such as the Himalayan snow

leopard.

Climograph data source: <https://borealshieldandplains.weebly.com/>

**Taiga**

These cool, moist forests occur from 50° N to 65° N. The short summer brings rain, and most of the plants are low-growing conifers like spruce, fir, larch, and pine, with an understory dominated by shrubs in the blueberry and rose families. Mosses commonly form an extensive and soggy groundcover. The soils are deep with accumulated organic matter because the low temperatures result in slow decomposition, but they are also acidic and poor in nutrients, helping to explain the short stature of most plants. Birds, insects, and other invertebrate animals are more abundant and diverse than those found in tundra biomes, but mammals are the most conspicuous consumers. Grazers include elk, moose, caribou, porcupines, hares, and a diversity of rodents. Bears, lynx, wolverines, weasels, mink, wolves, and foxes are well-known predators.

## Temperate coniferous forest

Two broad areas of temperate coniferous forest occur below 50° N in North America, northern Japan, and parts of Europe and continental Asia. Along the Pacific coast of North America, warm summers and mild winters, along with abundant precipitation in the winter, permit growth of enormous conifers such as Douglas Fir, Red Cedar, Sitka Spruce, and redwoods. Much of the undergrowth consists of grasses, ferns, and members of the blueberry family. Understory shrubs are uncommon. In the interior of North America, much less precipitation and colder winter temperatures support drought-resistant conifers such as Ponderosa and Lodgepole Pines and Englemann Spruce. Diverse invertebrate species live in the soils, supported by active microbial decomposers. Insect and

vertebrate diversity are all higher in temperate coniferous forests than in taiga communities.

## Deciduous forest

Forests dominated by hardwood deciduous trees occur across much of eastern North America, Europe, and Asia in climates with moderate seasonal temperature variation and precipitation all year long. Much of this biome has been subjected to human disturbance for agriculture and urban development. Deciduous forests usually contain 15 to 25 tree species, including maples, oaks, poplars, and birches. Springtime sun passes through seasonally leafless trees to reach a diverse understory flora. Soils are rich in nutrients from annual leaf fall, and the moderate temperatures and precipitation promote decomposition, while the cool winters promote accumulation of organic materials. Soils contain a

diversity of microbes and fungi, along with the protists and invertebrate animals that feed on them. Insects, birds, and mammals are relatively diverse, joined by snakes, lizards, and amphibians.

## Temperate grassland

Before human settlement, this biome occupied most of the midwestern United States and south central Canada, dominated by blue-stem and buffalo grasses. Disturbance by fire helps to maintain grass populations in this biome. Lack of precipitation also prevents many species of trees from surviving in this region, and those trees that do grow successfully are usually found in low areas that have more available moisture. Because of the presence of active decomposers, soils in temperate grasslands accumulate nutrients, providing some of the most productive agricultural lands in the world. Before colonization by humans, temperate grasslands of North America supported abundant and diverse grazers, including bison, pronghorns, horses, and mammoths. Wild horses and mammoths became extinct in North America about 11,000 years ago, and herds of

bison and pronghorn dwindled in the nineteenth century. Burrowing grazers such as prairie dogs remain relatively common, although their population sizes have fallen; these species support predators such as ferrets, badgers, foxes, and birds of prey.

## Desert

Desert occurs in continental interiors north and south of the equator from 15° to 35° latitude ([Fig. 47.6](#)). Wind patterns prevent this biome from receiving more than a few centimeters of precipitation annually. Plants commonly have deep roots, and many, including cactus and euphorb plants, have stems adapted to store water. Primary production is low, and soils are poor in nutrients but may have high surface salt due to evaporation. Given the low rates of primary production, primary consumers tend to be small, and include diverse lizards as well as rodents. Predators include snakes, cat species, coyotes, and birds such as owls, hawks, and eagles.

Climograph data source: National Climatic Data Center

## Chaparral

Like the locations of deserts, the distribution of chaparral reflects a narrow

range of climate conditions found on the western edge of continents from 32° to 40° latitude north and south of the equator. Precipitation ranges from 30 to 75 cm per year, usually falling in a period of 2 to 4 months. Typical plants are herbs that die and reseed themselves every year, evergreen shrubs, and small trees. Olives, eucalyptus, acacia, and oaks are typical woody species, always drought resistant and often adapted to withstand fire. The limited precipitation means chaparral soils are not rich in organic materials.

Climograph data source: <http://www.geoforcxc.com/natural-systems/weather-and-climate/ecosystems/tropicalcontinental-climate/>

## Savanna

Tall, perennial grasses dominate this biome, which occurs in warm, relatively dry regions of eastern Africa, South America, and Australia. Rain is seasonal and ranges from 75 to 150 cm per year. Scattered trees and shrubs usually drop their leaves in the dry season to conserve moisture. As in temperate grasslands, fire plays a key role in maintaining this biome. Large mammalian grazers are abundant and diverse; they include the migrating antelopes, zebras, and giraffes well known from Africa, but also kangaroos and other marsupials in Australia and large rodents in South America. Predator diversity can also be high, as exemplified by lions and other cat species, hyenas, and wild dogs. Dingoes are important predators in Australian savannas, but were

introduced only a few thousand years ago from southeastern Asia. Before that time, the top carnivores included large, now-extinct lizards, as well as snakes and smaller lizards still present in the biome.

## Tropical rainforest

The most diverse of all terrestrial biomes, tropical rainforests extend north and south of the equator from 10° N to 10° S. Temperatures are warm, and annual precipitation commonly exceeds 250 cm. Tropical rainforests harbor a great diversity of species; tree diversity alone often exceeds 300 species per hectare. Trees grow tall, and many have buttressed roots for support. Vines and other epiphytic plants are common. Most leaves are evergreen and leathery, and many have long pointed tips that facilitate drainage of excess moisture. Because of the high temperatures and heavy rains, decomposition by fungi and bacteria is rapid, preventing the accumulation of organic materials in clay-rich or sandy soils. Few large grazers are found in rainforests, but smaller mammals such as primates, bats, and rodents are highly diverse, as are birds, snakes, and lizards.

Insects are especially abundant and diverse. Ants alone make up as much as 30% of animal biomass in rainforests, and they are the principal grazers on rainforest trees.

## Aquatic biomes reflect climate, the availability of nutrients and oxygen, and the depth to which sunlight penetrates through water.

Life, of course, is not limited to the land; diverse communities thrive in both freshwater and marine (saltwater) environments. Organisms that live in water face functional challenges distinct from the challenges on land, and this helps to explain the nature of aquatic biomes. Terrestrial organisms evolved from ancestors living in water, but to understand global ecology, it is helpful to begin with familiar terrestrial biomes and then move on to aquatic examples, which we generally experience only indirectly.

The most obvious distinction between terrestrial and aquatic biomes is that water is denser than air. For primary producers, buoyancy in water can provide mechanical support, reducing or eliminating the need for structural tissues such as wood. Also, primary producers on land are tethered to the ground both by gravity and the need to extract nutrients and water from soil, but this is not the case in aquatic biomes. In aquatic environments, nutrients are dissolved in the water, allowing primary producers to live as buoyant cells within surface waters, taking in dissolved nutrients and harvesting sunlight, often far from shore.

As it the case on land, the structure and distribution of primary producers governs the occurrence and abundance of consumers. Aquatic plants and macroscopic algae are important primary producers in shallow aquatic environments, where they can take advantage of nutrients transported from land while remaining anchored to the riverbed, lakebed, or seafloor. In larger lakes and the open ocean, however, phytoplankton—photosynthetic microorganisms that float in sunlit waters—are the predominant primary producers, combining high rates of primary production with low biomass.

In shallow aquatic environments such as lake margins and coastal marine settings, much plant, algal, and animal debris accumulates in sediments, supporting abundant growth by bacteria and various invertebrates. These decomposers provide food for many larger consumers, including the larvae and juveniles of commercially important fish and invertebrate species. Fungi, so important in terrestrial biomes as decomposers, can also have important actions in decomposing plant litter in streams and lakes. Fungi are generally thought to play only a minor role in the oceans, although recent surveys of marine sediments show that in areas with abundant organic matter and little oxygen, microscopic fungi capable of fermentation can be prominent decomposers. Bacteria also play a critical role in cycling the remains of phytoplankton and other open-water organisms, both within the water and on deep lakebeds or seafloors.

Grazers such as snails and fish feed on marginal plants and algae, while single-celled protists and microscopic animals called zooplankton consume phytoplankton that floats in the water. As on

land, secondary consumers such as other fish or squid feed on the grazers, adding complexity to food webs. Plankton, whether photosynthetic or heterotrophic, generally have only limited powers of locomotion, but rather drift with the current. In contrast, some consumers swim actively through their watery surroundings; called nekton, they include fish, squid, and whales. Because oxygen gas dissolves in water only to a limited extent, surface waters directly beneath the atmosphere have an O<sub>2</sub> concentration about 20 times lower than that of the air. This compels larger animals to move constantly to keep their gill systems well oxygenated, or to live in places such as cold running streams and rocky marine coastlines where currents naturally produce well-oxygenated water.

The main freshwater biomes are lakes and rivers ([Fig. 47.13](#)). These vary tremendously in climate as well as in nutrient input and oxygen availability. Commonly, stratification reflects temperature differences between surface and deeper waters, since cool water is denser than warm water. In general, the turbulent flow of water ensures that rivers are well oxygenated. In contrast, some lakes are physically stratified, meaning that the density of bottom waters keeps them from mixing upward with shallow waters. Organic debris that sinks to deep waters provides food for respiring bacteria, which in turn draws down oxygen levels. Where nutrient influx is high, oxygen levels in such lakes can become severely depleted in their deeper parts; this outcome is particularly common where human activities have increased the nutrient loads entering the lake ([Chapter 48](#)). Seasonal cooling of surface waters can eliminate temperature differences from top to bottom, causing previously stratified water masses to mix and bringing

oxygen to deep waters and nutrients to the surface. The seasonal influx of nutrients to surface waters commonly results in seasonal variations in both primary producers and rates of photosynthesis.

*(Lakes) Ken Gillespie/Getty Images.*

FIG. 47.13 Common freshwater biomes.

## **Lakes**

Lakes and ponds range in size from tiny temporary pools to the Great Lakes of North America, which contain more than 20% of all freshwater habitats in the world. Lakes range geographically from the equator to above 80° N. The ions dissolved in the waters, pH, and salinity vary with the types of terrain in which lakes are found, and nutrient levels can range from low to extremely high. Aquatic plants and macroscopic green algae live along the shallow margins of lakes, and both algae and cyanobacteria are primary producers throughout the photic zone. Zooplankton include small arthropods and rotifers, whereas the nekton is dominated by fish. Turtles and birds also play important roles as grazers and predators in many lakes.

*(Rivers) Ignacio Palacios/Getty Images.*

## **Rivers**

Rivers are freshwater biomes characterized by moving water. Because of their currents, streams and rivers erode, transport, and deposit sediment, so that their shape continually changes. Rivers and streams, like lakes, vary tremendously in size and chemistry. Rivers are generally well oxygenated, although oxygen levels may be lower in slowly moving rivers on floodplains. As with lakes, plants and large algae grow along river margins, while phytoplankton photosynthesize throughout the water column. Insects are important consumers, but other invertebrates, fish, turtles, and birds can all be abundant and diverse. Salmon and some other fish spend much of their lives in the oceans but swim upriver to reproduce.

## **Marine biomes cover most of our planet's surface.**

Only approximately 2.5% of Earth's water is fresh, and most of this water occurs in glaciers, permafrost, and groundwater within soils. Overwhelmingly, the water on our planet is seawater. Covering 71% of Earth's surface and reaching a depth of nearly 11,000 m (almost 7

miles), the oceans constitute Earth's largest biomes. In fact, the oceans are so large and so diverse in their biology that ecologists commonly subdivide them into distinct zones based on depth and proximity to the shoreline ([Fig. 47.14](#)).

The dimensions of the oceans determine the distribution of nutrients, oxygen, and light. Runoff from the continents (supplemented by nitrogen fixation by marine cyanobacteria) provides most of the nutrients required by primary producers in the sea, but because sunlight rarely penetrates much deeper than about 200 m (called the [photic zone](#)), most of the ocean's volume is off limits for photosynthetic organisms. The [neritic zone](#) encompasses environments that are near the shore, with a shallow seafloor, relatively high availability of nutrients, and persistent sunlight. Distinct biomes within the neritic

zone include intertidal and coral reef biomes ([Case 8 Conserving Biodiversity Hotspots](#)). Deeper waters beyond the continental shelf make up the [oceanic zone](#).

Within the oceanic zone, biologists commonly distinguish between the pelagic biome in open ocean water and the deep sea biome on the deep seafloor ([Fig. 47.14](#)). In the open ocean, nutrients are commonly less abundant, and waters are deeper, so much of the pelagic biome does not receive sunlight. Life in the deep sea biome is largely sustained by organic debris that rains downward from surface waters, although chemoautotrophic bacteria and archaeons contribute as well. Particle- and filtering-feeding animals, as well as microbes, respire this rain of organic matter, which returns phosphorus and nitrogen to the water. Nutrient-rich deep waters are eventually transported back to the surface, in a process called upwelling. Upwelling waters occur mostly near the shores of continents, where they support locally high rates of photosynthesis. Upwelling is commonly seasonal, so primary producers in this zone change from one part of the year to another. Upwelling regions make up only about 1% of the ocean's surface area, but by some estimates, they support more than 20% of all commercial fish populations.

Many different groups of algae contribute to primary production on continental shelves, with diatoms, coccolithophorids, and dinoflagellates dominating in most regions. These algae turn over rapidly: most are eaten by grazers or lysed by viruses within a few days. As a consequence, their total biomass is commonly lower than that of zooplankton that graze on them, inverting the trophic pyramid

characteristic of terrestrial ecosystems ([Chapter 46](#)). In the middle of large ocean basins, broad areas called gyres, which are bounded by major currents, lie far from continental and upwelling sources of nutrients; their low primary productivity is dominated by cyanobacteria and tiny algae discovered only recently.

Viruses play a particularly large role in marine biomes, lysing as much as 30% of phytoplankton daily in coastal ecosystems and releasing large amounts of organic molecules into the water column, the water that overlies the seafloor. The organic matter supports large populations of respiring bacteria and archaeons, which play an important role in returning carbon to the environment as carbon dioxide ([Chapter 24](#)). These microbial populations also support diverse populations of larger consumers.

Earlier in this chapter, we noted that winds drive ocean circulation, but winds affect only the uppermost waters of the sea. The surface layer that is mixed by the wind, broadly equivalent to the photic zone, is well oxygenated. In contrast, in deeper waters, oxygen can become depleted by respiration as microbes feed on sinking organic matter. In a few places where primary production is high on the surface, the oxygen level in water masses just beneath the mixed layer declines to essentially zero. In these areas, an oxygen-minimum zone forms that supports mostly anaerobically respiring microbial populations and features a limited presence of zooplankton and animals. On the deep seafloor and in the waters above the seafloor, oxygen is present but food is sparse, consisting only of a slow rain of particles from shallower depths. Lifeforms consist of scattered populations of animals

(especially fish, brittle stars, and polychaete worms), heterotrophic protists, and microbes. One notable exception occurs at hydrothermal vents, where high concentrations of sulfide, hydrogen, and methane support primary production by chemosynthetic bacteria and archaeons. These, in turn, support locally dense populations of animals.

Key marine biomes are summarized in [Fig. 47.15](#).

*Source: (Intertidal) Dan L. Perlman/EcoLibrary*

FIG. 47.15 Common marine biomes.

### **Intertidal**

The part of the neritic (shallow-water) zone closest to shore is the intertidal biome, the part of coastlines between the high and low tide marks. Intertidal organisms are exposed to the atmosphere on a daily basis; thus they are challenged by periodic desiccation as well as by temperature extremes that accompany exposure to direct sunlight. As a consequence, the intertidal biome has distinctive species associations. In sandy intertidal zones, or tidal flats, many animals burrow into the wet sand to escape exposure at low tide. In rocky intertidal zones, organisms

such as mussels and barnacles may close their shells tightly when the tide is out. Waves can sweep organisms away; to avoid this fate, especially along rocky coastlines, both algae and animals securely attach themselves to the substrate. Nutrient levels can be high, favoring strong algal growth. Consumers include a variety of sea stars, sea urchins, mollusks, barnacles, and polychaete worms. Intertidal biomes exhibit the greatest diversity where tidal exposure is relatively short. Tidal pools harbor diverse animal and algal species.

*Source: (Coral reefs) DIRSCHERL Reinhard/  
hemispicture.com/Getty Images*

## **Coral reefs**

Coral reefs form another neritic biome—indeed, the most diverse biome in the oceans. The best-known reefs occur in shallow, tropical to subtropical environments where the skeletons of corals form physical structures that rise above the seafloor. Nutrient levels are commonly low, but primary production is high and mostly tied to dinoflagellate algae that live within the tissues of corals. Rapid recycling of nutrients between the corals and their algal symbionts ensures high levels of primary production. Free-living algae occur in reefs, but are kept at low abundance by grazing fish. Many species of invertebrates live within the reefs, often in nooks and crannies among coral heads that provide shelter from predators. Fish

diversity can be especially high. Coral reefs also occur in the deep sea, but build gradually there, as coral growth occurs only slowly in the absence of symbiotic algae.

*Source: (Pelagic realm) Michael Aw/SeaPics.com*

## **Pelagic**

The pelagic biome—the part of the ocean that is neither close to shore nor close to the seafloor—forms the bulk of the oceanic system. Both plankton and nekton live within the water column. In the upper 200 m or so of the pelagic biome, sunlight permits photosynthesis, with diverse algae and cyanobacteria acting as primary producers. In deeper waters, sunlight is absent and life is sustained by the rain of organic particles from surface waters. Zooplankton are mostly small arthropods, while fish and cephalopods are key components of the nekton. Although this is true in both surface and deep waters, animals are less abundant in deep waters. Fish and squids are conspicuous consumers, but recent research shows that, in the upper water column, heterotrophic protists may actually be more abundant and diverse than fishes. Bacteria and archaeons occur throughout the pelagic biome.

Source: (Deep sea) Barrett Lia/SeaPics.com.

## Deep sea

Kilometers below the surface, deep seawaters are cold and dark, though not sterile. Sinking detritus supports sparse populations of animal consumers, as well as bacteria and archaeons that feed on organic particles or generate energy and organic molecules by chemosynthetic pathways tied to the nitrogen cycle ([Figure 24.20](#)). Despite their limited biomass, deep-sea biomes exhibit species diversity as high as those of shallow marine communities. Nevertheless, the composition of communities in deep-sea biomes differs relatively little from place to place around the world, so the total diversity of these environments is lower than that found within the photic zone globally. Dense animal populations occur locally on the deep seafloor, where hydrothermal vents expel fluids containing high abundances of hydrogen, hydrogen sulfide, and methane. These compounds support locally high levels of primary production by chemosynthetic bacteria, many of them present as symbionts within the tissues of vent animals ([Chapter 24](#)).

### Self-Assessment Questions

5. Why can wet soils occur both near the equator, where rainfall is

high, and at high latitudes, where rainfall is low?

6. Choose five terrestrial biomes, describe their climate and vegetation, and explain why they differ from one another.
7. How do marine biomes differ between the surface ocean and the deep seafloor?

## 47.3 GLOBAL PATTERNS

Biomes show how the physical environment influences the abundance, form, and diversity of species in different parts of the planet. In [Chapter 46](#), we discussed another aspect of the interactions between organisms and their environments: the ways that ecosystems cycle energy and nutrients. What do we see when we look at these patterns globally, rather than at the ecosystem or biome level? In this section, we focus on global patterns of primary production and biodiversity, both of which depend on interactions between Earth and life.

### Global patterns of primary production reflect variations in climate and nutrient availability.

The biomes we just discussed all depend on a foundation of primary production. This brings up an important question: what controls rates of photosynthesis? Sunlight plays a role. Although all ecosystems, from polar deserts to equatorial forests, receive the same total number of hours of sunlight annually, the intensity of solar radiation declines from the equator to the poles because of Earth's curvature (see [Fig. 47.1](#)). Seasonality also becomes more pronounced toward the poles, influencing the ability of primary producers to sustain growth throughout the year at higher latitudes (see [Fig. 47.2](#)).

In addition to sunlight, water and nutrients govern the rate of primary production in most ecosystems. In [Chapter 27](#), we saw that plants perform a physiological balancing act, opening their stomata to allow carbon dioxide into their leaves but losing water vapor as a

result. Because photosynthesis requires both carbon dioxide and water, the photosynthetic rate, defined as the amount of carbon dioxide fixed into organic matter in a given time interval, is closely tied to water availability. Lack of regular access to water limits the productivity of photosynthetic organisms in deserts and seasonally arid landscapes, explaining why irrigation increases crop yields in arid places such as southern California, northern Africa, and the Middle East.

Even where water is not a limiting factor, rates of photosynthesis are constrained by the availability of nutrients. For this reason, application of fertilizer rich in nutrients generally increases crop yields. Plants, algae, and photosynthetic bacteria all need nitrogen, phosphorus, sulfur, iron, and an array of trace elements to grow, and a shortage of any one of these nutrients can limit primary production. In forests, nitrogen is commonly the soil nutrient that is least abundant relative to the needs of plants. In the open ocean, nitrogen can also be limiting, although more commonly a scarcity of phosphorus limits photosynthesis. In other parts of the ocean, nitrogen and phosphorus are both present in abundance, but primary production is limited by a deficiency of iron, which is needed for many enzymes and electron transport molecules ([Fig. 47.16](#)).

#### HOW DO WE KNOW?

### FIG. 47.16

Does iron limit primary production in some parts of the oceans?

#### BACKGROUND

Plants, algae, and other primary producers require nitrogen and phosphorus to make proteins, nucleic acids, lipids, and other biomolecules. In turn, the availability of these nutrients is thought to limit primary production in the oceans. Photosynthetic organisms generally photosynthesize until their environment becomes depleted in a nutrient required for growth. In many parts of the oceans, nitrogen (most commonly in the form of nitrate ion,  $\text{NO}_3^-$ ) is found in extremely low levels in the photic zone, identifying it as a limiting nutrient. Phosphorus (as phosphate ion,  $\text{PO}_4^{3-}$ ) is also depleted in most surface waters, indicating that it, too, can limit rates of photosynthesis. Regionally, however, nitrogen and phosphorus concentrations can both be high. This indicates that primary producers are not making use of these available nutrients and strongly suggests that some other factor is limiting primary production.

#### HYPOTHESIS

In some parts of the oceans, iron—required for the functioning of enzymes critical to photosynthesis and nitrogen uptake—is the nutrient in lowest supply relative to the needs of primary producers. In such cases, it limits rates of photosynthesis.

#### EXPERIMENT

In the late 1980s, American oceanographers John Martin and Steve Fitzwater became intrigued by subarctic waters of the northeastern Pacific Ocean, where high nitrogen and phosphorus concentrations suggested that some other nutrient was limiting primary production. They collected samples of seawater, along with its photosynthetic phytoplankton, and added small amounts of iron to different samples: 1, 5, or 10 nanomoles per kilogram of sample (in the control sample, no iron was added). As photosynthesis proceeded over the course of a week, the researchers made daily measurements of chlorophyll concentration (an indicator of photosynthetic rate), as well as of the concentrations of nitrogen ( $\text{NO}_3^-$  the

nitrate ion in [Fig. 47.16b](#)) and phosphorus ( $\text{PO}_4^{3-}$  the phosphate ion in [Fig. 47.16c](#)) in the sample treatments.

## RESULTS

As the graphs show, over the course of the experiments, samples to which iron (Fe) was added showed increased chlorophyll concentrations ([Fig. 47.16a](#)) and decreased levels of nitrogen ([Fig. 47.16b](#)) and phosphorus ([Fig. 47.16c](#)), with higher additions of iron generally showing more pronounced effects. In contrast, controls with no added iron showed little change over the course of the experiment.

## CONCLUSION

In samples from the northeastern Pacific Ocean, addition of iron increased rates of photosynthesis and resulted in primary producers taking up more nitrogen and phosphorus. This supports the hypothesis that, in these waters, iron—not nitrogen or phosphorus—limits primary production.

## FOLLOW-UP WORK

Since this initial experiment, many researchers have conducted similar studies with consistent results in areas of the surface ocean containing relatively high levels of nitrogen and phosphorus. Some researchers have suggested that seeding these ocean waters with iron could increase primary production and lead to the sinking of organic carbon into the deep sea. This would remove carbon dioxide from the atmosphere, helping to alleviate global climate change associated with increasing human-

generated CO<sub>2</sub> emissions. To date, when this approach has been tried, results have been mixed, with experiments showing a spike of increased photosynthesis after the addition of iron, followed by an interval of enhanced respiration, with little carbon ultimately sinking into the deep sea.

SOURCE Martin, J. H., and S. E. Fitzwater. 1988. "Iron-Deficiency Limits Phytoplankton Growth in the Northeast Pacific Subarctic." *Nature* 331:341–343.

The idea that primary production is limited by the nutrient that is least available relative to the needs of primary producers is called **Liebig's Law of the Minimum**, after Justus von Liebig, a nineteenth-century German scientist who first popularized the concept. Climate and nutrient limitation therefore play important roles in determining the primary productivity of individual ecosystems. It stands to reason, then, that global patterns of primary production reflect planetary-scale variations in climate and nutrient availability.

**Fig. 47.17** illustrates the global distribution of primary production on land. The similarity of this figure to maps of global evapotranspiration and precipitation (see **Fig. 47.10**) shows the strong control exerted by climate on patterns of terrestrial primary production. Warm and wet climates near the equator support highly productive forests, whereas dry habitats and cold environments with limited growing seasons have lower levels of primary productivity.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 47.17 Primary production on land. High rates of primary production occur where climates are warm and wet. Data from W. Cramer *et al.*, 1999, “Comparing Global Models of Terrestrial Net Primary Productivity (NPP): Overview and Key Results,” *Global Change Biology* 5 (suppl 1): 1–15.

By contrast, [Fig. 47.18](#) illustrates how rates of photosynthesis vary in large lakes and the ocean. In the sea, the relationship to global climatic zones is not so clear, which is not surprising because, in aquatic ecosystems, water is not a limiting factor for photosynthesis. The principal pattern shown in [Fig. 47.18](#) is one of high photosynthetic rates along the margins of continents and especially low rates in the central gyres of circulating oceans. Rates of primary production are high near continents because runoff of nitrogen and phosphorus from the continents supplies abundant nutrients to the sea. Upwelling zones, mostly coastal areas where nutrient-rich deep waters return to the surface, are also regions of high primary production. In contrast, the

interiors of large ocean basins contain little biologically available nitrogen or phosphorus, so rates of primary production are low in these regions.

Global patterns of primary production help to determine the properties of biomes. Moreover, as we will see in the next section, primary production helps determine global patterns of biological diversity.

## Biodiversity is highest at the equator and lowest toward the poles.

On a half-hour walk through a deciduous forest—for example, in the northeastern United States or southeastern Canada—we can expect to

see maybe a dozen different kinds of trees: two or three kinds of oaks perhaps, a couple of maple species, birch, beech, hornbeam, ironwood, one or two pine species, and possibly a sycamore, poplar, or spruce, depending on just where we are. Standing in front of a tree and turning around, we can almost always see several more trees of the same kind. In contrast, on a similar walk through a forest in the Amazon or in Borneo, we would pass 300 or 400 different tree species, with almost no two trees of the same kind right next to each other. The great Victorian naturalist Alfred Russel Wallace took note of the low population density of trees in tropical forests and observed, “If the traveller ... notices a particular species and wishes to find more like it, he may often turn his eyes in vain in every direction.”

Our intuitive feel for biodiversity is reflected in the global distribution of plant species richness shown in [Fig. 47.19](#). Equatorial rainforests harbor the highest number of plant species, and in general the amount of plant diversity decreases as we move from the equator toward the poles. This change in species diversity from the equator to the poles is called the [latitudinal diversity gradient](#). Deserts have particularly low plant diversity, a pattern linked to their low primary productivity. In contrast, chaparral climates—temperate regions with dry summers and wet winters, often called Mediterranean climates because they characterize lands around the Mediterranean Sea—can support large numbers of plant species. This pattern is seen, for example, along the southern tip of Africa, southwestern Australia, and Mediterranean Europe. In these regions, additional factors only indirectly linked to climate influence regional plant diversity, including habitat diversity (in Mediterranean regions, a mixture of woodland,

savannahs, and grassland) and frequent fires (disturbance, discussed in [Chapter 45](#)).

Mammals, birds, insects, and many other kinds of animal show similar patterns of species diversity, with the highest species diversity found near the equator and the lowest near the poles. As an example, [Fig. 47.20](#) shows the global distribution of mammal species. To get a sense of animal diversity in tropical rainforests, consider that one survey found more than 700 species of leaf beetle in a single small set

of trees in the Amazon, a number equal to the total diversity of leaf beetles in all of eastern North America. A single tree in this same forest harbored 43 species of ants, exceeding the total for all of Great Britain.

What causes the latitudinal diversity gradient, and what are its consequences? Does this global pattern reflect the ecological processes that characterize communities? Ideas abound on why the tropics contain so many species. One hypothesis that has garnered broad support looks to the relative ages of tropical and higher-latitude biomes. Tropical biomes tend to be older, having evolved over tens of millions of years, whereas biomes at higher latitudes have changed identity as the climate changed over the past few million years. For instance, parts of North America that were covered by glaciers 20,000 years ago now support forests and grasslands. Because tropical habitats have existed much longer than temperate ones, biologists hypothesize

that species have had more time to evolve and diversify at low latitudes. Several studies of diversification rate, such as in frogs, show comparable rates of diversification in temperate and tropical biomes, supporting the hypothesis that the higher tropical diversity reflects the longer interval over which diversification has taken place.

Time, however, is just one of several factors that influence diversity. Another hypothesis is that temperate communities have fewer species because it is relatively difficult to adapt successfully to cold, dry winters and the range of weather typically experienced at higher latitudes. A tree growing in a temperate area like New England experiences a wide range of temperatures over a year (and sometimes even over a single day) as winds blow and snow falls, or heat waves move through the area. Because species living at high latitudes are adapted to a greater range of conditions, on average, than those nearer the equator, they tend to have larger geographic ranges than tropical species, which are adapted to the narrow range of environmental variation experienced in any particular place.

One hypothesis suggests that the many insects and fungi specialized to attack particular kinds of trees are generally more abundant in wet tropical forests, so trees of a given species tend to be as far apart as they can be, thus reducing the chance of being found by their enemies. This spacing leaves more room for different species in any given place. In addition, more land surface area is available at low latitudes, so the species–area relationship ([Chapter 44](#)) may play a role in the latitudinal diversity gradient.

Very likely, the latitudinal diversity gradient reflects all these influences, and perhaps more not yet studied. One lesson is clear, though: where there are more species of plants, there are also more species of animals and other consumers. Tropical temperatures and high humidity have permitted a wide range of plant species to evolve over the past 100 million years, creating many niches for the animals that depend on them.

Both on land and in the sea, biodiversity hotspots occur predominantly in tropical to subtropical environments. In part, this distribution simply reflects the higher species diversity typical of lower latitudes, but it also highlights that tropical communities contain a relatively high proportion of endemic species, species found in one place and nowhere else. Because of the way that biodiversity hotspots are distributed around the globe, the burden of conservation efforts falls disproportionately on developing countries.

## CASE 8 CONSERVING BIODIVERSITY: RAINFOREST AND CORAL REEF HOTSPOTS

### How do evolutionary and ecological history explain biodiversity?

Earth's biomes are the result of natural selection and environmental change through time. For this reason, the fossil record can shed light on how current patterns of diversity came to be. In general, fossils tell us little about the origins of tropical forests. On the island of Hispaniola,

however, there is a remarkable exception: nuggets of amber that provide an extraordinary window on life in the island's rainforest 30 to 23 million years ago.

Amber is fossilized tree resin, and in Hispaniola it comes from the tree *Hymenea*, a genus of plants within the pea family. *Hymenea* trees grew in the Hispaniola rainforest 30 to 23 million years ago, much as they do today. Lizards, tree frogs, insects, plants, and fungi were all captured in their sticky sap, which hardened into amber, preserving a record of forest diversity and ecology ([Fig. 47.21](#)).

Source: a. Maria Arts/Shutterstock; b and c. Courtesy George Poinar.

FIG. 47.21 Fossils in 30–23-million-year-old Dominican amber. Tree resins (a) trap insects and other organisms and harden into amber, preserving their contents as fossils. Fossils from Dominican amber document the evolutionary history of (b) orchid-pollinating stingless bees, now extinct on Hispaniola, and (c) *Anolis* lizards that, like their modern descendants, hunted insects in trees.

Studies of these fossils reveal ecological relationships similar to some observed on Hispaniola today. Not surprisingly, some of the most abundant animals in the amber are insects whose modern counterparts have ecological associations with *Hymenea*. Ancient ants that patrolled the bark of ancient *Hymenea* and other tropical trees in search of food, beetles that fed on trees that secrete resin as a defense mechanism, and

stingless bees that gathered resins for their nests are all preserved intact in the amber. Many of the insects seen in this amber, perhaps even the majority, are practically indistinguishable from species that continue to exist today on Hispaniola.

Vertebrate fossils are rare in Dominican amber, but they include *Anolis* lizards closely related to lizards found in Hispaniola today that are specialized for life in the canopies and high on the trunks of forest trees. In other words, resource partitioning ([Chapter 45](#)) began long ago in the Hispaniola rainforest.

Studies of these kinds of fossils add a deeper dimension of time to our understanding of how ecosystems have come to be. Whether forest, reef, or grassland, every ecosystem contains the present-day survivors of groups representing a broad range of origins in evolutionary time and geographic space. The amber fossils remind us that what G. Evelyn Hutchinson called “the ecological theater and the evolutionary play” have been intertwined throughout our planet’s history, producing the diversity of species we see today.

#### Self-Assessment Questions

8. Why do patterns of global primary production on land show strong latitudinal variation, whereas primary production in the oceans varies more strongly with distance from shore?
9. Describe the general pattern of diversity from the equator to the poles. Provide two hypotheses to explain this pattern of diversity.
10. From what you know about how species diversity changes with

latitude, predict how species diversity changes with altitude.

---

## CORE CONCEPTS SUMMARY

**47.1 CLIMATE:** Solar radiation, wind and ocean currents, and topography determine the distribution of major climactic zones on Earth.

Equatorial climates are warm and polar climates are cold because solar radiation strikes Earth's curved surface head-on at the equator and at an increasing angle at increasingly higher latitudes. [page 1067](#)

Because of the tilt of Earth on its axis, solar radiation strikes the Northern and Southern Hemispheres unevenly at different parts of Earth's orbit, causing seasonality. [page 1068](#)

Rising warm air near the equator and sinking cool air drives winds that transport heat from the equator toward the poles. [page 1068](#)

Prevailing winds drive ocean currents that transport heat from the equator toward the poles. [page 1069](#)

Topographical features, such as mountains, regionally modify global circulation patterns. [page 1071](#)

**47.2 BIOMES:** Biomes are broad, ecologically uniform areas whose characteristic species reflect regional climate.

The distribution of the plants that characterize terrestrial biomes reflects factors such as climate and soil. [page 1072](#)

Regional climate determines the ratio of potential evapotranspiration to precipitation, a key determinant of vegetation

type, primary production, and biodiversity in terrestrial biomes.

[page 1073](#)

Aquatic biomes reflect the spatial distribution of nutrients and the depth to which sunlight penetrates water. [page 1074](#)

**47.3 GLOBAL PATTERNS:** Global patterns of primary production and biological diversity reflect climate, nutrient availability, and evolutionary history.

Climate and nutrient availability determine global patterns of primary production. [page 1086](#)

In most terrestrial ecosystems, water and nutrients limit rates of primary production. [page 1086](#)

In the sea, nutrients commonly limit primary production. [page 1088](#)

Species diversity generally declines from the equator toward the poles, a pattern known as the latitudinal diversity gradient. [page 1088](#)

Earth's biomes are the historical outcome of environmental change through time and natural selection. [page 1090](#)

# CHAPTER 48 The Anthropocene

## Humans as a Planetary Force

Michael Utech/Getty Images

---

### CORE CONCEPTS

**48.1 THE ANTHROPOCENE EPOCH:** Some scientists call the time in which we are living the Anthropocene Epoch to reflect humans' significant

impact on the planet.

**48.2 HUMAN INFLUENCE ON THE CARBON CYCLE:** Humans have a major impact on the carbon cycle, primarily through the burning of fossil fuels, which returns carbon dioxide to the atmosphere at high rates.

**48.3 HUMAN INFLUENCE ON THE NITROGEN AND PHOSPHORUS CYCLES:** Humans have an important impact on the nitrogen and phosphorus cycles, primarily through the use of fertilizer in agriculture.

**48.4 HUMAN INFLUENCE ON EVOLUTION:** The impact of humans on the environment is changing the setting in which evolution acts.

**48.5 CONSERVATION BIOLOGY:** Conservation biology aims to safeguard biodiversity for future generations.

**48.6 SCIENTISTS AND CITIZENS IN THE TWENTY-FIRST CENTURY:** In the twenty-first century, biologists, doctors, engineers, teachers, and informed citizens have vital roles to play in understanding our changing planet and making wise choices for our future.

---

By almost any measure, you were born into humanity's golden age. Beginning with the invention of the steam engine, humans have mastered the ability to harness Earth's store of chemical energy, dramatically extending the power of our own and other animals' muscles. You probably don't find it remarkable to drive across a continent in less than a week or fly across an ocean overnight, but your great-great-grandparents would have been astonished. At the same time, advances in antibiotics and public health have drastically reduced infectious disease in many parts of the world. Smallpox, long one of

life's deadliest realities, has been eliminated, and polio may eventually follow the same path. In addition, the Green Revolution of the last 70 years has culminated in today's unprecedented amounts of food for a hungry planet ([Case 6 Agriculture](#)).

One consequence of this success is an increasing human population: our numbers have doubled since 1970, exceeding 7.6 billion as of 2018. Another ramification is that our actions increasingly affect the world around us directly or indirectly. In this chapter, we look at some of these impacts, and what we can do about them. Can we sustain or control current patterns of population growth and resource use? Can we ensure that future generations will be able to enjoy and benefit from the diversity of life we see today? As discussed in the following sections, there is reason for both concern and optimism. Together, scientific insight, technical ingenuity, and wise citizenship provide our best hope of conserving our natural world while sustaining hard-won gains in food, energy, and health through the twenty-first century and beyond.

# 48.1 THE ANTHROPOCENE EPOCH

Increasingly, scientists refer to the modern time as the [Anthropocene Epoch](#), from the Greek *anthropos*, meaning “human,” and *kainos*, meaning “recent.” This name emphasizes the dominant impact of humans on the present day Earth. Our collective impact is partly a consequence of our sheer numbers, which in turn drive our energy and land use, but it also reflects the individual and societal choices we make.

## Humans are a major force on the planet.

More humans are alive today than ever before, and our numbers are climbing rapidly. A world that had approximately 500 million inhabitants when Christopher Columbus set sail in 1492 now supports more than 7.6 billion people ([Fig. 48.1](#)). By the time you retire, our numbers will probably exceed 9 billion.

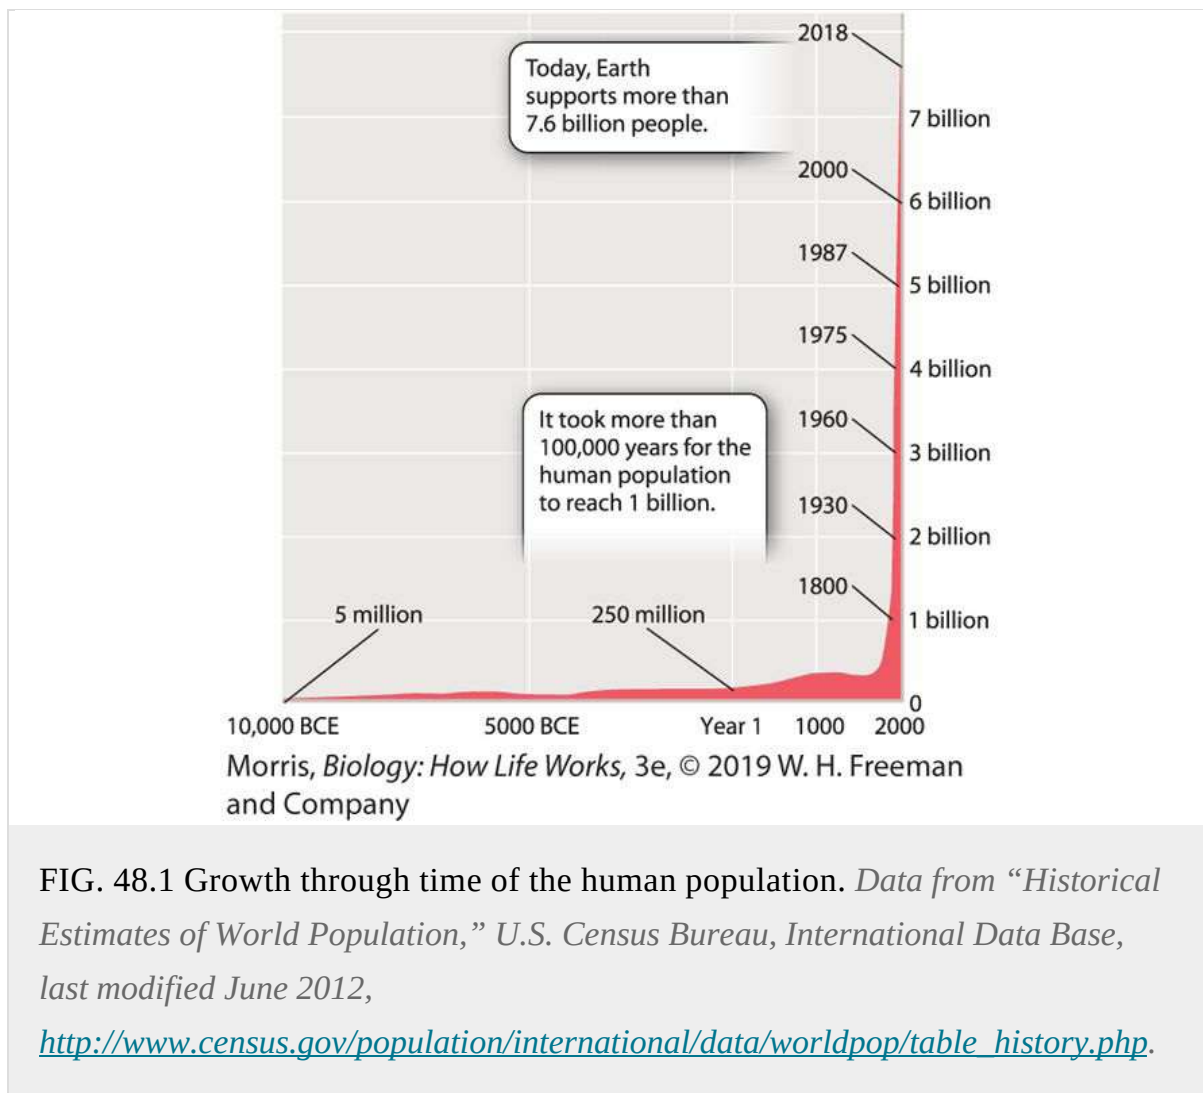

FIG. 48.1 Growth through time of the human population. *Data from “Historical Estimates of World Population,” U.S. Census Bureau, International Data Base, last modified June 2012, [http://www.census.gov/population/international/data/worldpop/table\\_history.php](http://www.census.gov/population/international/data/worldpop/table_history.php).*

Of course, population size doesn't tell the whole story. Whether driving a car, living in a heated apartment, plugging in a computer, or eating fruit shipped from another hemisphere, you use a great deal more energy than your ancestors did. [Fig. 48.2](#) shows daily energy use per person in selected countries. As you can see in this bar chart, energy use by individuals varies greatly from one part of the world to another. Americans, Canadians, Europeans, and Australians live energy-intensive lives, whereas populations in rural Africa and parts of Asia consume relatively little energy per person.

FIG. 48.2 Energy use by individuals among countries. Energy use is distributed unevenly among countries. *Data from United Nations Department of Economic and Social Affairs, 2009, World Economic and Social Survey 2009: Promoting Development, Saving the Planet, New York: United Nations, p. 44, <http://www.un.org/en/development/desa/news/policy/wess-2009.shtml>.*

In truth, our direct use of energy reflects only part of our impact on the planet. Nearly everything humans use requires both land and energy. All of us consume food grown in fields, fertilized and harvested through energy, and shipped to a local store. We live in houses built of wood, brick, and stone, and use clothing, furniture, and appliances fashioned from plant materials grown in fields and forests or from minerals extracted from Earth by mining. It takes land to grow plants, and energy to sow seeds, make and distribute fertilizer, harvest useful materials, and manufacture, ship, and clean the finished products.

The **ecological footprint** concept represents an attempt to quantify our individual claims on global resources by adding up all the energy,

food, materials, and services we use and estimating how much land is required to provide those resources. [Fig. 48.3](#) plots the average ecological footprint per person against the Human Development Index, a measure of standard of living maintained by the United Nations, for many countries. Not surprisingly, developed countries tend to have large ecological footprints: it takes more than 7 hectares of land to support an average American. By contrast, in many parts of Asia and Africa, the average citizen is supported by only a single hectare.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Source: European Environmental Agency, <http://www.eea.europa.eu/data-and-maps/figures/correlation-of-ecological-footprint-2008>.

FIG. 48.3 Our ecological footprint. The graph shows the number of hectares needed to support an average person in different countries compared with their ranking on the Human Development Index, a measure of standard of living.

In many countries, living standards have risen over the past 50 years, nearly always increasing the mean ecological footprint of their

citizens. By some estimates, the total ecological footprint of humanity now exceeds the actual surface area of Earth. Taken together, then, trends in population size and the ecological footprint highlight both the remarkable technological successes of the past century and the challenges we face as citizens, policy makers, scientists, and engineers in the decades to come.

#### Self-Assessment Questions

1. Take a look at [Fig. 48.1](#). How long did it take the human population to double from 1 billion to 2 billion? How about from 2 billion to 4 billion? What does this pattern say about the rate of population growth?
2. Why does the mean “ecological footprint” of a country’s citizens increase as its standard of living increases?

## 48.2 HUMAN INFLUENCE ON THE CARBON CYCLE

In [Chapter 46](#), we discussed the carbon cycle, explaining how photosynthesis removes carbon dioxide ( $\text{CO}_2$ ) from the atmosphere and respiration replaces it. The Keeling curve (see [Fig. 46.1](#)) shows that atmospheric  $\text{CO}_2$  levels have increased annually over the past 60 years, and analyses of air bubbles trapped in glacial ice indicate that this pattern of increase began even earlier, with the onset of the Industrial Revolution in the nineteenth century (see [Fig. 46.3](#)).

Clearly, humans have become major contributors to the carbon cycle, particularly the part of the cycle in which ancient organic matter, or fossil fuel, is oxidized to  $\text{CO}_2$ , returning  $\text{CO}_2$  to the atmosphere ([Fig. 48.4](#)). As discussed in [Chapter 46](#), the amount of  $\text{CO}_2$  we add to the atmosphere each year by burning fossil fuel is about 100 times that produced by all Earth's volcanoes taken together. And, as we also saw in [Chapter 46](#), measurements over the past several decades of the relative abundances of different isotopes of carbon in atmospheric  $\text{CO}_2$  indicate that the  $\text{CO}_2$  now being added to our air comes primarily from the combustion of fossil fuels (see [Fig. 46.4](#)). Clearing forests for agriculture generates still more  $\text{CO}_2$  ([Fig. 48.4](#)). When preparing land for agriculture, the existing vegetation is generally burned off, converting much of the organic carbon in biomass and soil organic matter to  $\text{CO}_2$ . No counteracting process removes  $\text{CO}_2$  at comparable rates.

Sources: a. Tim McCaig/Getty Images; b. Stockbyte/Getty Images.

FIG. 48.4 Human-generated sources of carbon dioxide. Every year, humans convert organic matter to carbon dioxide at rates far higher than those found in nature, predominantly by (a) burning fossil fuels and (b) biomass burning, as seen in this Amazon forest.

As atmospheric carbon dioxide levels have increased, so has mean surface temperature.

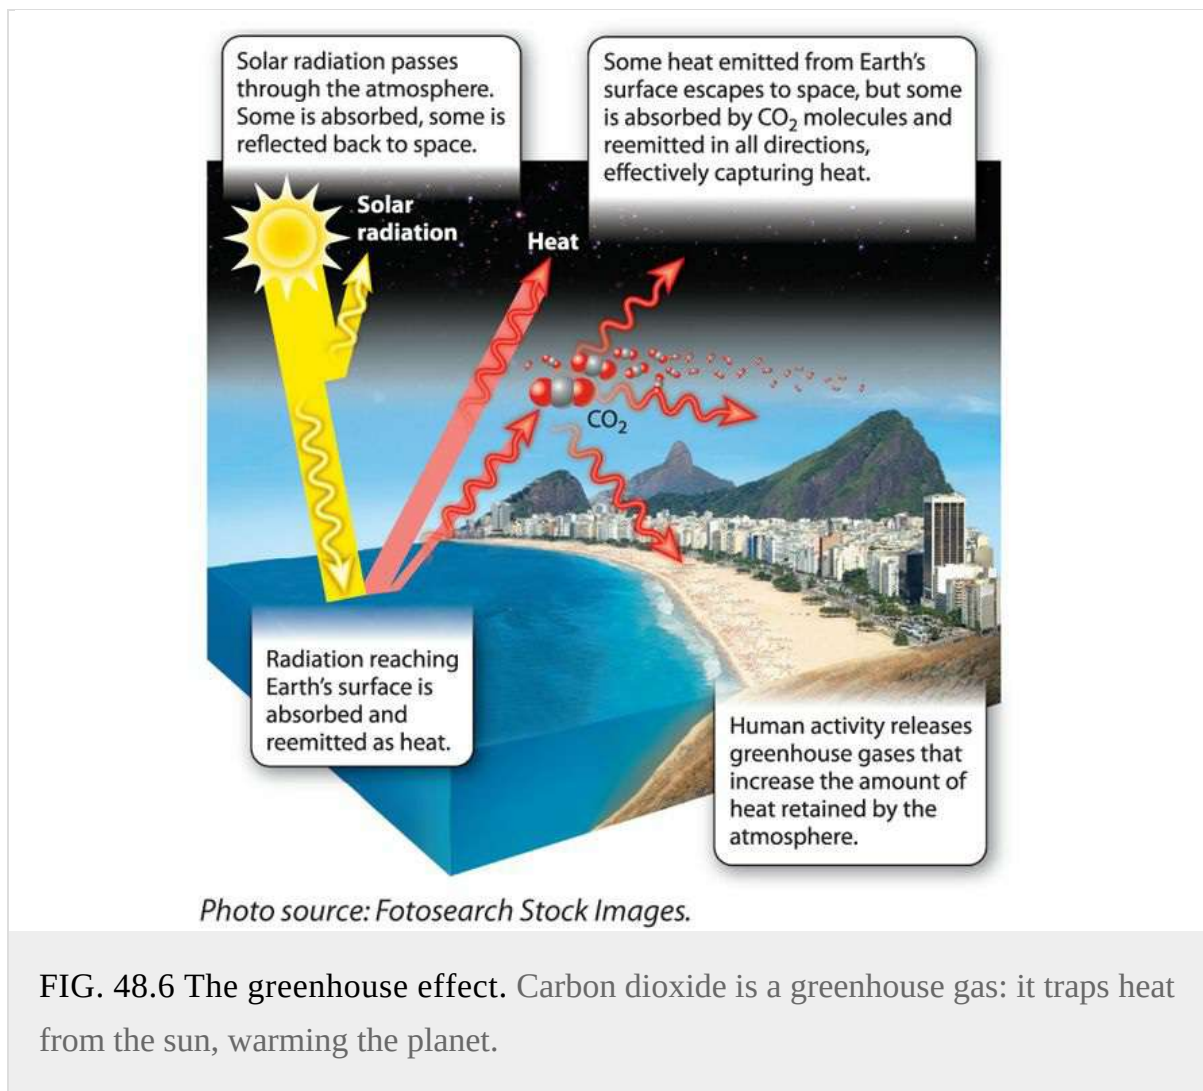

For the past century, scientists, sailors, and interested citizens have monitored temperature at weather stations around the world. More

recently, satellites have enabled us to measure temperature in places as remote as the high Arctic and the middle of the ocean. The results are clear: in most parts of the world, mean annual temperature during the decade 1999–2008 was warmer than the average temperatures for 1940–1980 (**Fig. 48.5**). In some places, the temperature change has been slight; in others, especially at high latitudes, the increase has been as much as 2°C.

We can measure CO<sub>2</sub> levels in the atmosphere, and they are increasing. We can measure global temperature, and it is increasing. Is

increasing CO<sub>2</sub> responsible for the observed temperature changes? To address this question, we must understand that CO<sub>2</sub> is a **greenhouse gas**, a gas that absorbs heat energy and then emits it in all directions. As shown in **Fig. 48.6**, solar radiation (yellow in **Fig. 48.6**) passes freely through the atmosphere, from top to bottom. Some incoming radiation is reflected from Earth's surface, and the rest is absorbed by the land and sea. In turn, some of the energy absorbed by Earth's surface is radiated back again as infrared radiation, or heat (red in **Fig. 48.6**). Greenhouse gases in the atmosphere absorb the infrared radiation reflected up from Earth's surface and emit it in all directions. Some is directed upward, out of the atmosphere, but half of the trapped heat is directed downward, toward Earth. The net effect is like that of the glass panes of a greenhouse, which allow sunlight to enter but prevent heat from leaving.

Carbon dioxide is just one of several important greenhouse gases in the atmosphere: water vapor is another, and methane a third. Without these gases absorbing and trapping heat, average surface temperatures would fall below freezing and life would not be possible. However, because CO<sub>2</sub> is increasing rapidly, its greenhouse effect is also increasing. Likewise, methane levels are rising rapidly, in large part because of increasing food production. Most of the methane added to the atmosphere each year is generated by methane-producing archaeons ([Chapter 24](#)), which thrive in the guts of cattle and in the waterlogged paddies where rice is cultivated. More beef and expanded

rice paddies result in higher rates of methane production. The thawing of permafrost at high latitudes releases additional methane that was trapped in frozen soils when the ice formed long ago.

Physics can help us determine how much atmospheric warming is due to increases in greenhouse gases. Each molecule of greenhouse gas absorbs and emits a specific amount of heat, and calculations show that the increases in atmospheric greenhouse gases measured over the past 50 years have increased the difference between incoming (solar) and outgoing radiation by approximately 2.5 watts per square meter. This difference winds up adding heat to the oceans and atmosphere. The scientific consensus, as reflected in reports from the Intergovernmental Panel on Climate Change, is that this greenhouse effect is the principal cause of the observed temperature change over the course of the twentieth century. Scientific consensus also holds that global temperature will continue to rise as atmospheric CO<sub>2</sub> continues to increase in the twenty-first century.

If this view is correct, human activities are changing the world. But can we really eliminate the possibility that the observed increases in greenhouse gases and temperature have natural causes? After all, as we saw in [Chapter 46](#), the long-term geologic record indicates that climate and atmospheric composition have changed dramatically and repeatedly throughout our planet's history, long before humans walked the Earth. Perhaps volcanic emissions have increased, driving the observed changes. As it turns out, volcanic activity cannot explain current global warming; measurements of the isotopic composition of atmospheric CO<sub>2</sub> effectively eliminate volcanic eruptions as a principal

source of the increasing CO<sub>2</sub> level (see [Fig. 46.4](#)).

Moreover, we can monitor the effects of volcanoes as they occur, and we can gauge the effects of past eruptions because volcanic ash accumulates along with the ice in continental glaciers. Historically, the major effect of large volcanic eruptions has been to *decrease* temperature because volcanic ash and aerosols reflect incoming solar radiation back into space. Furthermore, the impact of volcanic eruptions lasts only a few years; it doesn't drive the kind of century-long temperature increase that we are currently observing.

What about the possibility that the amount of solar radiation entering the atmosphere has varied through time? The sun's output oscillates, and we know from direct measurements how solar radiation has varied during the past 70 years. The effect of this variation can be calculated, and it is small relative to greenhouse effects. It does not seem that variable solar radiation can account for the amount of temperature change that we have observed. In short, natural processes alone cannot explain the temperature increases observed in recent decades ([Fig. 48.7](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Source: K. Haustein et al., 2017, "A Real-Time Global Warming Index," *Scientific Reports* 7:15417.

FIG. 48.7 Changes in monthly mean global temperature over the past 70 years, with model results for human and natural contributions to the observed temperature increase. The models match the temperature data only when the influence of human activities is taken into account.

Scientists now overwhelmingly agree that atmospheric CO<sub>2</sub> levels are rising, that temperature is increasing, and that the physics of greenhouse gases relates the two effects. Beyond these facts, however, it is difficult to say with certainty how human-induced global trends in climate will affect a given area.

Why don't we know for certain? Modeling future climatic

conditions is challenging because of the many complex interactions that contribute to climate. Climate models attempt to understand how climate works by applying equations that relate a simplified set of variables and interactions. Using mathematical models that accurately approximate current climate, scientists can change the inputs into a climate model—adding CO<sub>2</sub> to the atmosphere, for example, or changing the extent of forest cover. The model then generates results that can be used to predict future climate. All models must be checked against actual observations, and most are sensitive to assumptions made in constructing the model. That said, climate models do a relatively good job of explaining global-scale features of climate and climatic change.

Nevertheless, questions remain. How, in detail, might cloud cover change over the next century, and how would such a change affect temperature and precipitation in, for example, midwestern North America? What will be the effect of adding more air pollutants, such as the black carbon particles released into the air when coal or wood burns? Will black carbon increase warming by absorbing solar radiation, or decrease it by reflecting radiation back into space? And what about feedbacks: will the consequences of climate change lead to further climate change? For example, will methane and carbon dioxide released by human activities melt permafrost at high latitudes, contributing to further temperature increases? How will oceanic and atmospheric circulation patterns change, and how will these changes affect climate?

We still seek definitive answers to all these questions. Nonetheless,

most climate models suggest that mean global temperature will increase by 1°C to 4°C during the twenty-first century, depending on our own actions. That increase is not expected to occur uniformly throughout the globe (**Fig. 48.8**). As has been true during the past 50 years, changing circulation patterns may cool some places and warm others, with particularly pronounced warming occurring at high latitudes. Likewise, rainfall is likely to increase in some areas, and decline in others.

FIG. 48.8 A prediction for global warming by the end of the twenty-first century based on current rates of CO<sub>2</sub> increase.

As discussed in **Chapter 47**, climate can be defined as average weather over a long time interval. From one year to the next, however,

weather varies tremendously: there will be cold years and warm years, wet ones and dry ones. Because weather is so variable, evidence for climate change comes not from individual weather events but rather from records kept over decades. We can draw few conclusions from the single observation that global temperature for June 2018 was  $0.75^{\circ}\text{C}$  ( $1.4^{\circ}\text{F}$ ) higher than the June average for the twentieth century. However, the fact that June 2018 was the 402nd month in a row that was warmer than its twentieth-century average tells us that the world is warming.

Models also predict how rainfall patterns may change as Earth warms. To test their accuracy on this front, oceanographers analyzed 1.7 million measurements of seawater salinity taken over the past century. The oceans were chosen because they contain 97% of our planet's water and receive 80% of its rainfall. The salinity of surface seawater reflects both the addition of fresh water by rain, which decreases salinity, and evaporation, which increases it. For this reason, changing salinity can indicate whether the balance of rainfall and evaporation is shifting over broad regions of Earth. Consistent with many model predictions, wet areas of Earth are becoming wetter and dry regions drier.

## Changing environments affect species distribution and community composition.

What will be the consequences of contemporary climate change?

Without question, some locations will benefit. For example,

temperature increase in New England and Scandinavia will mean longer growing seasons. Other regions will suffer. As precipitation patterns change, many places will become drier, including already water-limited areas of the southwestern United States. A number of climate models predict that some of the strongest declines in rainfall will occur in regions that currently produce much of the corn and wheat that feed the world. Already, farmers in southeastern Australia have experienced the worst droughts in a century, and with them unprecedented damage from brushfires. Over much of North America, 2012 was the driest summer in many decades, and extreme drought returned in the western half of the continent in 2014. Such events are consistent with model predictions, which also include an increased frequency of strong hurricanes along the western margin of the Atlantic Ocean. Scientists will be watching carefully to see whether such extreme events increase in frequency in coming years. Weather patterns that were normal in the nineteenth and twentieth centuries may not continue to hold in future decades.

To understand how different species will respond to climate change, we return to basic principles of ecology and evolution. We tend to think about natural selection in terms of populations adapting to a constant or slowly changing environment. In the twenty-first century, however, the environment will probably be a rapidly moving target, so genotypes that conferred high fitness in the past may not prove advantageous in the future.

Plants illustrate the complicated ways in which organisms respond to environmental change. Meticulous notes taken during the 1840s by

Henry David Thoreau provide an inventory of plant species diversity in woodlands west of Boston, Massachusetts. Climate records show that mean annual temperature in this area has increased by about 2.5°C since Thoreau began his survey; in response, many, but not all, species now flower a week earlier than they did in the nineteenth century ([Fig. 48.9](#)). A number of species have declined in abundance or even disappeared since Thoreau's time, and these tend to be the plants least able to change their flowering time ([Chapter 28](#)). This example highlights the simple but important observation that different plant species respond in distinct ways to changing climate, which favors some populations over others. Earlier onsets of leaves, flowers, and fruit have also been documented throughout the temperate zones of North America, Europe, and Asia.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 48.9 Plant responses to warming temperatures. Observations over a century and a half show that (a) the time of first flowering has become earlier as (b) regional temperatures have become warmer in the woods of Concord, Massachusetts. Data from A. J. Miller-Rushing and R. B. Primack, 2008, "Global Warming and Flowering Times in Thoreau's Concord: A Community Perspective," *Ecology* 89(2):332–341, doi: 10.1890/07-0068.1.

The example of Thoreau's woods shows that as climate changes,

some plants can modify their flowering time. Experimental evidence indicates that many plants also show a direct growth response to elevated levels of CO<sub>2</sub>. Where nitrogen in the soil is abundant, increased carbon dioxide levels tend to stimulate growth and, therefore, increase removal of CO<sub>2</sub> from the atmosphere by photosynthesis. One might hope that increased rates of photosynthesis would help to draw CO<sub>2</sub> from the atmosphere, but in most terrestrial environments, soil nitrogen levels are low, limiting any growth response to elevated CO<sub>2</sub>. Moreover, increased drought stress and more frequent outbreaks of insect pests and wild fires may counteract any capacity for accelerated growth and CO<sub>2</sub> removal.

Plants grown in air with CO<sub>2</sub> levels like those predicted for the end of this century often change the way that they distribute the products of photosynthesis to different organs: the amount of nitrogen in plant tissues commonly declines, as does the proportion of resources devoted to reproduction. This difference doesn't reflect genetic change, but rather an individual plant's physiological response to altered environmental conditions. But if environmental change persists for a long time, the varying abilities of different plants to respond physiologically will result in changing allele frequencies, as some variants survive and reproduce better than others. That is, plant populations may evolve by natural selection in response to climate change.

Evolution is one response to climate change, but, given the pace at which atmospheric composition and climate are changing, many populations may not have time to adapt. In this case, populations will

either migrate or become extinct. Fossils deposited as Earth's climate warmed at the end of the last ice age show that many plant species dramatically changed their geographic distributions in response to changing climate. As discussed in [Chapter 28](#), trees don't move, but they can migrate by dispersing seeds to new areas. Between 18,000 and 8000 years ago, Red Pine and Jack Pine migrated thousands of kilometers to the north from the Gulf of Mexico, where they had lived during the ice age, to their current distributions in the northern United States and Canada ([Fig. 48.10a](#)). Hickory also migrated northward, expanding its range rather than simply shifting from one place to another as ice retreated and climate warmed ([Fig. 48.10b](#)).

FIG. 48.10 Plant migration in response to past climate change. Records of fossil pollen over the 13,000 years since the last ice age document (a) the northward migration or (b) northward range expansion of selected tree species.

Migration is a potentially important response to environmental

changes projected for the twenty-first century, but it requires a continuous route to get from one place to another, and it can be a challenge to find these direct paths on continents broken up by agricultural lands and cities. For this reason, some biologists advocate “assisted migration”: the deliberate transplantation of plant populations from existing habitats to new ones more favorable to growth. To make sure that assisted migration does more good than harm, we need to do further research to understand how plants grow and compete in new ecological situations and under different environmental conditions.

**Fig. 48.11** shows an estimate of the sensitivity of plants around the world to projected twenty-first-century climate. Areas in red are especially vulnerable: plants at high latitudes are particularly sensitive to warming, whereas tropical rainforests are also vulnerable to predicted decreases in cloud cover. In other areas, plants are most sensitive to predicted changes in water availability. Species in these regions could face diminished population size, decreased growth rates, or even extinction.

## CASE 8 CONSERVING BIODIVERSITY: RAINFOREST AND CORAL REEF HOTSPOTS

### How has global environmental change affected coral reefs around the world?

Increasing atmospheric CO<sub>2</sub> is not just influencing life on land. It is also having an observable impact on organisms in the oceans, not least on the coral reefs that provide hotspots of biological diversity in the marine realm. The Great Barrier Reef is visible from space, its wave-washed necklace of limestone stretching more than 2000 km along the

northeastern coast of Australia ([Fig 48.12](#)). A global diversity hotspot, the reef's 1500 fish species (a tenth of all known fishes), more than 4000 species of clams and snails, and myriad other species prompt basic questions about ecology and diversity, many of which we have addressed in previous chapters. Lately, however, one question has come to dominate scientific discussion of the Great Barrier Reef: will it exist a century from now?

Source: NASA.

FIG. 48.12 The Great Barrier Reef. The world's largest coral reef, lying off the coast of Australia, is visible from space.

Corals are the principal architects of the Great Barrier and most other reefs ([Chapter 42](#)), so coral biology is the key to understanding both the reef's unusual diversity and its vulnerability in the face of environmental change. Most reef corals obtain nutrition from unicellular algae that live within their tissues. The algal symbionts in reef corals provide food for their host, in return receiving nutrients, a means of waste disposal, and a stable environment. The efficient cycling of carbon, nitrogen, and phosphorus between corals and their symbionts underpins the biological richness of coral reefs. Reef corals accomplish another noteworthy feat: they make skeletons of calcium carbonate ( $\text{CaCO}_3$ ) that over time build the reef's three-dimensional framework.

The very processes that facilitate reef growth—biomineralization and microbial symbiosis—are exposing their Achilles' heel in the twenty-first century. Today, on the Great Barrier Reef, throughout the Caribbean, and elsewhere, corals are dying. Bleaching, indicated by the white skeletons of dead corals, occurs when the symbiotic algae that feed the corals abandon their hosts, thereby sentencing them to death ([Fig. 48.13](#)). Corals and their symbionts are sensitive to warming, and algae cannot remain in corals when temperatures exceed a critical threshold. Increasing seawater temperature also facilitates the spread of infections that can kill coral. In 2016, the northern part of the Great Barrier Reef experienced a record-breaking heat wave, and the associated bleaching and disease reduced coral cover by as much as 60%. Historically, major bleaching has hit the Great Barrier Reef only sporadically, perhaps once or twice per decade, and at least some of the corals affected in these events have survived and regained their

symbiotic algae. In 2017, however, massive bleaching visited the reef again, contributing to continued stress and massive coral mortality. Scientists expect that as the world continues to warm, temperature stress will intensify, dramatically changing the ecology of the Great Barrier ecosystem.

*Source: Scubazoo/Science Source.*

FIG. 48.13 Coral bleaching. This coral shows a pattern of whitening that occurs when corals lose their algal symbionts.

Another long-term threat comes from increasing CO<sub>2</sub> levels in the ocean. As noted in [Chapter 46](#), not all the CO<sub>2</sub> produced by humans during the past century has accumulated in the atmosphere: one-fourth to one-third has been absorbed by the ocean. That's good news for slowing climate change, because it means there is less CO<sub>2</sub> in the atmosphere to trap heat. Conversely, it is potentially bad news for marine habitats, because CO<sub>2</sub> dissolves in seawater to form carbonic acid (H<sub>2</sub>CO<sub>3</sub>) ([Chapters 6](#) and [37](#)). Unlike climate change, the effects of increasing CO<sub>2</sub> on ocean pH are straightforward: increasing the abundance of CO<sub>2</sub> in the oceans causes the pH of seawater to decrease,

a phenomenon known as [ocean acidification](#).

In the past 50 years, as the concentration of  $\text{CO}_2$  in the atmosphere has increased from approximately 315 ppm to as much as 410 ppm, the pH of surface oceans has correspondingly dropped by 0.1 unit ([Fig. 48.14](#)). That may not seem like a lot, but recall that the pH scale is logarithmic. Thus, a 0.1-unit drop represents an increase in hydrogen ions of about 30%. In turn, ocean acidification causes the levels of carbonate ions in seawater to decrease, making it more difficult for some marine algae and corals to build their  $\text{CaCO}_3$  skeletons ([Fig. 48.15](#)).

FIG. 48.14 Trends in atmospheric CO<sub>2</sub> levels (red), seawater CO<sub>2</sub> levels (blue), and seawater pH (purple) in the central Pacific Ocean. *Data from S. C. Doney et al., 2009, "Ocean Acidification: The Other CO<sub>2</sub> Problem," Annual Review of Marine Science 1:169–192.*

Some corals can survive this change. For example, experiments on two Mediterranean corals showed that at a pH level 0.8 unit below that of present-day seawater, the corals grew naked—essentially as sea anemones—and recovered their skeletons upon return to normal seawater. But, if ocean acidification persists over timescales much longer than coral generations, the structural framework for tropical reefs may be irrevocably lost.

#### HOW DO WE KNOW?

### FIG. 48.15

## How will rising twenty-first-century CO<sub>2</sub> levels affect coral reefs?

#### BACKGROUND

Essentially all attempts to model our environmental future predict that, by the end of the twenty-first century, atmospheric CO<sub>2</sub> will increase from its current level to more than 500 ppm. As CO<sub>2</sub> levels continue to rise in the atmosphere, the amount of CO<sub>2</sub> absorbed by the oceans will also increase. This increase will lower the pH of seawater, changing its chemistry in a way that might make it more difficult for some animals and algae to precipitate the calcium carbonate skeletons that are key to their biological function.

#### HYPOTHESIS

Increasing twenty-first-century ocean acidification will limit the ability of

corals to build skeletons, eroding the capacity of corals to build and maintain reefs.

#### EXPERIMENT 1

In 2014, American biologist Rebecca Albright and her colleagues identified a lagoon within the Great Barrier Reef where coral reefs were isolated from regional currents. In their first experiment, they set up an apparatus that emitted sodium hydroxide (NaOH) for three weeks into a current that flowed in one direction over adjacent reefs. (As shown in the photo, the fluids that alter local seawater chemistry contained a red dye, enabling researchers to monitor the flow of the fluid across the reef.)

NaOH is a base, so it had the effect of increasing the pH of water flowing over the reef to values that more closely resembled the pH of seawater before the Industrial Revolution. Albright and her coworkers measured rates of community calcification (net increase or decrease in the skeletal mass of reef corals and coralline algae) in the affected reef both before and after the NaOH treatment, and did the same for an adjacent control area not influenced by the NaOH.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

#### EXPERIMENT 2

In a second, complementary experiment, Albright and her colleagues

added CO<sub>2</sub> to waters flowing over one reef area, in an effort to simulate the projected pH of late twenty-first-century seawater. Again, they measured rates of community calcification and compared those to a control area in which no additional CO<sub>2</sub> was added to the water.

## RESULTS

In the first experiment, when NaOH increased pH to pre-Industrial Revolution levels, net community calcification increased by approximately 7%. No change in calcification was observed in the control area ([Fig. 48.15a](#); error bars reflect natural day-to-day variability in the reefs). In contrast, in the second experiment, the addition of CO<sub>2</sub> reduced net community calcification by 34%; again, no change was observed in the control area ([Fig. 48.15b](#)).

## CONCLUSION

Corals and other reef-building organisms in the Great Barrier Reef are sensitive to ocean acidification, showing decreased ability to form CaCO<sub>3</sub> skeletons both relative to pre-Industrial Revolution seawater chemistry and under conditions likely to occur over the twenty-first century.

## FOLLOW-UP WORK

Reef corals show a consistent vulnerability to pH decline, although some populations appear to be more resistant than others. Resistant corals might provide a means to sustain reefs in the future, but their ecology will differ

from those we see today.

## What can be done?

From the preceding discussion, it is clear that rising CO<sub>2</sub> has both direct effects on the physiology of land and sea organisms and indirect effects related to climate change and ocean chemistry. To ensure our environmental future, scientists must understand the climate system and biological responses to climate change much better than they do now. Because the principal source of rising CO<sub>2</sub> is the burning of fossil fuels, the solutions we develop as citizens will clearly focus on energy, including both how we obtain it and how we use it. As the global population continues to increase and people aspire to higher standards of living, human impact on the carbon cycle will continue to grow, at least if we continue business as usual. Business as usual, however, may not be a viable option for the long term because population growth may simply outstrip resource availability, especially for petroleum.

Ultimately, much of our success in both slowing rates of climate change and sustaining energy supplies will depend on our ability to use energy more efficiently and to generate new forms of power, most likely from the sun, wind, and nuclear sources.

Half a century ago, geologist M. King Hubbard predicted from patterns of oil use and the rate at which new oil fields are discovered that petroleum production in the United States would peak in the 1970s

and decline thereafter. Global production, he suggested, would peak later, in the early decades of the twenty-first century. As King predicted, conventional petroleum production in the United States peaked in 1972 and has fallen since then to about half its peak rate of production. Nevertheless, unconventional petroleum resources, made available in no small part by hydraulic fracturing, or fracking, is expected to restore total petroleum production in the United States to near-1970s levels by 2020. (Fracking is a technique in which large volumes of fluid and sand are injected into shale rock, fracturing the rock and releasing trapped oil or gas.)

Another change not anticipated by Hubbard is that fossil fuel demand is expected to peak before mid-century, as alternative energy sources become more widespread. Such changes in both supply and demand suggest petroleum production will not decline as early as Hubbard predicted. Even so, it will still decline before the end of the twenty-first century, both in the United States and globally. Coal, natural gas, and unconventional reserves such as the oil sands found widely in western Canada can quench the world's thirst for fossil fuels for another century or more, and biofuels (fuels generated from plant biomass) may also help conserve petroleum. Nevertheless, the energy produced in this way will be expensive, and climate change will continue.

Natural gas (methane, CH<sub>4</sub>) looms large in estimates of twenty-first-century energy generation. Fracking has revolutionized natural gas extraction; in the United States alone, shale gas production has increased by 1300% since 2007. Of all fossil fuels, combustion of

natural gas generates the most energy for each mole of CO<sub>2</sub> released to the environment; thus, generating electricity by natural gas has advantages over burning coal. Combusting natural gas leads to CO<sub>2</sub> emissions, however, and gas leaks from expanding wells and pipelines add more methane, a strong greenhouse gas, to the atmosphere. Scientists and citizens continue to debate whether the toxic fluids used in fracking will contaminate groundwater in regions where shale gas is produced. Another issue in the debate of costs versus benefits is earthquakes: notable upticks in the frequency of moderate earthquake activity accompany the injection of fluids into the shale rock during fracking.

Like fossil fuels, alternative energy sources—wind, the sun, tidal energy, and nuclear power ([Fig. 48.16](#))—all have important pros and cons, not the least of which, in the case of nuclear power, is the problem of long-term storage of radioactive waste. At the same time, all of these sources have the potential to benefit humanity by reducing the amount of CO<sub>2</sub> emitted per kilowatt of energy generated, conserving finite natural resources, and helping to contain the cost of energy production. The development of more fuel-efficient cars, airplanes, and buildings will also help us maintain our energy-intensive lifestyle while decreasing its environmental consequences. As individuals, we can choose energy-efficient transportation and appliances and develop habits that decrease energy waste. When one person turns off the light in an empty room, the energy saved is tiny, but when millions of people do it, the benefits add up.

FIG. 48.16 Alternative energy sources, including (a) solar and (b) wind energy.

Wise choices by citizens and consumers can slow the increase in atmospheric  $\text{CO}_2$  levels, but the  $\text{CO}_2$  already in the atmosphere will not go away quickly. As noted earlier, we have dramatically increased the rate at which  $\text{CO}_2$  is added to the atmosphere, but we have not changed the rate at which it is removed. Therefore, even if we could cut  $\text{CO}_2$  emissions by 90% tomorrow,  $\text{CO}_2$  would not return to nineteenth-century levels for hundreds or even thousands of years.

Another possible solution to this problem is to actively remove  $\text{CO}_2$  from the air. Reforestation of previously cleared landscapes removes carbon from the atmosphere because plants build biomass from  $\text{CO}_2$  during photosynthesis ([Chapter 8](#)). It is also possible to capture  $\text{CO}_2$  as it rises upward through smokestacks, although it is currently expensive to do so. Importantly, several pilot projects have provided a proof-of-concept for scrubbing  $\text{CO}_2$  directly from the atmosphere. Both the scale of operation needed to make a difference in global  $\text{CO}_2$  and the costs of doing so remain challenging, but if we could develop this technology at reasonable cost, it would apply a significant brake to

climate change.

Clearly, forestry and twenty-first-century technology have potentially important roles to play in undoing the consequences of humans' actions on the carbon cycle over the past hundred years. For the most part, however, gaining control over our environmental future will entail wise personal and governmental choices about how we obtain and use energy.

#### Self-Assessment Questions

3. Scientists have pointed out that if humans stopped emitting CO<sub>2</sub> into the air today, atmospheric CO<sub>2</sub> levels would not return to pre-Industrial Revolution levels for hundreds of years. Why is this so?
4. What is the difference between global warming and the greenhouse effect?
5. What are two ways organisms can respond to changes in CO<sub>2</sub> levels and temperatures?
6. What are several possible solutions to the problem of increased atmospheric CO<sub>2</sub>?

## 48.3 HUMAN INFLUENCE ON THE NITROGEN AND PHOSPHORUS CYCLES

Human activities influence the environment not because we operate outside the carbon cycle, but because we have become an important part of it. Our interest in improved crop production has also resulted in unprecedented human impact on the nitrogen and phosphorus cycles. Once again, environmental changes tied to human nitrogen and phosphorus use are altering the ecological landscape for species in lakes and the ocean.

### Nitrogen fertilizer transported to lakes and the sea causes eutrophication.

As discussed in [Chapter 24](#), all organisms require nitrogen to synthesize proteins, nucleic acids, and other molecules. Although nitrogen is plentiful in the atmosphere as  $N_2$  gas, this form is not biologically available to animals and plants. Nitrogen-fixing bacteria and archaeons convert  $N_2$  to biologically available forms of nitrogen, called fixed nitrogen, such as ammonia ( $NH_3$ ) and nitrate ( $NO_3^-$ ). Plants then obtain nitrogen from ammonia and nitrate in the soil, and animals get the nitrogen from the food they eat. Crops, harvested year after year in the same fields, deplete available nitrogen, so sustaining high yields requires that farmers add biologically available nitrogen to the soil as fertilizer.

Through the use of fertilizer and other activities, humans add

approximately 240 million tons of fixed nitrogen to the biosphere each year, similar to the amount fixed naturally by microbes. The majority of this human-generated fixed nitrogen is created industrially by reacting nitrogen gas and hydrogen in the presence of a catalyst to produce ammonia. Most commercially produced ammonia is further processed into nitrate, which is spread across fields as fertilizer to increase crop production. Success in feeding the world's people owes much to fertilization with nitrates, but only about one-third of the nitrogen added to croplands actually ends up in food. That is, much of the nitrate fertilizer leaves fields as surface runoff and travels by rivers to lakes or the ocean. In addition, denitrifying bacteria use some of the added nitrate for respiration, returning  $\text{N}_2$  to the atmosphere—and also generating  $\text{N}_2\text{O}$ , yet another potent greenhouse gas.

In lakes and oceans, the fertilizing effects of agricultural runoff are finally realized, albeit in unintended ways. The added nutrients lead to a great increase in primary production by algae and cyanobacteria in a process called [\*\*eutrophication\*\*](#). These algal and cyanobacterial masses eventually sink to the bottom, where heterotrophic organisms, mostly bacteria, feed on them, fueling high rates of aerobic respiration. The bacteria's demand for oxygen can completely deplete  $\text{O}_2$  in bottom waters, with potentially catastrophic consequences for animal life on the seafloor or lakebed.

In the Gulf of Mexico, nutrients leached from croplands and transported down the Mississippi River have created an ominously named dead zone of oxygen-depleted bottom water. This dead zone expands seasonally from the mouth of the river west toward Texas; by

2017, it covered an area about the size of New Jersey ([Fig. 48.17](#)). Within the dead zone, fish and seafloor invertebrates die in masses. Several hundred dead zones have been identified in coastal oceans around the world, and most are expanding year by year. Those in the Gulf of Mexico and the Baltic Sea are among the largest.

*Source: Image courtesy of Liam Gumley, Space Science and Engineering Center, University of Wisconsin–Madison and the MODIS Science Team.*

FIG. 48.17 A dead zone, visible in this NASA satellite image as billows of green.

Nitrogen applied as fertilizer but spread by runoff and streamflow can affect the full range of ecological interactions discussed in [Chapters 43](#) through [47](#). Through its use, we benefit tremendously from increased crop production but pay a price in the eutrophication of lakes and oceans. We pay another price as well: as much as 1% to 2% of all fossil fuel consumption goes to make nitrogen fertilizer.

## Phosphate fertilizer is also used in agriculture, but has finite sources.

The other major nutrient used to fertilize fields is phosphate ( $\text{PO}_4^{3-}$ ), which creates a somewhat different problem. Like nitrate, much of the phosphate added to fields as fertilizer leaves as runoff, and phosphate runoff can be an important contributor to eutrophication. The Everglades of south Florida provide a good example. This ecosystem is built of plants that have adapted to the low phosphate levels characteristic of the Everglades. However, in recent decades phosphate levels in parts of the Everglades have increased up to a hundredfold. Chemical tracers show that these increased phosphate levels stem from phosphate fertilizer used on agricultural lands to the north. Bolstered by the presence of this nutrient, phosphate-loving cattails and other introduced plants are expanding at the expense of native plants, decreasing the diversity of this remarkable ecosystem.

Overuse of phosphates undoubtedly has detrimental effects on certain natural ecosystems, yet a key concern is the risk that we will eventually run out of phosphates to use as fertilizers. Unlike the case with nitrate, phosphate is not produced by an industrial process; that is, the only source of phosphate fertilizer is mining. Only a few places in the world have sedimentary rock with phosphates in high enough concentrations to be worth mining, and these stores are being depleted.

Globally, phosphate production peaked about 1990, raising serious questions about how the world's need for phosphate fertilizer will be satisfied in the future. In many ways, the problem of phosphate availability parallels that of petroleum production. As abundant sources

become depleted, we will have to mine poorer and poorer resources, raising production costs and ultimately calling into question our capacity to sustain agricultural production.

Human encroachment on the nitrogen cycle and long-term phosphate availability, then, converge on a single question: can we manage future agricultural production in ways that feed the growing human population in a sustainable fashion?

## What can be done?

The Green Revolution in agriculture began in the 1940s with the introduction of high-yield, disease-resistant varieties of wheat to Mexico ([Case 6 Agriculture](#)). In subsequent decades, new strains of corn, wheat, and rice; widespread application of industrial fertilizer; and the spread of farm machinery increased global crop production to levels that could scarcely have been imagined at the beginning of the twentieth century. As population growth has accelerated, however, the need to grow ever more food remains strong. Other factors, notably rising meat consumption in many countries and the increasing use of corn to generate biofuel, are also placing ever greater demands on global agriculture. It is estimated that, over the next decade alone, global corn and wheat production will need to increase by 15% to meet the world's demand for food.

How can we meet the needs of a growing population? Conventionally, agronomists see two options: we can devote more land to crops, or we can increase the yield of fields already in place. As shown in [Fig. 48.18](#), globally both the amount of land devoted to

growing corn and corn yield have increased steadily over the past 50 years. It is possible to increase yield further, as the yield per hectare in the United States, Canada, China, and western Europe far exceeds that of most other regions. Increasing yields, however, will require increasing the use of fertilizer and the use of fossil fuels to power farm machinery, with all the attendant problems of climate change and eutrophication. Increasing crop area also comes at a cost, as forests and natural grasslands go under the plow, decreasing the biological storage of carbon and threatening biodiversity.

FIG. 48.18 Corn yield and area in the United States and globally from 1961 to 2007. Global corn yield and area have increased at about the same rate, whereas U.S. corn yield has risen much more quickly than corn area because of energy-intensive agriculture and use of fertilizer. *Data from M. D. Edgerton, 2009, "Increasing Crop Productivity to Meet Global Needs for Feed, Food, and Fuel," Plant Physiology 149:9, <http://www.plantphysiol.org/content/149/1/7>.*

For more than a century, biologists have developed improved varieties of crop plants by breeding, the highly effective practice that Darwin called “variation under domestication” and used to frame his

arguments about natural selection. Today, we have another tool available: genetic engineering. Biologists can now introduce genes for desirable traits into crop plants, improving their yield, disease resistance, or nutritional value ([Chapter 30](#)). The potential benefits of genetically modified crops are obvious, but some biologists see risks as well, many of which are detailed in [Chapter 12](#).

Conventional breeding and genetic modification may improve crop yields, but, in a world of changing climate and evolving pests, these gains may have something of a “Red Queen” flavor to them ([Chapter 40](#)). In Lewis Carroll’s *Through the Looking-Glass*, the Red Queen tells Alice, “Now, here, you see, it takes all the running you can do, to keep in the same place. If you want to get somewhere else, you must run at least twice as fast as that!” Much of evolution appears to work this way: as the physical or biological environment changes, continued adaptation is needed just to maintain fitness. Strains of wheat, modified to improve drought tolerance, may simply maintain high yields in a changing environment, not increase them. Increases in yields through genetic modification may be possible, but limited. Thus, massive fertilization by nitrate and phosphate fertilizers will remain a key component of agriculture.

Another type of biological intervention, the reduction of pests, may help increase some crop yields. We are not the only species with a nutritional interest in croplands. Fungi, bacteria, protists, nematodes, insects, birds, and mice all target cornfields, sharply reducing yield. In the United States alone, such unwanted guests cause an estimated \$1.5 billion worth of damage per year. Conventional breeding and genetic

modification have produced improved resistance to pests, but fungus-resistant plants provide strong selective pressure for fungi that can circumvent the mechanisms of resistance, thereby gaining access to otherwise unavailable food.

After harvest, food spoilage also reduces the effective yield of agricultural lands. An estimated one-third of the food grown in the United States is never eaten, and figures for Europe are similar. Fungi and bacteria spoil food during storage and transportation, on supermarket shelves, and in refrigerators. The problem also exists in less developed countries. The United Nations estimates that in some parts of Africa, one-fourth of all crops spoil before they ever reach the market. More efficient storage, transportation, and packaging could sharply increase the effective yield of fields and pastures.

As with energy, achieving a sustainable future for agriculture will require the combined efforts of creative biologists, ingenious engineers, and wise citizens. Geneticists and physiologists can help develop plant breeds that improve crop yields while using less fertilizer. Working with microbiologists, engineers can discover new ways of storing and transporting food, which will increase the likelihood that it will be eaten before it spoils. As individuals, we make daily choices about the food we eat. We can choose to eat more plant products, for example. The basic ecological logic of the trophic pyramid ([Chapter 46](#)) tells us that a hectare of grain fed directly to humans feeds more people than the meat of cattle fed on the same crops. We can also choose to eat locally grown products where possible, saving energy while decreasing the likelihood of spoilage.

### Self-Assessment Questions

7. What are the causes and consequences of eutrophication?
8. What are several possible solutions to the problem of feeding a growing human population?

## 48.4 HUMAN INFLUENCE ON EVOLUTION

It has sometimes been claimed that, as humans exert increasing influence on nature, evolution will grind to a halt. Nothing could be further from the truth. As examples in the preceding sections show, what is changing, and what will continue to change as the human footprint grows, is the selective landscape within which evolution operates. Some species, such as rats and cockroaches, thrive in the urban environments we have constructed for our own benefit. Others will expand or decline as we replace prairies and forests with cropland and pastureland. What are our conscious and inadvertent effects on evolution and biodiversity?

**Human activities have reduced the quality and size of many habitats, decreasing the number of species they can support.**

As noted in [Chapter 1](#), humans make use of nearly 25% of the entire photosynthetic output on land through the crops and livestock we harvest, the biomass we burn, and the primary production we eliminate when we clear-cut forests. Ecologists also estimate that crops cover 10% to 15% of Earth's land surface, and pastureland another 6% to 8% ([Fig. 48.19](#)).

The conversion of natural ecosystems to cropland decreases the area of natural habitats, as does the expansion of cities and towns. As discussed in [Chapter 45](#), the theory of island biogeography predicts that as the size of a habitable area decreases, species diversity within the habitat will decline. Habitat loss in tropical rainforests poses a particularly important threat to biodiversity ([Fig. 48.20](#)). These forests represent the greatest concentrations of species diversity on land, but clear-cutting to make room for grazing and croplands has destroyed more than half of their pre-Industrial Revolution area. It is estimated that deforestation over the next century could eliminate 40% to 50% of all tree species in the Amazon forest.

FIG. 48.20 Forests under threat. (a) The map shows the extent of deforestation worldwide. (b) This desolate scene in Amazonia was once an expanse of tropical rainforest. Nearly 20% of the Amazon rainforest has been cleared for crops, pasture, or mining.

As the forest disappears, so, too, will untold numbers of insect, mite, and other animal species. The renowned biologist E. O. Wilson has estimated that Earth is losing 0.25% of its species annually—that is, 5000 to 25,000 species per year—depending on how many species actually exist. Even where ecosystems remain physically intact, pollution can erode populations. For example, recent studies in Europe show that levels of neonicotinoid pesticides in soil and water accurately predict patterns of population decline in bees and birds.

In the words of another distinguished biologist, Paul Ehrlich, “The fate of biological diversity for the next 10 million years will almost certainly be determined during the next 50–100 years by the activities of a single species.”

## Overexploitation threatens species and disrupts ecological relationships within communities.

For thousands of years, humans have harvested food from the sea, tapping a resource that long seemed both free and endless. Citizens of Newfoundland, however, know better. Journals from John Cabot’s voyage of 1498 tell of cod so abundant that a person “could walk across their backs,” and for two centuries cod supported the Newfoundland economy. The amount of cod caught each year increased markedly in the 1960s; surveys estimated that as much as 60% of adult cod was being harvested. By the late 1980s, however, harvests had plummeted ([Fig. 48.21](#)). By 1992, cod stocks were estimated at 1% of 1960 levels (which were themselves well below those in Cabot’s time). Thus, with fish stocks on the verge of collapse, cod fishing was halted.

Unfortunately, the tragedy of cod in Newfoundland is not an isolated story. By 2003, yields in nearly 30% of all fishing areas in the open ocean had declined by 90% or more. With collapsing fish stocks comes a loss in food production, economic decline, and, hidden beneath the surface of the sea, a shift in community structure, as species that compete with or depend on exploited fish species respond to changed conditions of natural selection.

Recent research in Newfoundland offers reasons for both hope and concern on this front. Around 2010, after two decades of persistently low numbers, cod populations on the Grand Banks began to rise again. By 2015, cod stocks reached levels not seen since 1992, indicating that with careful management, damaged fisheries might recover.

Unfortunately, stocks plummeted again in 2017, underscoring the need for continuing vigilance. On a positive note, through careful management, the percentage of overexploited fishing areas in waters off the United States has declined by 50% since 2000.

Overexploitation occurs on land as well, perhaps most conspicuously affecting the majestic mammal species that have graced the African savanna for millennia. A global appetite for ivory has encouraged poaching, contributing to the reduction of elephant populations from an estimated 3–5 million animals in the 1930s to less than 10% of that today. Fueled by a (biologically unfounded) demand in parts of Asia for rhino horn as an aphrodisiac or folk medicine, poaching has similarly reduced populations of most rhinoceros species, limiting these once widespread animals to protected areas in both Africa and southeastern Asia. Note that habitat loss and overexploitation do not occur independently in these ecosystems; their effects are additive and, in some cases, synergistic, meaning that overexploitation amplifies the harmful effects of habitat loss, and vice versa.

## Humans play an important role in the dispersal of species.

Biodiversity loss has many causes. In addition to habitat destruction and overexploitation, one of the most insidious is the introduction of non-native species. Non-native species that become established in new ecosystems are commonly termed [invasive species](#). Freed from the natural constraints on their population growth, these species can expand dramatically when introduced into new areas, sometimes with

negative consequences for native species and ecosystems.

Species can sometimes be transported long distances by natural processes. For example, the Gulf Stream and North Atlantic Drift occasionally carry coconuts from the Caribbean to the coast of Ireland. Migratory birds can transport microorganisms across continents. In the Anthropocene Epoch, however, humans have dramatically increased dispersal. Ships fill their ballast tanks with seawater in Indonesia and empty it into Los Angeles Harbor, carrying organisms across the Pacific Ocean. Insects in fruit from South America wind up on a dock in London. Humans have become major agents of dispersal, adding new complexity to twenty-first-century ecology.

It has been estimated that 49,000 non-native species have been introduced into the United States ([Fig. 48.22](#)). Many of these provide food or pleasure (for example, ornamental plants), and only a few have escaped into natural ecosystems. Some of the invasive species that have become established in their new surroundings do little beyond increasing community diversity, but others put strong pressure on native species.

Sources: a. James K. York/Dreamstime.com; b. Dr. David J. Jude, School of Natural Resources and Environment, University of Michigan; c. John Mitchell/Science Source.

FIG. 48.22 Invasive species. (a) Kudzu (*Pueraria lobata*), a Japanese vine, was introduced to the United States in 1876 and now covers more than 3 million hectares. (b) The Zebra Mussel (*Dreissena polymorpha*), introduced into the Great Lakes from Europe in 1985, disrupts lake ecosystems, threatening native biological diversity. (c) The Brown Tree Snake (*Boiga irregularis*), introduced into Guam from Asia and Australia shortly after World War II, has decimated indigenous bird populations across the island.

Kudzu, for example, is a plant that was originally imported from Japan to slow soil erosion. It now covers more than 3 million hectares in the southeastern United States, displacing native plants through competition for space and resources ([Fig. 48.22a](#)). The Zebra Mussel, a European bivalve that hitchhiked to the Great Lakes in the ballast water of cargo ships, has also multiplied dramatically in its new

habitat, displacing native species and clogging intake pipes to power plants ([Fig. 48.22b](#)). Nearly 500 introduced plant species contribute disproportionately to crops lost each year to competition from weeds. And in Australia, more than 10% of all indigenous mammal species have become extinct in the past 200 years, largely because European colonists introduced cats and red foxes into their new home.

Invasive species have particularly devastating effects on islands because island species have commonly evolved with relatively few competitors or predators. Bones in Hawaiian lava caves record more than 40 bird species that existed 1000 years ago but are now extinct, eliminated by the rats and pigs introduced by Polynesian colonists, as well as by landscape alteration. Introduced predators have had a similar impact on the island of Guam. Brown tree snakes introduced from Australasia since World War II have reduced native bird and reptile diversity by 75% ([Fig. 48.22c](#)).

Such introductions contribute to the changing diversity and ecology of twenty-first-century landscapes, but it may be the spread of modern diseases that should impress (and concern) us most. In a world filled with airplanes and oceangoing ships, bacteria and viruses spread much more rapidly than they did in our pre-industrial past. The H1N1 (swine) flu, a global concern in 2009, is a notable example. The first diagnosed case was identified on April 13, 2009, in Mexico, and by mid-May of that year the flu had been reported on five continents.

**Humans have altered the selective landscape for many pathogens.**

From the Black Death of the fourteenth century to the flu pandemic of 1918, disease has played a major role in human history. In the Anthropocene Epoch, we have unprecedented opportunities to control or even eradicate some of the great diseases of the past and present. At the same time, the strong selective pressures placed on pathogens by antibiotics pose a key challenge for twenty-first-century medicine.

Malaria, discussed in [Case 4](#), provides an example. In any given year, malaria infects an estimated 500 million people, causing 1 million or more deaths. Infection is particularly severe in parts of Africa, where the direct and indirect effects of malaria account for almost half of all childhood mortality. Insecticide-soaked bed nets have proved a highly effective means of protection against the disease in affected areas, reducing transmission by as much as 90%. Natural selection, however, has begun to chip away at success in controlling the disease: mosquito strains have begun to emerge that are resistant to some insecticides.

Quinine, a chemical extracted from the bark of the cinchona tree, was the first effective treatment for malaria, and remained in widespread use until the 1940s. Since that time, many new antibiotics have been developed. Over time, their usefulness has declined as resistance to each of these drugs has evolved in populations of *Plasmodium*, the infectious agent of malaria. More recently, artemisinins, antibiotics based on a traditional Chinese plant remedy, have proved effective in treatment. Again, however, resistant strains of malaria have been identified.

The arms race between antibiotics and pathogens is not limited to

malaria, but rather characterizes nearly the whole range of diseases caused by viruses, bacteria, protists, and fungi that infect humans. For example, tuberculosis, a lung infection spread by inhalation of the bacterium *Mycobacterium tuberculosis*, causes 1.8 million deaths annually, mostly in sub-Saharan Africa, where many people are also infected with HIV ([Chapter 41](#)). Antibiotic treatment is effective against tuberculosis, but many people who are infected do not or cannot comply with the strict regimen of daily treatment for 6 months, hastening the evolution of drug-resistant *M. tuberculosis* strains. An incomplete course of antibiotics does not eradicate all of the bacteria, thereby selecting for those bacteria that are least susceptible to the antibiotic. In 2016, approximately 600,000 new cases of antibiotic-resistant tuberculosis were reported. More concerning, a small percentage of these infections has been characterized as “extremely drug resistant,” meaning that the pathogens resist both standard treatments and alternative antibiotics developed over the past 25 years ([Fig. 48.23](#)). In effect, extremely drug-resistant tuberculosis is untreatable.

FIG. 48.23 Distribution of extremely drug-resistant tuberculosis. By 2016, 44 countries had reported at least 1000 cases of extremely drug-resistant tuberculosis. *Data from World Health Organization, Global Tuberculosis Report 2017.*

Because bacteria can pass genes horizontally ([Chapter 24](#)), antibiotic resistance that evolves in one species can jump to another species. Thus, the bacterial incubators for drug resistance can arise anywhere and spread rapidly. And the problem is getting worse: between 2000 and 2015, daily doses of antibiotics increased globally by 65%, mainly in developing countries.

Clearly, despite the remarkable gains of the twentieth century, public health will remain a key issue in the decades ahead. Improved sanitation, in the form of clean drinking water and safe food, can do much to reduce transmission of infectious diseases. In addition, the search continues for vaccines that can further reduce or even eliminate some historic scourges. Even so, the ongoing evolution of drug resistance requires the continuing efforts of scientists to stay one step ahead of pathogens.

## Are amphibians ecology's “canary in the coal mine”?

In the nineteenth century and well into the twentieth century, British, American, and Canadian coal miners sometimes took canaries with them down long mine shafts. Canaries are more sensitive than humans to carbon monoxide and other toxic gases that can accumulate in mines. When the canaries passed out, the miners knew it was time to

leave. Because many amphibian species have narrow environmental tolerances and exchange gases through their skin, they can be especially sensitive to environmental disruption. For this reason, some biologists see them as “canaries” for the global environment.

If amphibians are indeed our early-warning system, we should be concerned. Fully one-third of all amphibian species are threatened with extinction, and more than 40% have undergone significant population decline over the past decade ([Fig. 48.24](#)). What accounts for this pattern? Nearly all of the environmental issues discussed in this chapter come into play. Amphibian habitat is being destroyed in many parts of the world, especially old-growth forests that provide damp, food-rich environments in abundance. Pesticides and other toxins of human manufacture take their toll as well. For example, the common herbicide atrazine has been shown experimentally to impair development in frogs. Studies of placental cells grown in the laboratory suggest that atrazine in our food may also affect human reproduction. When atrazine was applied to human placental cells, it caused overexpression of genes associated with abnormal fetal development. Because of concerns about public health, atrazine has been banned in several European countries.

Source: Marie Read/Science Source.

FIG. 48.24 Amphibians under threat. The Harlequin Toad (*Atelopus varius*), native to Costa Rica and Panama, has been classified as critically endangered.

Recently, infection has also been implicated in amphibian decline. The fungus *Batrachochytrium dendrobatidis* (*Bd*) infects the skin of frogs and impairs many of the skin's functions. Recent studies of *Bd* show the classic features of epidemics—rapid geographic spread and high mortality—along the expanding front of fungal populations. How *Bd* spreads and whether it acts with other aspects of global change remain controversial, but there can be no doubt that disease has joined habitat destruction and pollution as a major cause of amphibian decline.

#### Self-Assessment Questions

9. How do invasive species affect species diversity of communities and ecosystems?
10. How does the Red Queen hypothesis apply to interactions of pathogens and antibiotics?
11. What are three examples of species that have benefited and three

examples of species that have been harmed by human activity?

## 48.5 CONSERVATION BIOLOGY

Biological diversity, or **biodiversity**, refers to the summed variation of life on Earth ([Chapter 45](#)). It encompasses genetic and population variation within species; the number of species in local communities, biomes, or the planet as a whole; and the variations in species composition among ecosystems across the planet. We don't know how many species exist on our planet, although the number certainly runs into the millions and may exceed 10 million. Whether local or global, patterns of biodiversity reflect all of the processes discussed in earlier chapters: natural selection, physiology and other aspects of biological function, ecological interactions among species, and the distribution of physical environments. Increasingly, biodiversity also reflects human activities.

As discussed earlier in this chapter, habitat destruction, overexploitation, pollution, and invasive species all pose threats to biodiversity, and in the twenty-first century, climate change threatens biodiversity as well. A 2016 census of population size for more than 3700 species of mammals, birds, fishes, and amphibians found that the total number of vertebrate animals in nature has declined by 60% over the past 50 years, prompting concern about mass extinction comparable to the great biological cataclysms of the past. Unlike past mass extinctions, however, current threats come not from meteorites or massive volcanism, but rather from humans. Importantly, as human activities lie at the heart of threats to biodiversity, we can make choices that will help us to preserve and protect the natural world.

**Conservation biology** addresses the challenge of sustaining biodiversity in a changing world crowded with people.

---

## CASE 8 CONSERVING BIODIVERSITY: RAINFOREST AND CORAL REEF HOTSPOTS

### What are our conservation priorities?

Before examining how biologists and policy makers are working to conserve biodiversity, we should take a moment to consider what we wish to preserve. At the broadest level, most biologists would hope to sustain our shared heritage of global species richness—a tall order on a planet increasingly marked by human activities. Not all ecosystems are equal in terms of biodiversity. Indeed, following the lead of British conservationist Norman Myers, biologists have identified about two dozen **biodiversity hotspots** on land. Hotspots are relatively small areas that have unusually high numbers of endemic species and that are under threat from human activities. Endemic species are species found in one place and nowhere else. By definition, hotspots contain at least 1500 endemic plant species and have lost 70% of their original habitat area. Biodiversity hotspots represent only about 2% of Earth's land surface, but they support more than half of the world's endemic plant species and nearly 43% of its endemic bird, mammal, reptile, and amphibian species. Therefore, biodiversity hotspots are high priorities for conservation efforts.

Biodiversity reflects both species richness within local communities and the variations in species composition from one community to

another, and from one biome to the next. While biodiversity hotspots have garnered widespread interest, many conservation biologists wish to conserve species richness in local communities and regional ecosystems throughout the world. Good evidence suggests that biodiversity provides important [ecosystem services](#)—that is, benefits to humans—including cleaner air and water, greater primary productivity ([Chapter 46](#)), improved resilience to environmental disruption ([Chapter 45](#)), and untapped sources of food and molecular compounds for use in medicine and agriculture.

As discussed in [Chapter 14](#), genetic variation exists within as well as among species, and this variation is likely to play an important role in conserving species in a time of climate change. Genetic variants in plants provide the raw materials for breeding crops that can thrive in habitats that may become warmer or drier than at present. And within marine species vulnerable to global change, geneticists are beginning to find local populations with enhanced capacity to evolve tolerance to warmer temperature or decreased pH. Such variants may help to sustain the commercial shellfishing in the twenty-first century and provide robust coral populations able to sustain tropical reefs.

## Conservation biologists have a diverse toolkit for confronting threats to biodiversity.

As shown in [Fig. 48.25](#), thousands of plant and animal species face the threat of extinction. Among mammals, for example, nearly 10% of all species are endangered or critically endangered, meaning that they are

unlikely to persist without human intervention. Declines in population size and geographic range make another 10% of mammal species vulnerable to extinction.

FIG. 48.25 Biodiversity at risk. A substantial proportion of vertebrate species has been classified as vulnerable (likely to become endangered in the absence of intervention), endangered (likely to become extinct in the absence of intervention), or critically endangered (very high risk of extinction in the wild). In the twenty-first century, these proportions are increasing year by year. *Data from C. Hogan, 2014, "Endangered Species,"*  
<http://www.eoearth.org/view/article/51cbdac7896bb431f69323a>.

The scope of the problem is large, requiring a variety of conservation strategies to address it. Some programs focus on individual species, targeting specific threats that have reduced or could reduce populations below sustainable levels. Widely publicized efforts

to protect elephants and rhinos provide examples. By protecting and restoring the habitats where these animals thrive, expanding efforts to curb poaching, and working to shut down trade in elephant ivory and rhinoceros horn, conservationists hope to build and maintain sustainable populations. In some cases, such as with the Arabian Oryx, long extinct in the wild but recently reintroduced to the deserts of the Arabian Peninsula, zoos and captive breeding programs have played a critical role in rebuilding populations. As the Arabian Oryx illustrates, species-specific programs are often successful. Similarly, the Southern White Rhino, known from a single local population a century ago, has prospered in protected reserves and now numbers more than 20,000 individuals. Whooping Cranes, majestic Northern American birds reduced to just 23 known individuals in 1940, now number more than 600.

While conservation strategies focused on specific species are appropriate and necessary, they are simply not practical for the greater diversity of species at risk. Fortunately, one key component of targeted conservation efforts helps to conserve many species at once: protecting and restoring ecosystems.

In 1872, Yellowstone National Park was established as the world's first national park. The idea was to set aside a wilderness region of outstanding beauty and preserve it for all time. Since then, national parks and other reserves have been established throughout the world, and they have played a key role in preserving our natural heritage. Reserves speak to the three major threats to biodiversity introduced earlier in this chapter. First, they protect habitat area and, in many

cases, provide land to restore degraded habitats. Second, they provide managed areas within which overexploitation and pollution can be eliminated or minimized. Third, they provide a buffer against invasive species. Notably, although we may value reserves because they protect charismatic animals such as lions, rhinos, or bison, they actually help to conserve entire ecosystems.

A great deal of research has shown that some designs for reserves work better than others. Not surprisingly, bigger is better. Species differ in the area needed to support sustainable populations, with top carnivores requiring particularly large territories to thrive. Thus, one large reserve functions better than four smaller reserves of the same total size. Also, because conservation is commonly more challenging along the edges of reserves, round or square areas function better than elongated or fragmented areas because they minimize edge effects. Importantly, successful plans for reserves include **corridors** that provide routes for migration from one reserve to another.

## Climate change provides new challenges for conservation biology in the twenty-first century.

Since 1985, the area of Australia's Great Barrier Reef covered by coral has declined by more than 50%, driven by three main processes: physical destruction by tropical cyclones, predation by Crown-of-Thorns Sea Stars, and bleaching. Over the same interval, reefs in the Caribbean Sea have similarly declined at a rate of about 1.5% per year, mostly because of storms, disease, bleaching, and the spread of algae

due to overexploitation of the fish that keep algal populations in check.

The declining health, size, and diversity of coral reefs reflect some of the same factors that challenge biodiversity on land. Outbreaks of Crown-of-Thorns Sea Stars may reflect both the overexploitation of predators on the sea stars and increased nutrient influx that appears to increase the survival of sea star larvae. Increased storm frequency and intensity, as well as bleaching, reflect the impacts of another factor: climate change. Human activities such as agriculture and fishing will continue into the future, but warming temperatures and ocean acidification will pose increasingly dire threats to reefs in coming decades. Thus, even as policies are put in place to protect reefs from local disturbances such as pollution and overexploitation, reef conservation and management will require strategies to mitigate the effects of global change.

The same is true on land. It is critical to maintain reserves that protect natural habitats and the species they support, but, on the timescale of the next century, the climate of protected areas will change, and with it the capacity of a reserve to support its native biodiversity. Under these conditions, conserving or creating corridors between habitats ([Chapter 44](#)) will play a particularly important role in enabling populations to adapt to climate change, aiding their move from an inhospitable reserve to another with local climate more amenable for growth and reproduction. Many ecologists think that natural corridors to promote migration will not be sufficient; that is, they believe that conservation biologists will need to implement a carefully considered program of assisted migration to match

populations with appropriate environments.

In southern Africa, conservation efforts have benefited substantially by grouping reserves across national borders and connecting them with corridors. For example, a broad conservation area now links national parks and other reserves in South Africa, Mozambique, and Zimbabwe, providing an enlarged area for conservation corridors that connect established reserves and permit seasonal migration ([Fig. 48.26](#)). A key point is that, within this conservation area, animals and people coexist. Many corridors, in Africa and elsewhere, necessarily pass through populated areas, so local support is essential. In southern Africa, people within the conservation area have been persuaded that the preservation of biodiversity is in their best economic interests.

national parks and other reserves in South Africa, Zimbabwe, and Mozambique are being linked by a broad conservation area that provides corridors for migration.

Within this area, animals and people coexist. *Data from*

<http://www.krugerpark.co.za/great-limpopo-transfrontier-park-south-africa.html>.

## Sustainable development provides a strategy for conserving biodiversity while meeting the needs of the human population.

By now it should be clear that resource use and conservation biology are closely intertwined: the fate of many species will depend on the decisions we make about food and energy for a burgeoning human population. With this point in mind, **sustainable development** has emerged as an important principle for trying to balance priorities for humans and the natural world. In principle, the concept is simple: the rate at which we use resources should be no higher than the rate at which they can be replenished.

Sustainable development is most easily understood in terms of species that grow and are harvested by humans. Thus, logging in the forests of western North America or the Amazon basin is sustainable only if tree harvest is matched by growth, keeping the forests intact. Similarly, fisheries are sustainable only if annual catch is no larger than the capacity of fish populations to grow and produce. By changing the way that fishermen are distributed across these areas and the species they fish, the harvest of fish along the Pacific coast of the United States has become more predictable (as has the income of fishermen) and

stocks of commercial species are increasing. Expanding marine reserves is also proving successful as a means to rebuild fish populations. At the same time, decisions by both fishermen and consumers are shifting the targets of commercial fishing away from vulnerable species and toward those that can be harvested sustainably.

It can be difficult to quantify sustainable yields for agriculture, as the cost of producing food includes the costs of fuel and fertilizer. Moreover, where episodic floods or droughts influence food supply, sustainable yields may vary from year to year. Despite these difficulties, the broader target of sustainable development—reducing our ecological footprint—has begun to influence agricultural practice and consumer choices. The task is formidable, but the goal is important: to ensure that meeting the needs of humans does minimal damage to Earth’s biodiversity.

Without question, there will be fewer species when the twenty-first century ends than when it began. Lost species mean lost opportunities for the discovery of novel compounds for medical research. Diminished biodiversity may make ecological communities less productive and less resilient to fires, hurricanes, or other environmental events. There is a pressing need to feed the world, but there are also many good reasons to conserve the biodiversity that has evolved over 4 billion years. Balancing these two imperatives will entail creative approaches to both science and policy, including thoughtful ways of using land that serve both people and conservation.

12. In what ways do habitat loss, overexploitation, and invasive species threaten biodiversity?
  13. How do reserves and corridors help to conserve biodiversity?
-

## 48.6 SCIENTISTS AND CITIZENS IN THE TWENTY-FIRST CENTURY

The decades ahead will be a time of great opportunity, but they will also present increasing challenges as humans' ecological footprint continues to grow around the world. How we will meet those challenges is, in large measure, up to you.

If you become a biologist, you will be able to help improve our planet's health in many different ways ([Fig. 48.27](#)). Field biologists are needed to document Earth's true biodiversity, even as much of it comes under threat. Physiologists are needed to help us understand how species respond to environmental change.

Sources: (Doctor) AP Photo/Sebastian John; (Science teacher) LWA/Dann Tardif/Getty Images; (Biochemist underwater) Alexis Rosenfeld/Science Source; (Testifying Department of Health and Human Services Assistant Secretary) Matthew Cavanaugh/EPA/REX/Shutterstock; (Earth Day tree planting) Chas Metivier/The Orange County Register/ZUMAPRESS.com.

FIG. 48.27 Human impact. Scientists, doctors, teachers, and informed citizens can make a difference.

Ecologists and population geneticists are needed to discover the principles that govern species interactions in communities so that we can understand how physiological responses to global change in one species will affect others. Only then will we be able to design effective ways to preserve the world's biodiversity. Molecular biologists will help us combat disease in new ways, and geneticists will develop crops that yield more food. Perhaps most important, biologists will work with economists, lawmakers, and others to ensure that government policies reflect what we know about the natural world on which we all depend.

If you become a doctor or a public health worker, you will have many opportunities to improve the health of people in countries around the world. Through laboratory research, physicians will discover new ways to treat cancer, malaria, AIDS, and other diseases. And, by treating patients in new ways, doctors will reduce the threat of antibiotic-resistant pathogens. Working with government and private agencies, public health workers will help ensure supplies of clean water and adequate food are available for people in parts of Africa, Asia, and wherever else the basic needs of life pose an ongoing challenge.

If you become an engineer, you will have the opportunity to design energy-efficient machines or establish improved ways of slowing the spoilage of food. Novel solutions for managing resources and balancing resource use with conservation will benefit all people.

If you become a teacher, you will have a particularly important role in making sure that our children have the knowledge they need to meet the challenges of the Anthropocene Epoch. And, by choosing to be a responsible citizen, you can help to ensure that your family, workplace, and government make wise choices. In an age of environmental change, knowledge of Earth and life provides a key framework for personal choice. As citizens, our votes shape governments, and biological education can help to ensure wise leadership.

We cannot change the world we've been given, but we can and will influence the one our children inherit. It is easy to despair about the future, but as the novelist Philip Pullman put it, "Hope is not the name

of a temperament, or of an emotion, but of a virtue.” Hope inspires action, and our collective capacity for positive change is great. Knowledge of biology will not by itself ensure that humanity’s golden age can be sustained in coming years, but it will surely be an important part of our solutions.

## CORE CONCEPTS SUMMARY

**48.1 THE ANTHROPOCENE EPOCH:** Some scientists call the time in which we are living the Anthropocene to reflect humans' significant impact on the planet.

Today, more than 7.6 billion people live on our planet. [page 1093](#)

Ecological footprint is the amount of land required to support an individual at an average standard of living for a community, country, or the world as a whole. [page 1094](#)

Our ecological footprint reflects all the activities that support our daily life, from growing and transporting the foods that we eat to supplying the materials and energy for our homes and the vehicles that provide our transportation. [page 1094](#)

**48.2 HUMAN INFLUENCE ON THE CARBON CYCLE:** Humans have a major impact on the carbon cycle, primarily through the burning of fossil fuels, which returns carbon dioxide to the atmosphere at high rates.

Carbon dioxide is a greenhouse gas, trapping heat and thereby keeping the surface of Earth warm. [page 1095](#)

Greenhouse gases play an important role in maintaining temperatures on Earth compatible with life, but increasing levels of greenhouse gases are resulting in higher mean surface temperatures. [page 1096](#)

Changing climate has already affected the distribution of species and the composition of communities, and will continue to do so in

the twenty-first century. [page 1098](#)

Increasing levels of CO<sub>2</sub> are increasing the temperature and decreasing the pH of the oceans, affecting marine organisms, including corals. [page 1100](#)

We can reduce CO<sub>2</sub> emissions, conserve finite natural resources, and contain the cost of energy by developing energy sources other than fossil fuels and improving energy efficiency. [page 1103](#)

### **48.3 HUMAN INFLUENCE ON THE NITROGEN AND**

**PHOSPHORUS CYCLES:** Humans have an important impact on the nitrogen and phosphorus cycles, primarily through the use of fertilizer in agriculture.

Humans add large amounts of industrially fixed nitrogen to the environment, which enters the biosphere as fertilizer to increase food production. [page 1104](#)

Approximately one-third of the nitrogen in fertilizer is taken up by crops; the rest is returned to the atmosphere by soil microorganisms or ends up in lakes and oceans, where it results in eutrophication, a boost in primary production that depletes oxygen and can lead to the death of fish and other aquatic organisms. [page 1104](#)

A second major nutrient in fertilizer is phosphorus, which is mined rather than produced industrially. The finite supply of phosphorus raises questions about our ability to sustain agricultural production in the future. [page 1105](#)

We have increased agricultural yields through the use of fertilizer,

high-yield and disease-resistant plants, and farm machinery. [page 1105](#)

To feed a growing population, we can devote more land to agriculture or increase productivity further, but each option brings with it additional costs. [page 1105](#)

**48.4 HUMAN INFLUENCE ON EVOLUTION:** The impact of humans on the environment is changing the setting in which evolution acts.

Humans have altered the landscape in dramatic ways, leading to the expansion of some species, such as corn and wheat, and the decrease and extinction of others. [page 1107](#)

Habitat degradation and loss may cause extinction in some of Earth's most diverse ecosystems, such as tropical rainforests. [page 1107](#)

Overexploitation of species by hunting, fishing, and logging threatens exploited species and could change the ecology of ecosystems where these species live. [page 1108](#)

Invasive species, spread by human activity, are major players in biodiversity loss. [page 1108](#)

The use of antibiotics is one of the success stories of twentieth-century medicine, but has led to the spread of antibiotic resistance, a major challenge for twenty-first-century biologists and physicians. [page 1110](#)

Amphibian populations have declined dramatically because of a

combination of habitat loss, pesticide use, and the spread of infection. [page 1110](#)

**48.5 CONSERVATION BIOLOGY:** Conservation biology aims to safeguard biodiversity for future generations.

Declining population sizes indicate that many species are vulnerable to extinction. Preserving the world's biological heritage will require the sustained efforts of scientists and citizens. [page 1111](#)

Reserves provide strong defense against habitat loss, overexploitation, and invasive species. [page 1112](#)

Corridors that allow species to move between reserves strengthen conservation and will be particularly important as global change affects reserves. [page 1113](#)

Sustainable development strives to match the rate at which we use resources to the rate at which they can be replenished. [page 1113](#)

**48.6 SCIENTISTS AND CITIZENS IN THE TWENTY-FIRST CENTURY:** In the twenty-first century, biologists, doctors, engineers, teachers, and informed citizens have vital roles to play in understanding our changing planet and making wise choices for our future.

Human impact can be positive as well as negative. [page 1114](#)

# Glossary

**10-nm fiber:**

A relaxed 30-nm chromatin fiber, the state of the chromatin fiber in regions of the nucleus where transcription is currently taking place.

**3' end:**

The end of a nucleic acid strand that carries a free 3' hydroxyl.

**30-nm fiber:**

A chromosomal conformation created by the folding of the nucleosome fiber of DNA and histones.

**3-phosphoglycerate (3-PGA):**

A 3-carbon molecule; during the Calvin cycle, two molecules of 3-PGA are the first stable products following the addition of carbon dioxide.

**5' cap:**

The modification of the 5' end of the primary transcript by the addition of a special nucleotide attached in an unusual chemical linkage.

**5' end:**

The end of a nucleic acid strand containing a free 5' phosphate group.

**ABC model:**

A model of floral development that invokes three activities—A, B, and C; each activity represents the function of a protein or proteins that specify organ identity in each whorl.

**abiotic factors:**

Aspects of the physical environment, such as temperature, water availability, or wind, that affect an organism or population.

**abomasum:**

The fourth chamber in the stomach of ruminants, where protein digestion occurs.

**abscisic acid:**

A plant hormone that triggers stomatal closure, stimulates root elongation, and maintains seed dormancy.

**absolute temperature (*T*):**

Temperature measured on the Kelvin scale.

**absorption:**

The direct uptake of molecules by organisms, commonly to obtain food. In vertebrate digestion, it is the process by which breakdown products are taken up into the bloodstream.

**accessory pigment:**

A light-absorbing pigment other than chlorophyll in the photosynthetic membrane; carotenoids are important accessory pigments.

**acclimatization:**

An adaptive change in body function to a new environment.

**acidic:**

Describes a solution in which the concentration of protons is higher than that of hydroxide ions (the pH is lower than 7).

**acrosome:**

An organelle that surrounds the head of the sperm containing enzymes that enable sperm to transverse the outer coating of the egg.

**actin:**

A protein that forms microfilaments; it associates with the motor protein myosin in muscles to contract and generate force.

**action potential:**

A brief membrane electrical signal transmitted from the nerve cell body along one or more axons.

**activation energy ( $E_A$ ):**

The energy input necessary to reach the transition state.

**activator:**

A compound that increases the activity of an enzyme.

**active site:**

The portion of an enzyme that binds substrate and converts it to product.

**active transport:**

The “uphill” movement of substances against a concentration gradient requiring an input of energy.

**adaptive (acquired) immunity:**

The part of the vertebrate immune system that is specific to a given pathogen and that

responds more strongly to subsequent infections.

**adaptive radiation:**

A period of unusually rapid evolutionary diversification in which natural selection accelerates the rate of speciation within a group, with new species adapted for specific niches.

**addition rule:**

The principle that the probability of either of two mutually exclusive outcomes occurring is given by the sum of their individual probabilities.

**adenine (A):**

A purine base.

**adenosine triphosphate (ATP):**

The molecule that provides energy in a form that all cells can readily use to perform the work of the cell.

**adherens junction:**

A beltlike junctional complex composed of cadherins that attaches a band of actin to the plasma membrane.

**adrenal glands:**

Paired glands located adjacent to the kidneys that secrete cortisol in times of stress.

**adrenal medulla:**

The inner part of the adrenal gland, which is stimulated by the sympathetic nervous system to secrete norepinephrine.

**advantageous mutations:**

Genetic changes that improve their carriers' chances of survival or reproduction.

**advertisement display:**

Behavior by which individuals draw attention to themselves or their status.

**aerobic:**

Utilizing oxygen.

**aerobic metabolism:**

Energy metabolism that uses oxygen gas to oxidize organic compounds, generating ATP; found in Bacteria, Archaea, and the mitochondria of eukaryotic organisms.

**age structure:**

The number of individuals within each age group of a population.

**agonist muscles:**

Muscle pairs that combine to produce similar motions.

**aldosterone:**

A hormone produced by the cortex of the adrenal glands that stimulates the distal convoluted tubule and collecting ducts to take up more salt and water.

**alga (plural, algae):**

A photosynthetic protist.

**alkaloid:**

Any one of a group of nitrogen-bearing compounds that can affect the nervous system of animals, produced by some plants as a defense against herbivores.

**allantois:**

In the amniotic egg, a membrane that encloses a space where metabolic wastes collect.

**allele frequency:**

The proportion of a specified allele among all the alleles of a gene in a population.

**alleles:**

The different forms of a gene, corresponding to different DNA sequences in each different form.

**allometry:**

An increase in body size accompanied by a change in shape; literally, “different measure.”

**allopatric:**

Describes populations that are geographically separated from each other.

**allosteric effect:**

A change in the activity or affinity of a protein as the result of binding of a molecule to a site other than the active site.

**allosteric enzyme:**

An enzyme whose activity is affected by binding a molecule at a site other than the active site. Typically, allosteric enzymes change their shape on binding an activator or inhibitor.

**alpha ( $\alpha$ ) carbon:**

The central carbon atom of each amino acid.

**alpha ( $\alpha$ ) helix:**

One of the two principal types of secondary structure found in proteins.

**alternation of generations:**

A sexual life cycle in which haploid and diploid phases alternate; especially in plants, the alternation of generations involving a multicellular haploid gametophyte and a multicellular diploid sporophyte.

**alternative splicing:**

A process in which primary transcripts from the same gene can be spliced in different ways to yield different mRNAs and therefore different protein products.

**altruistic:**

Describes self-sacrificial behavior in which an individual's actions decrease its own fitness while increasing that of another individual.

**Alveolata:**

A eukaryotic superkingdom, defined by the presence of cortical alveoli, small vesicles that, in some species, store calcium ions. Includes ciliates, dinoflagellates, and apicomplexans.

**alveoli (singular, alveolus):**

Clusters of tiny thin-walled sacs in the lungs where gas exchange by diffusion takes place; found at the ends of very fine respiratory bronchioles.

**amine hormone:**

A hormone that is derived from a single aromatic amino acid, such as tyrosine.

**amino acid:**

An organic molecule containing a central carbon atom attached to a carboxyl group, an amino group, a hydrogen atom, and a side chain. Amino acids are the building blocks of proteins.

**amino acid replacement:**

A change in the identity of an amino acid at a particular site in a protein resulting from a mutation in a gene.

**amino end:**

The end of a polypeptide chain that has a free amino group.

**amino group:**

NH<sub>2</sub>; a nitrogen atom bonded to two hydrogen atoms. An amino group is present covalently linked to the central carbon atom of an amino acid.

**aminoacyl (A) site:**

One of three binding sites for tRNA on the large subunit of a ribosome.

**aminoacyl tRNA synthetase:**

An enzyme that attaches a specific amino acid to a specific tRNA molecule.

**ammonification:**

The return of biological nitrogen to the environment as ammonia during the breakdown of organic matter by decomposers.

**amnion:**

In the amniotic egg, a membrane surrounding a fluid-filled cavity that allows the embryo to develop in a watery environment.

**amniotes:**

The group of vertebrate animals that produces amniotic eggs; this group includes lizards, snakes, turtles, crocodilians, birds, and mammals.

**amniotic egg:**

An egg that can exchange gases while retaining water, permitting reproduction in dry terrestrial habitats.

**Amoebozoa:**

A superkingdom of eukaryotes with amoeba-like cells that move and gather food by means of pseudopodia.

**Amphibia:**

A monophyletic group of vertebrates, including frogs and salamanders, with an aquatic larval form with gills and an adult terrestrial form that usually has lungs.

**amphipathic:**

Having both hydrophilic and hydrophobic regions.

**amplified:**

In PCR technology, an alternative term for “replicated.”

**amylase:**

An enzyme that breaks down carbohydrates.

**anabolism:**

The set of chemical reactions that build molecules from smaller units utilizing an input of energy, usually in the form of ATP. Anabolic reactions result in net energy storage within

cells and the organism.

**anaerobic metabolism:**

Energy metabolism in the absence of oxygen.

**analogous:**

Describes similar characters that evolved independently in different groups as a result of similar selection pressures; the noun form is *analogy*.

**anammox:**

Anaerobic ammonia oxidation; energy metabolism found in some bacteria in which ammonium ions are oxidized by nitrite, yielding nitrogen gas as a by-product.

**anaphase:**

The stage of mitosis in which the sister chromatids separate.

**anaphase I:**

The stage of meiosis I in which the two homologous chromosomes of each bivalent separate as they are pulled in opposite directions, but the sister chromatids remained joined at the centromere.

**anaphase II:**

The stage of meiosis II in which the centromere of each chromosome splits and the separated chromatids are pulled toward opposite poles of the spindle.

**anchor:**

A membrane protein that attaches to other proteins and helps to maintain cell structure and shape.

**angiosperms:**

The flowering plants; a monophyletic group of seed plants characterized by flowers, double fertilization, and fruits.

**angiotensin II:**

A hormone that causes the smooth muscles of arterioles throughout the body to constrict, which increases blood pressure as well as stimulates the release of the hormone aldosterone, increasing reabsorption of water and electrolytes by the kidneys.

**annealing:**

The coming together of complementary strands of single-stranded nucleic acids by base pairing.

**annelid worms:**

A phylum of worms (Annelida) that have a cylindrical body with distinct segments and a bilaterian body plan.

**annual clock:**

A biological clock that corresponds closely to a solar year.

**anoxygenic:**

Not producing oxygen; anoxygenic photosynthetic bacteria do not use water as an electron donor and so do not generate oxygen gas.

**antagonisms:**

Interactions in which at least one participant loses more than it gains.

**antagonist muscles:**

Muscle pairs that pull in opposite directions at a joint to produce opposing motions.

**anterior pituitary gland:**

An endocrine organ that forms the anterior lobe of the pituitary gland; it responds to hormones from the hypothalamus that stimulate it to release hormones in turn.

**anther:**

In flowering plants, a structure at the top of a stamen consisting of several sporangia in which pollen is produced.

**Anthropocene Epoch:**

The modern era, so named to reflect the dominant impact of humans on Earth.

**antibody:**

A large protein produced by plasma cells that binds to molecules called antigens.

**anticodon:**

The sequence of three nucleotides in a tRNA molecule that base pairs with the corresponding codon in an mRNA molecule.

**antidiuretic hormone (ADH):**

A posterior pituitary gland hormone that acts on the kidneys and controls the water permeability of the collecting ducts, thus regulating the concentration of urine that an animal excretes; also known as *vasopressin*.

**antigen:**

Any molecule that leads to the production of antibodies.

**antigenic drift:**

The gradual process by which mutation leads to changes in the amino acid sequences of antigens. For example, antigenic drift allows a population of viruses to evolve over time and evade memory B and T cells.

**antigenic shift:**

Reassortment of RNA strands in a viral genome, leading to sudden changes in cell-surface proteins.

**antigenic variation:**

The encoding of a protein at different times by any one of a number of different genes.

**antigen-presenting cell:**

A type of cell (including macrophages, dendritic cells, and B cells) that takes up an antigen and returns portions of it to the cell surface bound to MHC class II proteins.

**antiparallel:**

Oriented in opposite directions; the strands in a DNA duplex are antiparallel.

**aorta:**

A large artery through which oxygenated blood flows from the left ventricle of the heart to the head and rest of the body.

**aortic body:**

A sensory structure of the vertebrate aorta that monitors the levels of oxygen and carbon dioxide and the pressure of blood moving through the body.

**aortic valve:**

A valve between the left ventricle and the aorta.

**apical dominance:**

The suppression of growth of axillary buds by the shoot apical meristem.

**apomixis:**

A process in some species of flowering plants in which seeds develop in the absence of fertilization.

**appendicular:**

Describes the part of the vertebrate skeleton that consists of the bones of the shoulder, pelvis, and limbs.

**appendix:**

A narrow, tubelike structure that extends from the cecum. The appendix is a vestigial structure that has no clear function in nonherbivorous animals.

**aquaporin:**

A protein channel that allows water to cross the plasma membrane more readily than by diffusing through the lipid bilayer.

**aqueous:**

Watery.

**Archaea:**

One of the three domains of life, consisting of single-celled organisms with a single circular chromosome and no nucleus that divide by binary fission and differ from bacteria in many aspects of their cell and molecular biology.

**Archaeplastida:**

A eukaryotic superkingdom of photosynthetic organisms; includes the land plants.

**Ardi:**

A specimen of *Ardipithecus ramidus*, an early hominin, dating from about 4.4 million years ago.

**arteriole:**

A small branch of an artery.

**artery:**

A large, high-pressure vessel that moves blood flow away from the heart to the tissues.

**arthropods:**

A phylum of animals that includes insects, crabs and shrimp; contains more than half of all known animal species; distinguished by their segmented bodies and jointed legs.

**artificial selection:**

A form of directional selection similar to natural selection, but with selection done intentionally by humans, usually with a specific goal in mind, such as increased milk yield in cattle.

**ascomycetes:**

A monophyletic fungal subgroup of the Dikarya in which nuclear fusion and meiosis take place in an elongated saclike cell called an ascus; also called *sac fungi*.

**asexual reproduction:**

The reproduction of organisms by mitotic cell division or fragmentation. Offspring are clones of the parent.

**assimilation:**

The process by which organisms incorporate nutrients obtained from the environment into more complex molecules.

**associative learning (conditioning):**

Learning that two events are correlated.

**atom:**

The basic unit of matter.

**atomic mass:**

The mass of the atom determined by the number of protons and neutrons.

**ATP synthase:**

An enzyme that couples the movement of protons through the enzyme with the synthesis of ATP.

**atrioventricular (AV) node:**

A specialized region of the heart containing pacemaker cells that transmit action potentials from the sinoatrial node to the ventricles of the heart.

**atrioventricular (AV) valve:**

A valve between the right atrium and the right ventricle and between the left ventricle and left atrium.

**atrium (plural, atria):**

A heart chamber that receives blood from the lungs or the rest of the body.

**autocrine signaling:**

Signaling between different parts of one cell; the signaling cell and the responding cell are one and the same.

**autoimmune disease:**

A disease in which tolerance is lost and the immune system becomes active against antigens of the host.

**autonomic nervous system:**

The involuntary component of the peripheral nervous system, which controls internal functions of the body such as heart rate, blood flow, digestion, excretion, and temperature.

**autosome:**

Any chromosome other than the sex chromosomes.

**autotroph:**

An organism that is able to synthesize its own food using energy from sunlight or inorganic chemicals; a primary producer.

**auxin:**

A plant hormone that plays a major role in plant development through the establishment of concentration gradients that guide patterns of cell growth and differentiation.

**avirulent:**

In plants, describes pathogens that damage only a small part of the plant because the host plant is able to contain the infection. In animals, describes nonpathogenic microorganisms.

**axial:**

Describes the part of the vertebrate skeleton that consists of the skull and jaws of the head, the vertebrae of the spinal column, and the ribs.

**axillary bud:**

A meristem that forms at the junction between a leaf and the stem.

**axon:**

The fiberlike extension from the cell body of a neuron that transmits signals away from the nerve's cell body; the output end of a nerve cell.

**axon hillock:**

The junction of the nerve cell body and its axon, which initiates an action potential.

**B lymphocyte (B cell):**

A cell of the immune system that matures in the bone marrow of vertebrates and produces antibodies.

**Bacteria:**

One of the three domains of life, consisting of single-celled organisms with a single circular chromosome but no nucleus that divide by binary fission and differ from archaeons in many aspects of their cell and molecular biology.

**bacteriochlorophyll:**

A light-harvesting pigment found in photosynthetic bacteria; closely related to the chlorophyll found in plants, algae, and cyanobacteria.

**bacteriophage:**

A virus that infects bacterial cells.

**balancing selection:**

Natural selection that acts to maintain two or more alleles of a given gene in a population.

**ball-and-socket joint:**

A joint that allows rotation in many axes, like the hip and shoulder.

**basal lamina:**

A specialized form of extracellular matrix that underlies and supports all epithelial tissues; also called a basement membrane.

**base:**

A nitrogen-containing compound that makes up part of a nucleotide.

**base excision repair:**

A specialized repair system in which an incorrect DNA base and its sugar are both removed and the resulting gap is repaired.

**base stacking:**

Stabilizing hydrophobic interactions between bases in the same strand of DNA.

**basic:**

Describes a solution in which the concentration of protons is lower than that of hydroxide ions (the pH is higher than 7).

**basidiomycetes:**

A monophyletic fungal subgroup of the Dikarya, including smuts, rusts, and mushrooms, in which nuclear fusion and meiosis take place in a club-shaped cell called a basidium; also called club fungi.

**basophil:**

A type of granulocyte that, along with eosinophils, defends against parasitic infections but also contributes to allergies.

**behaviorally isolated:**

Describes individuals that only mate with other individuals on the basis of specific courtship rituals, songs, and other behaviors.

**beta ( $\beta$ ) sheet:**

One of the two principal types of secondary structure found in proteins.

**beta-( $\beta$ )-oxidation:**

The process of shortening fatty acids by a series of reactions that sequentially remove two carbon units from their ends.

**Bilateria:**

The monophyletic group of animals with bilateral symmetry.

**bilayer:**

A two-layered structure of the cell membrane with hydrophilic “heads” pointing outward toward the aqueous environment and hydrophobic “tails” oriented inward away from water.

**bile:**

A fluid produced by the liver that aids in fat digestion by breaking large clusters of fats into smaller lipid droplets.

**binary fission:**

The process by which cells of bacteria or archaeons divide to form two daughter cells.

**binding affinity:**

The tightness of the binding between the receptor and the signaling molecule.

**biodiversity:**

Biological diversity; the total number of species, or, more broadly, the diversity of genetic sequences, cell types, metabolism, life history, phylogenetic groups, communities, and ecosystems.

**biodiversity hotspots:**

Relatively small areas that have unusually high numbers of endemic species and that are under threat from human activities.

**biological species concept (BSC):**

As described by Ernst Mayr, the concept that “species are groups of actually or potentially interbreeding populations that are reproductively isolated from other such groups.” The BSC is the most widely used and accepted definition of a species, but cannot be applied to asexual organisms.

**biologist:**

A scientist who studies life.

**biology:**

The science of life and how it works.

**biome:**

The distinctive and stable assemblage of species found over a broad region of Earth; terrestrial biomes are each recognized by their distinctive vegetation.

**biotic factors:**

Any aspect of organisms that affects another organism.

**biotrophic pathogen:**

A plant pathogen that obtains resources from living cells.

**biparental inheritance:**

A type of inheritance in which the organelles in the offspring cells derive from those in both parents.

**bipedal:**

Habitually walking upright.

**bivalent:**

A four-stranded chromosomal structure formed in prophase I of meiosis composed of a pair of homologous chromosomes, each consisting of two chromatids, paired side by side and held together by one or more chiasmata.

**bivalves:**

A group of mollusks that includes clams, oysters, and mussels; they have an enclosing skeleton made up of two mineralized shells (valves) connected by a flexible hinge.

**bladder:**

A hollow organ in tetrapods (mammals, birds, reptiles, and amphibians) for the storage and elimination of urine; in fishes, a swim bladder controls air volume and buoyancy.

**blastocyst:**

A hollow, fluid-filled ball of cells with an inner cell mass that develops from the morula and is an early stage of embryo development in mammals.

**blastula:**

A hollow, fluid-filled ball of cells that develops from the morula and is an early stage of embryo development in animals.

**blending inheritance:**

The now-discredited model in which heredity factors transmitted by the parents become intermingled in the offspring instead of retaining their individual genetic identities.

**blood:**

The circulatory fluid in vertebrates.

**bone marrow:**

A fatty tissue between trabeculae and within the central cavity of a bone that contains many important cell populations.

**bony fish:**

Osteichthyes; fish that have a cranium, jaws, and mineralized bones. This group includes about 20,000–25,000 species.

**bottleneck:**

An extreme, usually temporary, reduction in population size that may result in marked loss of genetic diversity and, in the process, genetic drift.

**Bowman's capsule:**

A membranous sac that encases the glomerulus in the kidney.

**brain:**

The centralized concentration of neurons in an organ located in the head that processes complex sensory stimuli from the environment or from anywhere in the body.

**brainstem:**

Part of the vertebrate brain, formed from the midbrain, which activates the forebrain by relaying information from lower spinal levels.

**bronchiole:**

Any one of the fine branches of secondary bronchi.

**bud scale:**

Small modified leaves that protect shoot apical meristems from desiccation and damage due to cold.

**budding:**

A form of asexual reproduction in fungi, plants, and some animals in which a bud forms on the organism and eventually breaks off to form a new organism that is smaller than its parent.

**bulbourethral glands:**

Glands below the prostate gland that produce a clear fluid that lubricates the urethra for passage of the sperm.

**bulk flow:**

The movement of fluids over long distances through organisms due to pressure differences.

**C<sub>3</sub> plant:**

A plant that does not use 4-carbon organic acids to supply the Calvin cycle with carbon dioxide.

**C<sub>4</sub> plant:**

A plant in which carbon dioxide is incorporated into 4-carbon organic acids in mesophyll cells that are then used to supply the Calvin cycle in bundle sheath cells; results in the suppression of photorespiration.

**cadherin:**

A calcium-dependent adherence protein, important in the adhesion of cells to other cells in animals.

**calmodulin:**

A protein that binds with Ca<sup>2+</sup> and activates the enzyme myosin kinase.

**Calvin cycle:**

The process in which carbon dioxide is reduced to synthesize carbohydrates, with ATP and NADPH as the energy sources.

**Cambrian explosion:**

A transition period in geologic time during which the body plans characteristic of most bilaterian phyla diversified.

**canine:**

One of the teeth in carnivores specialized for piercing the body of prey.

**capacitation:**

A series of physiological changes that allow the sperm to fertilize the egg.

**capillary:**

A very small blood vessel, arranged in finely branched networks connecting arterioles to venules, where gases, nutrients and waste products are exchanged by diffusion with surrounding tissues.

**capsid:**

The protein coat that surrounds the nucleic acid genome of a virus.

**carbohydrate:**

An organic molecule containing C, H, and O atoms that provides a source of energy for

metabolism and that forms the starting point for the synthesis of all other organic molecules.

**carbon cycle:**

The intricately linked network of biological and physical processes that shuttles carbon among rocks, soil, oceans, air, and organisms.

**carboxyl end:**

The end of a polypeptide chain that has a free carboxyl group.

**carboxyl group:**

COOH; a carbon atom with a double bond to oxygen and a single bond to a hydroxyl group.

**carboxylation:**

A chemical reaction in which carbon dioxide is added to another molecule and a carboxylic acid group is produced. It occurs, for example, in the Calvin cycle when carbon dioxide is added to a 5-carbon molecule.

**cardiac cycle:**

The contraction of the two atria of the heart followed by contraction of the two ventricles.

**cardiac muscle:**

Muscle cells that make up the walls of the atria and ventricles and contract to pump blood through the heart.

**cardiac output (CO):**

The volume of blood pumped by the heart over a given interval of time; the key measure of heart function.

**carotid body:**

A chemosensory structure of the carotid artery that monitors the levels of carbon dioxide and oxygen, and the pH of blood moving to the brain.

**carpel:**

The ovule-producing organ in flowers.

**carrier:**

A transporter that facilitates movement of molecules.

**carrying capacity (*K*):**

The maximum number of individuals a habitat can support.

**cartilage:**

A type of connective tissue found, for example, in the walls of intervertebral discs and the joint surfaces between adjacent bones.

**cartilaginous fish:**

Chondrichthyes; a monophyletic group of fish that includes about 800 species of sharks, rays, and chimaeras.

**Casparian strip:**

A band of hydrophobic material that encircles each cell of the endodermis of a root, forcing water and solutes to reach the xylem by passing through the cytoplasm of endodermal cells.

**catabolism:**

The set of chemical reactions that break down molecules into smaller units and, in the process, produce ATP to meet the energy needs of the cell.

**causation:**

A relationship in which one event leads to another.

**cavitation:**

The abrupt replacement of liquid water in a xylem conduit by water vapor, which prevents water from being pulled through the xylem by transpiration.

**cecum:**

A chamber that branches off the large intestine; along with the colon, the site of hindgut fermentation.

**cell:**

The simplest self-reproducing entity that can exist as an independent unit of life.

**cell adhesion molecule:**

A cell-surface protein that attaches cells to one another and to the extracellular matrix.

**cell cycle:**

The collective name for the steps that make up eukaryotic cell division.

**cell division:**

The process by which a parent cell gives rise to two daughter cells.

**cell junction:**

A complex of proteins in the plasma membrane where a cell makes contact with another cell or the extracellular matrix.

**cell-mediated immunity:**

A form of immunity in which T cells recognize and act against pathogens directly.

**cell wall:**

A structural layer external to the plasma membrane that helps maintain the shape and internal composition of the cell; present in plants, fungi, many protists, archaeons, and bacteria.

**cellular blastoderm:**

In *Drosophila* development, the structure formed by the nuclei in the single-cell embryo when they migrate to the periphery of the embryo and each nucleus becomes enclosed in its own cell membrane.

**cellular respiration:**

A series of chemical reactions in which organic molecules are oxidized to carbon dioxide, converting the energy stored in organic molecules to ATP.

**cellulase:**

An enzyme that breaks down cellulose.

**central dogma:**

Originally, the idea that information flows from nucleic acids to proteins, but not in the opposite direction. More generally, the view that information transfer in a cell usually goes from DNA to RNA to protein.

**central nervous system (CNS):**

In vertebrates, the brain and spinal cord; in invertebrates, centralized information-processing ganglia.

**centromere:**

A constriction that physically holds sister chromatids together; the site of the attachment of the spindle fibers that move the chromosome in cell division.

**centrosome:**

A compact structure that is the microtubule organizing center for animal cells.

**cephalization:**

The concentration of nervous system components at one end of the body.

**cephalochoordates:**

A subphylum of Chordata that shares key features of body organization with vertebrates but lacks a well-developed brain and eyes, has no lateral appendages, and does not have a mineralized skeleton. *Amphioxus*, or the lancelet, is the best known example.

**cephalopods:**

A monophyletic group of mollusks, including squid, cuttlefish, octopus, and chambered nautilus, with distinctive adaptations such as well-developed eyes, a siphon derived from fused mantle tissue that directs movement by jet propulsion, and muscular tentacles that capture prey and sense the environment.

**cerebellum:**

Part of the vertebrate brain, formed from the hindbrain, which coordinates complex motor tasks by integrating motor and sensory information.

**cerebral cortex:**

Part of the vertebrate brain formed from a portion of the forebrain that is greatly expanded in mammals, particularly primates.

**cerebrum:**

The outer left and right hemispheres of the cerebral cortex.

**cervix:**

The end, or neck, of the uterus.

**chain terminator:**

A term for a dideoxynucleotide, which if incorporated into a growing daughter strand stops strand growth because there is no hydroxyl group to attack the incoming nucleotide.

**channel:**

A transporter with a passage that allows the movement of molecules through it.

**chaperone:**

A protein that helps shield a slow-folding protein until it can attain its proper three-dimensional structure.

**character:**

In the discipline of systematics, an anatomical, physiological, or molecular feature of an organism that varies among taxa.

**character state:**

The observed condition of a character, such as presence or absence of lungs or the arrangement of petals.

**checkpoint:**

One of multiple regulatory mechanisms that coordinate the temporal sequence of events in the cell cycle.

**chelicerates:**

One of the four main groups of arthropods, including spiders and scorpions, chelicerates have pincer-like claws and are the only arthropods that lack antennae.

**chemical bond:**

Any form of attraction between atoms that holds them together.

**chemical energy:**

A form of potential energy held in the chemical bonds between pairs of atoms in a molecule.

**chemical reaction:**

The process by which molecules are transformed into different molecules.

**chemiosmotic hypothesis:**

The hypothesis that the gradient of protons across a membrane provides a source of potential energy that is converted into chemical energy stored in ATP.

**chemoautotroph:**

A microorganism that obtains its carbon by the fixation of carbon dioxide, using energy derived from chemical reactions, not from sunlight.

**chemoreceptor:**

A receptor that responds to molecules that bind to specific protein receptors on the cell membrane of the sensory receptor.

**chemotroph:**

An organism that derives its energy directly from organic molecules such as glucose.

**chiasma (plural, chiasmata):**

A crosslike structure within a bivalent constituting a physical manifestation of crossing over.

**chitin:**

A modified polysaccharide containing nitrogen that makes up the cell walls of fungi and the hard exoskeletons of arthropods.

**chlorophyll:**

The major photosynthetic pigment contained in the photosynthetic membranes of eukaryotes and cyanobacteria; it plays a key role in the cell's ability to capture energy from sunlight. Chlorophyll appears green because it is poor at absorbing green wavelengths.

**chloroplast:**

An organelle in photosynthetic eukaryotes that converts energy of sunlight into chemical

energy by synthesizing simple sugars.

**chloroplast genome:**

In photosynthetic eukaryotes, the genome of the chloroplast.

**choanocyte:**

A type of cell that lines the interior surface of a sponge; choanocytes have flagella and function in nutrition and gas exchange.

**choanoflagellate:**

The closest protistan relatives of animals; mostly unicellular protists characterized by a ring of microvilli around the cell's single flagellum.

**cholecystokinin (CCK):**

A peptide hormone that causes the gallbladder to contract and thus release bile into the duodenum.

**cholesterol:**

An amphipathic lipid that is a major component of animal cell membranes.

**Chordata:**

One of the three major phyla of deuterostomes, this group includes vertebrates and closely related invertebrate animals such as sea squirts and lancelets.

**chorion:**

In the amniotic egg, a membrane that surrounds the entire embryo along with its yolk and allantoic sac.

**chromatin:**

A complex of DNA, RNA, and proteins that gives chromosomes their structure; chromatin fibers are either 30 nm in diameter or, in a relaxed state, 10 nm.

**chromatin remodeling:**

The process in which the nucleosomes are repositioned to expose different stretches of DNA to the nuclear environment.

**chromosome condensation:**

The progressive coiling of the chromatin fiber, an active, energy-consuming process requiring the participation of several types of proteins.

**chytrid:**

Primarily aquatic fungi that have simple, often unicellular bodies and that produce flagellated

gametes and spores.

**cilium (plural, cilia):**

Hairlike structures that extend from the surface of cells. Nonmotile cilia don't move and often have a sensory function; motile cilia propel the movement of cells or fluid surrounding the cell.

**circadian clock:**

A biological clock, on a near-daily cycle, that can be set by external cues and regulates many daily rhythms. In animals, the circadian clock may affect feeding, sleeping, hormone production, and core body temperature.

**circular muscle:**

Smooth muscle that encircles the body or an organ; in the digestive tract, a circular muscle layer contracts to reduce the size of the lumen. A circular muscle layer contracts alternately with longitudinal muscle to move contents through the digestive tract and to enable locomotion in animals with hydrostatic skeletons.

**circulation:**

The movement of a specialized body fluid in animals that carries oxygen and carbon dioxide, and nutrients and waste products, through the body.

**cis-regulatory element:**

A short DNA sequence adjacent to a gene, usually at the 5' end, that interacts with transcription factors.

**cisternae (singular, cisterna):**

The series of flattened membrane sacs that make up the Golgi apparatus.

**citric acid cycle:**

The third stage of cellular respiration, in which acetyl-CoA is broken down and carbon dioxide is released.

**cladistics:**

Phylogenetic reconstruction on the basis of shared evolutionary changes in characters, often called synapomorphies.

**class:**

In the Linnaean system of classification, a group of closely related orders.

**class I:**

A class of gene of the major histocompatibility complex that is expressed on the surface of all

nucleated cells.

**class II:**

A class of gene of the major histocompatibility complex that is expressed on the surface of macrophages.

**class III:**

A class of gene of the major histocompatibility complex that encodes several proteins of the complement system and proteins involved in inflammation.

**classical conditioning:**

Associative learning in which two stimuli are paired.

**cleavage:**

The successive mitotic divisions of the zygote after fertilization, in which the single large egg is divided into many smaller cells.

**climax community:**

A mature assembly, a final stage in succession, in which, in the absence of environmental disturbance, there is little further change in species composition.

**clitoris:**

The female homolog of the glans penis.

**clonal selection:**

A hypothesis proposing that the antigen instructs the antibody to fold in a particular way so that the two interact in a specific manner; now a central principle of immunology.

**clone:**

An individual that carries an exact copy of the nuclear genome of another individual; clones are genetically identical cells or individuals.

**closed circulatory system:**

A circulatory system made up of a set of internal vessels and a heart that functions as a pump to move blood to different regions of the body.

**Cnidaria:**

A phylum characterized by radial symmetry, two germ tissues in the embryo, a closed internal gastric cavity, and well-developed tissues but not organs; includes jellyfish, sea anemones, and corals.

**cochlea:**

A coiled chamber within the skull containing hair cells that convert sound (pressure) waves into an electrical impulse that is sent to the brain.

**codon:**

A group of three adjacent nucleotides in RNA that specifies an amino acid in a protein or that terminates polypeptide synthesis.

**coelacanth:**

Two species of lobe-finned fish found long thought to have been extinct for 80 million years but which still live today; along with lungfish, the nearest relatives of tetrapods.

**coelom:**

A body cavity surrounding the gut.

**coenzyme Q (CoQ):**

In respiration, a mobile electron acceptor that transports electrons from complexes I and II to complex III in the electron transport chain and moves protons from the mitochondrial matrix to the intermembrane space.

**coenocytic:**

Containing many nuclei within one giant cell; the nucleus divides multiple times, but the nuclei are not partitioned into individual cells.

**coevolution:**

The process in which species evolve together, each responding to selective pressures from the other.

**cognition:**

The ability of the brain to process and integrate complex sources of information, interpret and remember past events, solve problems, reason, and form ideas.

**cohesion:**

Attraction between molecules; one consequence of cohesion is surface tension.

**cohort:**

A group of the individuals born at a given time.

**collagen:**

A strong protein fiber found in bone, artery walls, tendons, and other connective tissues.

**collecting duct:**

A type of duct in the vertebrate kidney where urine collects.

**colon:**

Part of the hindgut and the site of reabsorption of water and minerals; also known as the *large intestine*.

**combinatorial control:**

Regulation of gene transcription by means of multiple transcription factors acting together.

**commensalism:**

An interaction between species in which one partner benefits with no apparent effect on the other.

**communication:**

The transfer of information between two individuals, the sender and the receiver.

**community:**

The set of all populations found in a given place.

**compact bone:**

Dense, mineralized bone tissue that forms the walls of a bone's shaft.

**companion cell:**

In angiosperms, a cell that carries out cellular functions such as protein synthesis for sieve tubes.

**comparative genomics:**

The analysis of the similarities and differences in protein-coding genes and other types of sequence in the genomes of different species.

**competition:**

An interaction in which the use of a mutually needed resource by one individual or group of individuals lowers the availability of the resource for another individual or group.

**competitive exclusion:**

The result of a competitive interaction in which one species is prevented from occupying a particular habitat or niche.

**complement system:**

The collective name for certain proteins circulating in the blood that participate in innate immune function and thus support other parts of the immune system.

**complementary:**

Describes the relationship of purine and pyrimidine bases, in which the base A pairs only

with T, and G pairs only with C.

**complementary DNA (cDNA):**

A DNA molecule produced by reverse transcriptase from an RNA template.

**complex carbohydrate:**

A long, branched chain of monosaccharides.

**complex trait:**

A trait that is influenced by multiple genes as well as by the environment.

**compound eye:**

An eye structure found in insects and other arthropods that consists of a number of ommatidia, individual light-focusing elements.

**concordance:**

The percentage of cases in which both members of a pair of twins show the trait when it is known that at least one member shows it.

**cone cell:**

A type of photoreceptor cell on the vertebrate retina that detects color.

**conjugation:**

The direct cell-to-cell transfer of DNA, usually in the form of a plasmid.

**connective tissue:**

A type of animal tissue that underlies epithelial tissues and is found elsewhere as well; it has an extensive extracellular matrix and few cells.

**conservation biology:**

The efforts by biologists and policymakers to address the challenge of sustaining biodiversity in a changing world crowded with people.

**conserved:**

Describes sequences that are similar in different organisms.

**constant (C) region:**

Describes an unchanging region of the H and L chains of an antibody.

**constitutive:**

Describes expression of a gene that occurs continuously.

**consumer:**

An organism that obtains the carbon it needs for growth and reproduction from the foods it eats and gains energy by respiring food molecules; heterotrophic organisms of all kinds that directly consume primary producers or consume those that do.

**continuous growth:**

A type of population growth in which the population increases or decreases continuously.

**contractile ring:**

In animal cells, a ring of actin filaments that forms at the equator of the cell perpendicular to the axis of what was the spindle at the beginning of cytokinesis.

**contractile vacuole:**

A type of cellular compartment that takes up excess water and waste products from inside the cell and expels them into the external environment.

**control group:**

The group that is not exposed to the variable in an experiment.

**cooperative binding:**

The increase in binding affinity with additional binding of oxygen.

**copy-number variation (CNV):**

Differences among individuals in the number of copies of a region of the genome.

**cork cambium:**

Lateral meristem that renews and maintains an outer layer that protects the stem against herbivores, mechanical damage, desiccation, and fire.

**corpus luteum:**

A temporary endocrine structure in the ovaries that secretes progesterone.

**correlation:**

The co-occurrence of two events or processes; correlation does not imply causation.

**Coriolis effect:**

The phenomenon in which, because of Earth's counterclockwise rotation about its axis, winds and oceanic currents in the Northern Hemisphere deflect to the right, and those in the Southern Hemisphere deflect to the left.

**cortex:**

In a stem, the region between the epidermis and the vascular bundles, composed of parenchyma cells. In the mammalian brain, the highly folded outer layer of gray matter, about

4 mm thick, made up of densely packed neuron cell bodies and their dendrites. In the mammalian renal system, the outer layer of the kidney.

**co-speciation:**

A process in which two groups of organisms speciate in response to each other and at the same time, producing matching phylogenies.

**countercurrent exchange:**

A mechanism in which two fluids flow in opposite directions, exchanging properties.

**countercurrent multiplier:**

A system that generates a concentration gradient as two fluids move in parallel but in opposite directions, as occurs in the loops of Henle in the vertebrate kidney.

**covalent bond:**

A chemical bond formed by a shared pair of electrons holding two different atoms together.

**CpG island:**

A cluster of CpG sites on a DNA strand where cytosine (C) is adjacent to guanosine (G); the “p” represents the phosphate in the backbone.

**cranial nerve:**

In vertebrates, a nerve that links specialized sensory organs to the brain; most contain axons of both sensory and motor neurons.

**craniates:**

A subphylum of Chordata, distinguished by a bony cranium that protects the brain; also known as *vertebrates*.

**crassulacean acid metabolism (CAM):**

A mechanism in plants that helps balance carbon dioxide gain and water loss by capturing carbon dioxide into 4-carbon organic acids at night, when transpiration rates are low, and then using it to supply the Calvin cycle during the day while stomata remain closed.

**CRISPR (clustered regularly interspaced short palindromic repeats):**

DNA sequences in Bacteria and Archaea that contain viral sequences and are used for defense; the basis of a DNA editing technique that allows researchers to modify any sequence in the genome.

**crisscross inheritance:**

A pattern in which an X chromosome present in a male in one generation is transmitted to a female in the next generation, and in the generation after that can be transmitted back to a

male.

**Cro-Magnon:**

The first known population of *Homo sapiens* in Europe, named for the site in France where specimens were first described.

**crop:**

In many birds, an expanded part of the esophagus, which serves as an initial storage chamber.

**cross-bridge:**

The binding of the head of a myosin molecule to actin at a specific site between the myosin and actin filaments.

**cross-bridge cycle:**

Repeated sequential interactions between myosin heads that bind to and release from sites on actin filaments, forming and unforming cross-bridges, that cause a muscle fiber to contract.

**crosscurrent:**

Running across another current at 90 degrees.

**crossover:**

The physical breakage, exchange of parts, and reunion between non-sister chromatids.

**crustaceans:**

One of the main groups of arthropods, including lobsters, shrimp, and crabs; distinguished by two pairs of antennae and their branched legs or other appendages.

**ctenophores:**

Comb-jellies; species in this phylum have a radial body plan but a flow-through gut; they propel themselves by cilia arranged like a comb along the long axis of the body.

**cultural transmission:**

The transfer of information among individuals through learning or imitation.

**cuticle:**

In plants, a protective layer of a waxy substance secreted by epidermal cells that limits water loss; in animals, an exoskeleton that covers the bodies of invertebrates such as nematodes and arthropods.

**C-value paradox:**

The disconnect between genome size and organismal complexity (the C-value is the amount of DNA in a reproductive cell).

**cyanobacteria:**

A monophyletic group of bacteria capable of oxygenic photosynthesis.

**cyclic electron transport:**

An alternative pathway for electrons during the photosynthetic electron transport chain that increases the production of ATP.

**cyclin:**

A regulatory protein whose levels rise and fall with each round of the cell cycle.

**cyclin-dependent kinase (CDK):**

A kinase that is always present within the cell but active only when bound to the appropriate cyclin.

**cytochrome-*b<sub>6</sub>f* complex (Cyt):**

Part of the photosynthetic electron transport chain, through which electrons pass between photosystem II and photosystem I.

**cytochrome *c*:**

The enzyme to which electrons are transferred in complex III of the respiratory electron transport chain.

**cytokine:**

A chemical messenger released by phagocytes that recruits other immune cells to the site of injury or infection.

**cytokinesis:**

In eukaryotic cells, the division of the cytoplasm into two separate cells.

**cytokinin:**

A plant hormone that stimulates cell division and delays leaf senescence.

**cytoplasm:**

The contents of the cell other than the nucleus.

**cytosine (C):**

A pyrimidine base.

**cytoskeleton:**

In eukaryotes, an internal protein scaffold that helps cells to maintain their shape and serves as a network of tracks for the movement of substances within cells.

**cytosol:**

The region of the cell inside the plasma membrane but outside the organelles; the jelly-like internal environment that surrounds the organelles.

**cytotoxic T cell:**

A type of T cell that is activated by cytokines released from helper T cells and that can kill other cells.

**daughter strand:**

In DNA replication, the strand synthesized from a parental template strand.

**day-neutral plant:**

A plant that flowers independently of any change in day length.

**decomposer:**

An organism that breaks down dead tissues, feeding on the dead cells or bodies of other organisms.

**delayed hypersensitivity reaction:**

A reaction initiated by helper T cells, which release cytokines that attract macrophages to the site of exposure, such as the skin.

**deleterious mutations:**

Genetic changes that are harmful to an organism.

**deletion:**

A missing region of a gene or chromosome.

**demography:**

The study of the size, structure, and distribution of populations over time, including changes in response to birth, aging, migration, and death.

**denaturation:**

The unfolding of proteins by chemical treatment or high temperature; the separation of paired, complementary strands of nucleic acid.

**dendrite:**

A fiberlike extension from the cell body of a neuron that receives signals from other nerve cells or from specialized sensory endings; the input end of a nerve cell.

**dendritic cell:**

A type of cell with long cellular projections that is typically part of the natural defenses found

in the skin and mucous membranes.

**denitrification:**

The process in which some bacteria use nitrate as an electron acceptor in respiration, releasing  $N_2$  to the environment.

**density-dependent:**

Describes processes affecting populations that are influenced by the number of individual organisms, such as the use of resources or susceptibility to predation or parasitism.

**density-independent:**

Describes factors such as severe drought that influence population size without regard for the density of the population.

**deoxyribonucleic acid (DNA):**

A linear polymer of four subunits; the information archive in all organisms.

**deoxyribose:**

The sugar in DNA.

**depolarization:**

An increase in membrane potential from a negative resting potential.

**dermis:**

The layer of skin beneath the epidermis, consisting of connective tissue, hair follicles, blood and lymphatic vessels, and glands. It supports the epidermis both physically and by supplying it with nutrients and provides a cushion surrounding the body.

**desiccation:**

Excessive water loss; drying out.

**desiccation tolerance:**

A suite of biochemical traits that allows cells to survive extreme dehydration by minimizing damage to membranes and macromolecules.

**desmosome:**

A buttonlike point of adhesion that holds the plasma membranes of adjacent cells together.

**deuterostome:**

A bilaterian in which the blastopore, the first opening to the internal cavity of the developing embryo, becomes the anus. The taxonomic name is Deuterostomia and includes humans and other chordates.

**Deuterostomia:**

Bilaterians in which the blastopore develops into the anus. Includes echinoderms, hemichordates, and chordates.

**development:**

The process in which a fertilized egg undergoes multiple rounds of cell division to become a multicellular organism, often with specialized tissues and organs.

**diaphragm:**

A domed sheet of muscle at the base of the lungs in mammals that separates the thoracic and abdominal cavities and contracts to drive inhalation.

**diaphysis:**

The middle region of a bone.

**diastole:**

The relaxation of the ventricles, allowing the heart to fill with blood.

**dideoxynucleotide:**

A nucleotide lacking both the 2 and 3 hydroxyl groups on the sugar ring.

**dietary mineral:**

In animals, a chemical element other than carbon, hydrogen, oxygen, or nitrogen that is required in the diet and must be obtained in food.

**differentiation:**

The process in which cells become progressively more specialized as a result of gene regulation.

**diffusion:**

The random motion of molecules, with net movement occurring from areas of higher to lower concentration of the molecules.

**digestion:**

The process of breaking down food into smaller molecules that can be absorbed.

**digestive tract:**

Collectively, the passages that connect the digestive organs; also known as the *gut*.

**Dikarya:**

A fungal group that includes about 98% of all described fungal species and in which dikaryotic cells are formed.

**dikaryotic ( $n + n$ ):**

Having two haploid nuclei, one from each parent, in each cell.

**diploblastic:**

Describes animals in which the embryo has two germ layers, the endoderm and the ectoderm, from which the adult tissues develop.

**diploid:**

Describes a cell with two complete sets of chromosomes.

**directional selection:**

A form of selection that results in a shift of the mean value of a trait in a population over time.

**discrete growth:**

A type of population growth in which the population size increases (or decreases) in one discrete step at the beginning of each new generation. It is typical of organisms that breed seasonally or annually.

**dispersal:**

The process in which some individuals colonize a distant place far from the main source population.

**display:**

A pattern of behavior used in communication that is species specific and tends to be highly repeatable and similar from one individual to the next.

**disruptive selection:**

A form of selection that operates in favor of extremes and against intermediate forms, selecting against the mean.

**distal convoluted tubule:**

The third portion of the renal tubule, in which urea is the principal solute and into which other wastes from the bloodstream are secreted.

**dizygotic (DZ):**

Describes twins that arise when two separate eggs, produced by double ovulation, are fertilized by two different sperm.

**DNA editing:**

Techniques used to “rewrite” a nucleotide sequence so that specific mutations can be introduced into genes to better understand their function, or to correct mutant versions of

genes to restore normal function.

**DNA fingerprinting:**

The analysis of a small quantity of DNA to uniquely identify an individual; also known as *DNA typing*.

**DNA ligase:**

An enzyme that uses the energy in ATP to close a nick in a DNA strand, joining the 3' hydroxyl of one end to the 5' phosphate of the other end.

**DNA polymerase:**

An enzyme that is a critical component of a large protein complex that carries out DNA replication.

**DNA replication:**

The process of duplicating a DNA molecule, during which the parental strands separate and new partner strands are made.

**DNA transposons:**

Repeated DNA sequences that replicate and can move from one location to another in the genome by DNA replication and repair.

**DNA typing:**

The analysis of a small quantity of DNA to uniquely identify an individual; also known as *DNA fingerprinting*.

**domain:**

One of the three largest limbs of the tree of life: Eukarya, Bacteria, or Archaea.

**dominant:**

Describes an allele or trait that is expressed in heterozygotes. Only one dominant allele is needed to express the phenotype.

**dormancy:**

A time period in the life of an organism when growth, development, and metabolism slow down or stop; in plants, a state in which seeds are prevented from germinating even though environmental conditions are favorable.

**dorsal nerve cord:**

A nerve cord that develops in a location dorsal to the notochord; this embryonic feature is unique to chordates.

**dosage compensation:**

The differential regulation of *X*-chromosomal genes in females and in males.

**double bond:**

A covalent bond in which covalently joined atoms share two pairs of electrons.

**double fertilization:**

In angiosperms, the process in which two sperm from a single pollen tube fuse with (1) the egg and (2) the two haploid nuclei of the central cell. The first fusion forms the zygote; the second develops into the nutritive endosperm.

**double helix:**

The structure formed by two strands of complementary nucleotides that coil around each other.

**Down syndrome:**

A condition resulting from the presence of an extra copy of chromosome 21; also known as *trisomy 21*.

**downstream gene:**

A gene that functions later than another in development.

**duodenum:**

The initial section of the small intestine, into which food enters from the stomach.

**duplication:**

A region of a chromosome that is present twice instead of once.

**duplication and divergence:**

The process of creating new genes by duplication followed by change in sequence over evolutionary time.

**dynamic instability:**

Cycles of polymerization and depolymerization in microtubules.

**dynein:**

A motor protein that carries cargo away from the plasma membrane toward the minus ends of microtubules.

**Ecdysozoa:**

A subclade of the protostome animals, characterized by the episodic molting of an exoskeleton during growth.

**Echinodermata:**

One of the three major phyla of deuterostomes, defined by five-part symmetry; this group includes sea urchins and sea stars.

**ecological footprint:**

The quantification of individual human claims on global resources by adding up all the energy, food, materials, and services used and estimating how much land is required to provide those resources.

**ecological isolation:**

Pre-zygotic isolation between individuals that specialize ecologically in different ways.

**ecological species concept (ESC):**

The concept that there is a one-to-one correspondence between a species and its niche.

**ecology:**

The study of how organisms interact with one another and with their physical environment.

**ecosystem:**

A community of organisms and the physical environment it occupies.

**ecosystem services:**

Benefits to humans provided by biodiversity, such as cleaner air and water, greater primary productivity, improved resilience to environmental disruption, and untapped sources of food and molecular compounds for use in medicine and agriculture.

**ectoderm:**

In animals, the outer germ layer, which differentiates into epithelial cells, pigment cells in the skin, nerve cells in the brain, and, in animals with eyes, the cornea and lens.

**ectomycorrhizae:**

One of the two main types of mycorrhizae; ectomycorrhizae produce a thick sheath of fungal cells (hyphae) that surround the root tip, as well as hyphae that grow between, but do not penetrate, cells in the interior of the root.

**ectotherm:**

An animal that obtains most of its heat to warm its body from the environment.

**egg:**

The larger, female gamete; also call an *ovum*.

**ejaculatory duct:**

The duct through which sperm travel from the vas deferens to the urethra.

**elastin:**

A protein fiber found in artery walls that provides elasticity.

**electrochemical gradient:**

A gradient that combines the charge gradient and the chemical gradient of protons and other ions.

**electromagnetic receptor:**

A receptor that responds to electrical, magnetic, or light stimuli.

**electron:**

A negatively charged particle that moves around the atomic nucleus.

**electron carrier:**

A molecule that carries electrons (and energy) from one set of reactions to another.

**electron transport chain:**

The system that transfers electrons along a series of membrane-associated proteins from an electron donor molecule to a final electron acceptor.

**electronegativity:**

The ability of atoms to attract electrons.

**element:**

A pure substance, such as oxygen, copper, gold, or sodium, that cannot be further broken down by the methods of chemistry.

**elongation:**

The process in protein translation in which successive amino acids are added one by one to the growing polypeptide chain.

**elongation factor:**

A protein that breaks the high-energy bonds of the molecule GTP to provide energy for ribosome movement and elongation of a growing polypeptide chain.

**embryo:**

An early stage of multicellular development that results from successive mitotic divisions of the zygote.

**endergonic:**

Describes reactions with a positive  $\Delta G$  that are not spontaneous and so require an input of energy.

**endocrine system:**

A system of cells and glands that secretes hormones into the bloodstream and works with the nervous system to regulate an animal's internal physiological functions.

**endocrine signaling:**

Signaling by molecules that travel through the bloodstream.

**endocytosis:**

The process in which a vesicle buds off from the plasma membrane, bringing material from outside the cell into that vesicle, which can then fuse with other membranes.

**endoderm:**

In animals, the inner germ layer, which differentiates into cells of the lining of the digestive tract and associated organs.

**endodermis:**

In plants, a layer of cells surrounding the xylem and phloem at the center of the root that controls the movement of nutrients into the xylem. Also, the inner lining of the cnidarian body.

**endomembrane system:**

A cellular system that includes the nuclear envelope, the endoplasmic reticulum, the Golgi apparatus, lysosomes, the plasma membrane, and the vesicles that move between them.

**endomycorrhizae:**

One of the two main types of mycorrhizae; endomycorrhizal hyphae penetrate into root cells, where they produce highly branched structures (arbuscules) that provide a large surface area for nutrient exchange.

**endophyte:**

A fungus that lives within leaves and that may help the host plant by producing chemicals that deter pathogens and herbivores.

**endoplasmic reticulum (ER):**

An organelle composed of a network of membranes that is involved in the synthesis of proteins and lipids.

**endoskeleton:**

A skeleton that develops within the body, as the bones of vertebrates.

**endosperm:**

A triploid tissue within angiosperm seeds that supplies nutrition to the embryo.

**endosymbiosis:**

A symbiosis in which one partner lives within the other.

**endotherm:**

An animal that produces most of its own heat as a by-product of metabolic reactions to maintain a warm body temperature.

**energetic coupling:**

The driving of a non-spontaneous reaction by a spontaneous reaction.

**energy:**

A property of objects that makes work possible; energy can be transferred from one object to another, and cannot be created or destroyed.

**energy balance:**

A form of homeostasis in which the amount of energy calories from food taken in equals the amount of calories used over time to meet metabolic needs.

**energy intake:**

Sources of energy taken into the body to support metabolism.

**energy use:**

The ways in which energy is expended by an organism.

**enhancer:**

A specific DNA sequence necessary for transcription.

**enthalpy ( $H$ ):**

The total amount of energy in a system.

**entropy ( $S$ ):**

The amount of disorder (or the number of possible positions and motions of molecules) in a system.

**envelope:**

A lipid structure that surrounds the capsids of some viruses; also used to describe the plasma membrane and cell wall of bacteria and polysaccharide structures that encompass cyanobacterial cells.

**environmental risk factor:**

A characteristic in a person's surroundings that increases the likelihood of developing a particular disease.

**environmental variation:**

Variation among individuals that is due to differences in the environment.

**enzyme:**

A protein that functions as a catalyst to accelerate the rate of a chemical reaction; enzymes are critical in determining which chemical reactions take place in a cell.

**eosinophil:**

A type of granulocyte that defends against parasitic infections but also contributes to allergies.

**epidermis:**

In animals, the outer layer of skin, which serves as a water-resistant, protective barrier. In plants, the outermost layer of cells in leaves, young stems (lacking secondary growth), and roots. In general, the outer layer of the body.

**epididymis:**

An organ that lies above the testes where sperm become motile and are stored prior to ejaculation.

**epigenetic:**

Describes effects on gene expression due to differences in DNA packaging, such as modifications in histones or chromatin structure.

**epiglottis:**

A flap of tissue at the bottom of the pharynx that prevents food from entering the trachea and lungs.

**epiphysis:**

The end region of a bone; blood vessels invading the epiphysis and diaphysis trigger the transformation of cartilage into bone.

**epiphyte:**

A plant that grows on branches or trunks of trees, without contact with the soil.

**epistasis:**

Interaction between genes that modifies the phenotypic expression of genotypes.

**epithelial tissue:**

A type of animal tissue that provides a lining for all of the spaces inside and outside the body; it is composed of closely packed cells.

**equational division:**

Another name for meiosis II because cells in meiosis II have the same number of chromosomes at the beginning and at the end of the process.

**esophagus:**

Part of the foregut; the passage from the mouth to the stomach.

**essential amino acid:**

An amino acid that cannot be synthesized by cellular biochemical pathways and instead must be ingested.

**estrogen:**

A hormone secreted by the ovaries that stimulates the development of female secondary sexual characteristics.

**estrus cycle:**

A cycle in placental mammals other than humans and chimpanzees characterized by phases in which females are sexually receptive.

**ethanol fermentation:**

The fermentation pathway in plants and fungi during which pyruvate releases carbon dioxide to form acetaldehyde and electrons from NADH are transferred to acetaldehyde to produce ethanol and  $\text{NAD}^+$ .

**Eukarya:**

The eukaryotes; one of the three domains of life, in which cells have a true nucleus and divide by mitosis.

**eukaryote:**

An organism whose cells have a true nucleus.

**Eumetazoa:**

A group of anatomically diverse animals that are united by a number of synapomorphies, including the development of diverse cell types, distinct tissues, and gastrulation.

**eusocial:**

Describes behavior most commonly observed in species of Hymenopteran insects, in which they have overlapping generations in a nest, cooperative care of the young, and clear and

consistent division of labor between reproducers (the queen of a honeybee colony) and nonreproducers (the workers).

**eutrophication:**

The process in which the addition of nutrients to a body of water greatly stimulates the growth of plants, algae, and cyanobacteria, often leading to a decrease in dissolved oxygen concentration and therefore a decline in species diversity.

**evapotranspiration:**

The sum of water evaporated directly from soils and water bodies plus the amount transpired by plants.

**evo-devo:**

The short name for evolutionary developmental biology, a field of study that compares the genetic programs for growth and development in different species in order to understand how diversity has evolved within and between groups.

**evolution:**

Changes in the genetic make-up of populations over time, sometimes resulting in adaptation to the environment and the origin of new species.

**evolutionarily conserved:**

Characteristics that persist relatively unchanged through diversification of a group of organisms and therefore remain similar in related species.

**evolutionarily stable strategy:**

A type of behavior that cannot readily be driven to extinction by an alternative strategy.

**excitation–contraction coupling:**

The process that produces muscle force and movement, by coupling the excitation of the muscle cell by a motor neuron to contraction of the muscle.

**excitatory postsynaptic potential (EPSP):**

A positive change in the postsynaptic membrane potential.

**excretory tubule:**

In renal systems, a type of tube that drains waste products and connects to the outside of the body.

**exergonic:**

Describes reactions with a negative  $\Delta G$  that release energy and proceed spontaneously.

**exhalation:**

The expelling of oxygen-poor air by the elastic recoil of the lungs and chest wall.

**exit (E) site:**

One of three binding sites for tRNA on the large subunit of a ribosome.

**exocytosis:**

The process in which a vesicle fuses with the plasma membrane and empties its contents into the extracellular space or delivers proteins to the plasma membrane.

**exon:**

A sequence that is left intact in mRNA after RNA splicing.

**exoskeleton:**

A rigid skeletal system that lies external to the animal's soft tissues.

**experimentation:**

A disciplined and controlled way of learning about the world and testing hypotheses in an unbiased manner.

**exponential growth:**

The pattern of population increase that results when  $r$  (the per capita growth rate) is constant through time.

**expressed:**

Turned on or activated, as a gene or protein.

**extension (joint):**

The joint motion in which bone segments move apart.

**extension (PCR):**

A step in the polymerase chain reaction (PCR) for producing new DNA fragments in which the reaction mixture is heated to the optimal temperature for DNA polymerase, and each primer is elongated by means of deoxynucleoside triphosphates.

**external fertilization:**

Fertilization that takes place outside the body of the female; in some aquatic organisms, for example, eggs and sperm are released into the water.

**extracellular matrix:**

A meshwork of proteins and polysaccharides outside the cell; the main constituent of connective tissue.

**extraembryonic membrane:**

In the amniotic egg, one of several sheets of cells that extend out from the developing embryo and form the yolk sac, amnion, allantois, and chorion.

**extravasation:**

The process in which phagocytes that travel in the blood move from a blood vessel to the site of infection.

**eyecup:**

An eye structure found in flatworms that contains photoreceptors that point up and to the left or right.

**F<sub>1</sub> generation:**

The first filial, or offspring, generation.

**F<sub>2</sub> generation:**

The second filial generation; the offspring of the F<sub>1</sub> generation.

**facilitated diffusion:**

Diffusion through a membrane protein, bypassing the lipid bilayer.

**facilitation:**

An indirect interaction between two species in which one species changes the environment in such a way as to benefit another species.

**facultative:**

In mutualisms, describes one in which one or both sides can survive without the other. In metabolism, describes a means of obtaining energy that is sometimes but not always used.

**fallopian tube:**

A tube from each ovary, through one of which a released oocyte passes; also called *oviduct*.

**family:**

A group of closely related genera.

**fast-twitch:**

Describes muscle fibers that generate force quickly, producing rapid movements, but that also consume more energy and fatigue more quickly than slow-twitch fibers.

**fatty acid:**

A long chain of carbons attached to a carboxyl group; three fatty acid chains attached to glycerol form a triacylglycerol, a lipid used for energy storage.

**feature detector:**

A specialized sensory receptor or group of sensory receptors that respond to important signals in the environment.

**fermentation:**

A variety of metabolic pathways that produce ATP from the partial oxidation of organic molecules without oxidative phosphorylation or an electron acceptor, such as oxygen.

**ferns and horsetails:**

A monophyletic group of vascular plants in which both the gametophyte and sporophyte generations are free living and that disperse by spores.

**fertilization:**

The union of gametes to produce a diploid zygote.

**fetus:**

An embryo in mammals.

**fiber:**

In angiosperms, a narrow cell with thick walls that provides mechanical support in wood. In animals, a muscle cell, which produces forces within an animal's body and exerts forces on the environment.

**filament:**

In animals, a thin thread of proteins that interacts with other filaments to cause muscles to shorten. In plants, the part of the stamen that supports the anther.

**filial imprinting:**

Imprinting in which newborn offspring rapidly learn to treat any animal they see shortly after birth as their mother.

**filtration:**

The separation of solids from fluids, as when circulatory pressure pushes fluid containing wastes through specialized filters into an extracellular space.

**first-division nondisjunction:**

Failure of chromosome separation in meiosis I.

**first law of thermodynamics:**

The law of conservation of energy: energy can neither be created nor destroyed—it can only be transformed from one form into another.

**fitness:**

A measure of the extent to which an individual's genotype is represented in the next generation.

**fixed:**

In genetics, describes the situation in which all individuals in a population are homozygous for the same allele of a particular gene; the noun form is *fixation*. In metabolism, refers to the processes by which simple inorganic molecules are converted into biologically available forms, especially carbon fixation and nitrogen fixation.

**fixed action pattern (FAP):**

A sequence of behaviors that, once triggered, is followed through to completion.

**flagellum (plural, flagella):**

An organelle that propels the movement of cells; short flagella are also called cilia.

**flexion (joint):**

The joint motion in which bone segments rotate closer together.

**fluid:**

When describing membranes, the ability of membrane lipids to move in the plane of the membrane.

**fluid mosaic model:**

A model that proposes that the lipid bilayer is a fluid structure that allows molecules to move laterally within the membrane and is a mosaic of two types of molecules, lipids and proteins.

**flux:**

The rate at which a substance—for example, carbon—flows from one reservoir to another.

**folding domain:**

A region of a protein that folds in a similar way across a protein family relatively independently of the rest of the protein.

**follicle:**

A type of cell that makes up the shell of cells surrounding an oocyte that supports the developing oocyte.

**follicle-stimulating hormone (FSH):**

A hormone secreted by the anterior pituitary gland that stimulates the male and female gonads to secrete testosterone in males and estrogen and progesterone in females.

**follicular phase:**

The phase of the menstrual cycle during which FSH acts on granulosa cells, resulting in the maturation of several oocytes, of which, usually, only one becomes completely mature.

**food web:**

A map of the interactions that connect consumer and producer organisms; the movement of carbon through the biological components of an ecosystem.

**force:**

An interaction that changes the movement of an object, such as a push or pull by one object interacting with another object.

**forebrain:**

The region of the vertebrate brain that governs cognitive functions.

**foregut:**

The first part of an animal's digestive tract, including the mouth, esophagus, and stomach.

**founder event:**

A type of genetic drift that occurs when only a few individuals establish a new population.

**fragmentation:**

A form of asexual reproduction in which new individuals arise by the splitting of one organism into pieces, each of which develops into a new individual.

**frameshift mutation:**

A mutation in which an insertion or deletion of some number of nucleotides that is not a multiple of three causes a shift in the reading frame of the mRNA, changing all following codons.

**frequency of recombination:**

The proportion of recombinant chromosomes among the total number of chromosomes observed.

**frontal lobe:**

The region of the brain located in the anterior region of the cerebral cortex, important in decision making and planning.

**fruit:**

In angiosperms, the structure that develops from the ovary, sometimes united with adjacent tissues, and serves to protect immature seeds and enhance dispersal once the seeds are mature.

**fruiting body:**

A multicellular structure in some fungi that facilitates the dispersal of sexually produced spores.

**functional groups:**

Groups of one or more atoms that have particular chemical properties of their own, regardless of what they are attached to.

**fundamental niche:**

The full range of climate conditions and food resources in which individuals in a species may live.

**fungi:**

An abundant and diverse group of heterotrophic eukaryotic organisms, principally responsible for the decomposition of plant and animal tissues.

**G protein:**

A protein that binds to the guanine nucleotides GTP and GDP.

**G protein-coupled receptor:**

A receptor that couples to G proteins, which bind to the guanine nucleotides GTP and GDP.

**G<sub>0</sub> phase:**

The gap phase in which cells pause in the cell cycle between M phase and S phase; it may last for periods ranging from days to more than a year.

**G<sub>1</sub> phase:**

The gap phase in which the size and protein content of the cell increase and specific regulatory proteins are made and activated in preparation for S-phase DNA synthesis.

**G<sub>2</sub> phase:**

The gap phase in which the size and protein content of the cell increase in preparation for M-phase mitosis and cytokinesis.

**gain-of-function mutation:**

Any mutation in which a gene is expressed in the wrong place or at the wrong time.

**gallbladder:**

The digestive organ in which bile produced by the liver is stored.

**gamete:**

A reproductive haploid cell; gametes fuse in pairs to form a diploid zygote. In many species,

there are two types of gametes: eggs in females, sperm in males.

**gametic isolation:**

Incompatibility between the gametes of different individuals (typically belonging to different species).

**gametogenesis:**

The formation of gametes.

**gametophyte:**

In alternation of generations, describes the haploid multicellular generation that gives rise to gametes.

**ganglion (plural, ganglia):**

A group of nerve cell bodies that processes sensory information received from a local, nearby region, resulting in a signal to motor neurons that control some physiological function of the animal.

**gap junction:**

A type of connection between the plasma membranes of adjacent animal cells that permits materials to pass directly from the cytoplasm of one cell to the cytoplasm of another.

**gas exchange:**

The transport of gases such as oxygen and carbon dioxide between an organism and its environment.

**gastrin:**

A peptide hormone produced in the stomach that stimulates cells lining the stomach to increase their production of HCl.

**gastropods:**

A group of mollusks consisting of snails and slugs.

**gastrula:**

A stage of early embryo development in animals when cells of the hollow blastula migrate and reorganize to form a multilayered structure in which different cell types begin to differentiate.

**gastrulation:**

A highly coordinated set of cell movements in animals in which the cells of the blastula migrate inward, creating germ layers of cells within the embryo.

**gel electrophoresis:**

A technique that is used to separate DNA, RNA, or proteins based on size and/or charge, using an electric current passed through a jelly-like substance.

**gene:**

The unit of heredity; the stretch of DNA that affects one or more traits in an organism, usually through an encoded protein or noncoding RNA.

**gene expression:**

The production of a functional gene product.

**gene family:**

A group of genes with related functions, usually resulting from multiple rounds of duplication and divergence.

**gene flow:**

The movement of alleles from one population to another through interbreeding between members of each population.

**gene pool:**

All the alleles present in all individuals in a population or species.

**gene regulation:**

The various ways in which cells control gene expression.

**general transcription factors:**

A set of proteins that bind to the promoter of a gene whose combined action is necessary for transcription.

**genetic code:**

The correspondence between codons and amino acids, in which 20 amino acids are specified by 64 codons.

**genetic drift:**

A random change in the frequency of an allele due to the statistical effects of finite population size.

**genetic incompatibility:**

Genetic dissimilarity between two organisms, such as different numbers of chromosomes, that is sufficient to act as a post-zygotic isolating factor.

**genetic information:**

Information carried in DNA, organized in the form of genes.

**genetic map:**

A diagram showing the relative positions of genes along a chromosome.

**genetic risk factor:**

Any mutation that increases the risk of a given disease in an individual.

**genetic test:**

A method of identifying the genotype of an individual.

**genetic variation:**

Differences in genotype among individuals in a population.

**genetically modified organism (GMO):**

An organism that has been genetically engineered, such as modified viruses and bacteria, laboratory organisms, agricultural crops, and domestic animals; also known as a *transgenic organism*.

**genome:**

The genetic material transmitted from a parental cell or organism to its offspring.

**genome annotation:**

The process by which researchers identify the various types of sequence present in genomes.

**genomic rearrangement:**

In immunology, the process of joining different gene segments as a B cell differentiates to produce a specific antibody. In genetics, evolutionary changes in gene order or organization.

**genotype:**

The genetic makeup of a cell or organism; the particular combination of alleles present in an individual.

**genotype-by-environment interaction:**

Unequal effects of the environment on different genotypes, resulting in different phenotypes.

**genotype frequency:**

The proportion of a specified genotype among all the genotypes for a particular gene or set of genes in a population.

**genus (plural, genera):**

A group of closely related species.

**geographic isolation:**

Spatial segregation of individuals.

**geologic timescale:**

The series of time divisions that mark Earth's long history.

**germ cells:**

The reproductive cells that produce sperm or eggs and the cells that give rise to them.

**germ layers:**

Three sheets of cells in animals—the ectoderm, mesoderm, and endoderm—formed by migrating cells of the gastrula that differentiate further into specialized cells and tissues.

**germ-line mutation:**

A mutation that occurs in eggs and sperm or in the cells that give rise to these reproductive cells and therefore is passed on to the next generation.

**gibberellic acid:**

A plant hormone that stimulates the elongation of stems.

**Gibbs free energy ( $G$ ):**

The amount of energy available to do work.

**gills:**

Highly folded delicate structures in aquatic animals that facilitate gas exchange with the surrounding water.

**gizzard:**

In birds, alligators, crocodiles, and earthworms, a compartment with thick muscular walls in the digestive tract where food mixed with ingested rock or sediment is broken down into smaller pieces.

**glans penis:**

The head of the human penis.

**glial cell:**

A type of cell that surrounds neurons and provides them with nutrition and physical support.

**glomeromycetes:**

A monophyletic fungal group of apparently low diversity but tremendous ecological importance that occurs in association with plant roots.

**glomerulus:**

A tufted loop of porous capillaries in the vertebrate kidney that filters blood.

**glycerol:**

A 3-carbon molecule with OH groups attached to each carbon.

**glycogen:**

The form in which glucose is stored in animals.

**glycolysis:**

The breakdown of glucose to pyruvate; the first stage of cellular respiration.

**glycosidic bond:**

A covalent bond that attaches one monosaccharide to another.

**Golgi apparatus:**

The organelle that modifies proteins and lipids produced by the endoplasmic reticulum and acts as a sorting station as they move to their final destinations.

**gonad:**

In mammals, the part of the reproductive system where haploid gametes are produced. Male gonads are testes, where sperm are produced. Female gonads are ovaries, where eggs are produced.

**gonadotropin-releasing hormone (GnRH):**

A hormone released by the hypothalamus that stimulates the anterior pituitary gland to secrete luteinizing hormone and follicle-stimulating hormone.

**gram-positive bacteria:**

Bacteria that retain, in their thick peptidoglycan walls, the diagnostic dye developed by Hans Christian Gram. (Bacteria with thin walls, which do not retain the dye, are said to be gram negative.)

**grana (singular, granum):**

Interlinked structures resembling flattened sacs that form the thylakoid membrane.

**granulocyte:**

A type of phagocytic cell that contains granules in its cytoplasm.

**granuloma:**

A structure formed by lymphocytes surrounding infected macrophages that helps to prevent the spread of an infection and aids in killing infected cells.

**gravitropic:**

Orientation of growth in response to gravity. A negative gravitropic response, as in stems, is growth upward against the force of gravity; a positive gravitropic response, as in roots, is with the force of gravity.

**gray matter:**

Densely packed neuron cell bodies and dendrites that make up the cortex, a highly folded outer layer of the mammalian brain about 4 mm thick.

**greenhouse gas:**

A gas in the atmosphere that allows incoming solar radiation to reach the Earth's surface, but absorbs radiation re-emitted as heat, trapping it in the atmosphere and causing the temperature to rise.

**ground tissues:**

In plants, all tissues other than the epidermis and vascular tissues.

**group selection:**

Selection caused by the differential success of groups rather than individuals.

**growth factor:**

In animals, any one of a group of small, soluble molecules, usually the signal in paracrine signaling, that affect cell growth, cell division, and changes in gene expression.

**growth plate:**

A region of cartilage near the end of a bone where growth in bone length occurs.

**growth ring:**

One of the many rings apparent in the cross section of the trunk of a tree, produced by decreases in the size of secondary xylem cells at the end of the growing season, that make it possible to determine the tree's age.

**guanine (G):**

A purine base.

**guard cell:**

One of two cells surrounding the central pore of a stoma.

**gustation:**

The sense of taste.

**gut:**

Collectively, the passages that connect digestive organs; also known as the *digestive tract*.

**gymnosperms:**

Seed plants whose ovules are not enclosed in a carpel; gymnosperms include pine trees and other conifers, as well as cycads, gnetophytes, and ginkgo.

**habituation:**

The reduction or elimination of a behavioral response to a repeatedly presented stimulus.

**hagfish:**

A vertebrate animal with a cranium built of cartilage but no jaws; hagfish feed on marine worms and dead and dying sea animals.

**hair cell:**

A specialized mechanoreceptor that senses movement and vibration.

**half-life:**

The time it takes for an amount of a substance to reach half its original value. Radioactive half-life is the time it takes for half of the atoms in a given sample of a substance to decay.

**haploid:**

Describes a cell with one complete set of chromosomes.

**haplotype:**

The particular combination of alleles present in any defined region of a chromosome.

**Hardy–Weinberg equilibrium:**

A state in which allele and genotype frequencies do not change over time, implying the absence of evolutionary forces. It also specifies a mathematical relationship between allele frequencies and genotype frequencies.

**heart:**

The pump of the circulatory system, which moves blood to different regions of the body.

**heart rate (HR):**

The number of heartbeats per unit time.

**heartwood:**

The center of the stem in long-lived trees, which does not conduct water.

**heavy (H) chains:**

Two of the four polypeptide chains that make up an antibody molecule.

**helicase:**

A protein that unwinds the parental double helix at the replication fork.

**helper T cell:**

One type of T cell that assists other cells of the immune system by secreting cytokines, thus activating B cells to secrete antibodies, for example.

**hematocrit:**

The fraction of red blood cells within the blood of vertebrates.

**Hemichordata:**

One of the three major phyla of deuterostomes, this group includes acorn worms and pterobranchs.

**hemidesmosome:**

A type of desmosome in which integrins are the prominent cell adhesion molecules.

**hemoglobin:**

An iron-containing molecule specialized for oxygen transport.

**hemolymph:**

The circulatory fluid in invertebrates.

**heterokaryotic:**

Describes a stage in the life cycle of some fungi, in which plasmogamy is not followed immediately by karyogamy and the cells have unfused haploid nuclei from both parents.

**hemophilia:**

A trait characterized by excessive bleeding that results from a recessive mutation in a gene encoding a protein necessary for blood clotting.

**herbivory:**

The consumption of plant tissues.

**heritability:**

In a population, the proportion of the total variation in a trait that is due to genetic differences among individuals.

**heterotroph:**

An organism that obtains its carbon from organic molecules synthesized by other organisms.

**heterozygote advantage:**

A form of balancing selection in which the heterozygote's fitness is higher than that of either of the homozygotes, resulting in selection that ensures that both alleles remain in the population at intermediate frequencies.

**heterozygous:**

Describes an individual who inherits different types of alleles from the parents, or genotypes in which the two alleles for a given gene are different.

**hierarchical:**

Describes gene regulation during development, in which the genes expressed at each stage in the process control the expression of genes that act later.

**hindbrain:**

Along with the midbrain, the region of the vertebrate brain that controls basic body functions and behaviors.

**hindgut:**

The last part of an animal's digestive tract, including the large intestine and rectum.

**hinge joint:**

A simple joint that allows one axis of rotation, like the elbow and knee.

**hippocampus:**

A posterior region of the limbic system within the mammalian brain involved in spatial cognition and long-term memory formation.

**histamine:**

A chemical messenger released by mast cells and basophils; an important contributor to allergic reactions and inflammation.

**histone code:**

The pattern of modifications of the histone tails that affects the chromatin structure and gene transcription.

**histone tail:**

A string of amino acids that protrudes from a histone protein in the nucleosome.

**homeodomain:**

The DNA-binding domain in homeotic proteins, whose sequences are very similar from one homeotic protein to the next.

**homeostasis:**

The active regulation and maintenance, in organisms, organs, or cells, of a stable internal physiological state in the face of a changing external environment.

**homeotic (*Hox*) gene:**

A gene that specifies the identity of a body part or segment during embryonic development.

**hominins:**

A member of one of the different species in the group leading to humans.

**homologous:**

Describes characters that are similar in different species because of descent from a common ancestor; the noun form is *homology*.

**homologous chromosomes:**

Pairs of chromosomes, matching in size and appearance, that carry the same set of genes; one of each pair was received from the mother, the other from the father.

**homozygous:**

Describes an individual who inherits an allele of the same type from each parent, or a genotype in which both alleles for a given gene are of the same type.

**horizontal gene transfer:**

The transfer of genetic material between organisms that are not parent and offspring.

**hormone:**

A chemical signal that influences physiology and development in both plants and animals; in animals, hormones are released into the bloodstream and circulate throughout the body.

**host cell:**

A cell in which viral replication occurs.

**host plant:**

A plant species that can be infected by a given pathogen.

**hotspot:**

In genetics, a site in the genome that is especially mutable. In ecology, a region with high levels of biodiversity, often with large numbers of endemic species.

**human chorionic gonadotropin (hCG):**

A hormone released by the developing embryo that maintains the corpus luteum.

**hybrid offspring:**

The offspring produced by a cross; sometimes applied specifically to interbreeding between two closely related species.

**hybridization:**

Interbreeding between two different varieties or species.

**hydrogen bond:**

A bond between a hydrogen atom in one molecule and an electronegative atom in another molecule.

**hydrophilic:**

“Water loving”; describes a class of molecules with which water can undergo hydrogen bonding.

**hydrophobic:**

“Water fearing”; describes a class of molecules poorly able to undergo hydrogen bonding with water.

**hydrophobic effect:**

The exclusion of nonpolar molecules by polar molecules, which drives biological processes such as the formation of cell membranes and the folding of proteins.

**hydrostatic skeleton:**

A skeletal system in which fluid contained within a body cavity is the supporting element.

**hydroxyapatite:**

The calcium phosphate mineral found in bone.

**hypersensitive response:**

A type of plant defense against infection in which uninfected cells surrounding the site of infection rapidly produce large numbers of reactive oxygen species, triggering cell wall reinforcement and causing the cells to die, thus creating a barrier of dead tissue.

**hyperthermophile:**

An organism that requires an environment with high temperature.

**hyphae:**

In fungi, highly branched multicellular filaments that provide a large surface area for absorbing nutrients.

**hypothalamus:**

The underlying brain region of the forebrain, which interacts with the autonomic and

endocrine systems to regulate the general physiological state of the body.

**hypothesis:**

A tentative explanation for one or more observations that makes predictions that can be tested by experiments or additional observations.

**IgA:**

One of the five antibody classes, IgA is typically a dimer and the major antibody on mucosal surfaces.

**IgD:**

One of the five antibody classes, IgD is a monomer and is typically found on the surface of B cells; it helps initiate inflammation.

**IgE:**

One of the five antibody classes, IgE is a monomer that plays a central role in allergies, asthma, and other immediate hypersensitivity reactions.

**IgG:**

The most abundant of the five antibody classes, IgG is a monomer that circulates in the blood and is particularly effective against bacteria and viruses.

**IgM:**

One of the five antibody classes, IgM is a pentamer in mammals and a tetramer in fish and is particularly important in the early response to infection, activating the complement system and stimulating an immune response.

**ileum:**

A section of the small intestine that, with the jejunum, carries out most nutrient absorption.

**imitation:**

Observing and copying the behavior of another.

**immediate hypersensitivity reaction:**

A reaction characterized by a heightened or an inappropriate immune response to common antigens.

**immunodeficiency:**

Any disease in which part of the immune system does not function properly.

**imprinting (genetics):**

Silencing of gene expression by chemical modification of DNA or chromatin that differs

according to the parent of origin.

**in vitro fertilization (IVF):**

A process in which eggs and sperm are brought together in a petri dish, where fertilization and early cell divisions occur.

**inbred line:**

A true-breeding, homozygous strain.

**inbreeding depression:**

A reduction in fitness resulting from breeding among relatives causing homozygosity of deleterious recessive mutations.

**incisor:**

One of the teeth in the front of the mouth, used for biting.

**incomplete dominance:**

Inheritance in which the phenotype of the heterozygous genotype is intermediate between those of homozygous genotypes.

**incomplete penetrance:**

The phenomenon in which some individuals with a genotype corresponding to a trait do not show the phenotype, either because of environmental effects or because of interactions with other genes.

**incus:**

A small bone in the vertebrate middle ear that helps amplify the sound waves that strike the tympanic membrane.

**induced pluripotent stem cell (iPS cell):**

A cell that has been reprogrammed to become pluripotent by activation of certain genes, most of them encoding transcription factors or chromatin proteins.

**inducer:**

A small molecule that elicits gene expression.

**inflammation:**

A physiological response of the body to injury that removes the inciting agent if present and begins the healing process.

**inhalation:**

The drawing of oxygen-rich air into the lungs by the expansion of the thoracic cavity.

**inhibitor:**

A synthesized compound that decreases the activity of an enzyme.

**inhibitory postsynaptic potential (IPSP):**

A negative change in the postsynaptic membrane potential.

**initiation:**

The stage of translation in which methionine is established as the first amino acid in a new polypeptide chain.

**initiation factor:**

A protein that binds to mRNA to initiate translation.

**innate:**

Describes behaviors that are instinctive and carried out regardless of earlier experience.

**innate (natural) immunity:**

The part of the immune system that provides protection in a nonspecific manner against all kinds of infection; it does not depend on exposure to a pathogen.

**inner cell mass:**

A mass of cells in one region of the inner wall of the blastocyst from which the body of the embryo develops.

**insects:**

The most diverse of the four main groups of arthropods, with a head, thorax, and abdomen, and six walking legs.

**instantaneous speciation:**

Speciation that occurs in a single generation.

**integral membrane protein:**

A protein that is permanently associated with the cell membrane and cannot be separated from the membrane experimentally without destroying the membrane itself.

**integrin:**

A transmembrane protein, present on the surface of virtually every animal cell, that enables cells to adhere to the extracellular matrix.

**intercostal muscles:**

Muscles of vertebrates attached to adjacent pairs of ribs that assist the diaphragm by elevating the ribs on inhalation and depressing them during exhalation.

**intermediate filament:**

A polymer of proteins, which vary according to cell type, that combine to form strong, cable-like filaments that provide animal cells with mechanical strength.

**intermembrane space:**

The space between the inner and outer mitochondrial membranes.

**internal fertilization:**

Fertilization that takes place inside the body of the female.

**interneuron:**

A neuron that processes information received by sensory neurons and transmits it to motor neurons in different body regions.

**internode:**

The segment between two nodes on a shoot.

**interphase:**

The time between two successive M phases.

**intersexual selection:**

A form of sexual selection involving interaction between males and females, as when females choose from among males.

**interspecific competition:**

Competition between individuals of different species.

**intervertebral disc:**

A gel-filled support structure found between the bony vertebrae of the backbone that enables flexibility and provides cushioning of loads.

**intrasexual selection:**

A form of sexual selection involving interactions between individuals of one sex, as when members of one sex compete with one another for access to the other sex.

**intraspecific competition:**

Competition between individuals of the same species.

**intrinsic rate of increase:**

The per capita growth rate; the maximum rate of growth when no environmental factors limit population increase.

**intron:**

A sequence that is excised from the primary transcript and degraded during RNA splicing.

**invasive species:**

Non-native species; since they are removed from natural constraints on population growth, invasive species can expand dramatically when introduced into new areas, sometimes with devastating consequences for native species and ecosystems.

**inversion:**

The reversal of the normal order of a block of genes.

**involuntary component:**

The part of the peripheral nervous system that controls unconscious reactions.

**ion:**

An electrically charged atom or molecule.

**ion channels:**

Channel-like membrane proteins that open and close, thereby altering the flow of ions across the plasma membrane.

**ionic bond:**

A chemical bond in which two ions with opposite charges associate with each other due to their difference in electronegativity.

**island population:**

An isolated population; may apply to true islands (land surrounded by water) or to ecological islands that similarly isolate their inhabitants (for example ponds, for fish).

**isomers:**

Molecules that have the same chemical formula but different structures.

**isometric:**

Describes the generation of muscle force without a change in muscle length.

**isometry:**

An increase in body size while keeping the same overall shape; literally, “same measure.”

**isotopes:**

Atoms of the same element that have different numbers of neutrons.

**jejunum:**

A section of the vertebrate small intestine that, with the ileum, carries out most nutrient absorption.

**juxtaglomerular apparatus:**

The structure formed by specialized cells of the efferent arteriole leaving the glomerulus of each nephron, which secretes the hormone rennin into the bloodstream.

**karyogamy:**

The fusion of two nuclei following plasmogamy.

**karyotype:**

A standard arrangement of chromosomes, showing the number and shapes of the chromosomes representative of a species.

**key stimulus:**

A stimulus that initiates a fixed action pattern.

**keystone species:**

Pivotal populations that affect other members of the community in ways that are disproportionate to their abundance or biomass.

**kidneys:**

In vertebrates, paired organs of the renal system that remove waste products and excess fluid; their action contributes to homeostasis.

**kin selection:**

A form of natural selection that favors the spread of alleles promoting behaviors that help close relatives.

**kinesin:**

A motor protein, similar in structure to myosin, that transports cargo toward the plus end of microtubules.

**kinesis (plural, kineses):**

A random, undirected movement in response to a stimulus.

**kinetic energy:**

The energy of motion.

**kinetochore:**

The protein complexes on a chromatid where spindle fibers attach.

**kingdom:**

A group of closely related phyla.

**Klinefelter syndrome:**

A sex-chromosomal abnormality in which an individual has 47 chromosomes, including two X chromosomes and one Y chromosome.

**knee-extension reflex:**

A reflex commonly tested by physicians to evaluate peripheral nervous and muscular system function.

**K-strategist:**

A species that produces relatively few young but invests considerable resources into their support.

**labia majora:**

Outer folds of skin in the vulva.

**labia minora:**

Inner folds of skin in the vulva that meet at the clitoris.

**lactic acid fermentation:**

The fermentation pathway in animals and bacteria during which electrons from NADH are transferred to pyruvate to produce lactic acid and  $\text{NAD}^+$ .

**lagging strand:**

A daughter strand that has its 5' end pointed toward the replication fork, so as the parental double helix unwinds, a new DNA piece is initiated at intervals, and each new piece is elongated at its 3' end until it reaches the piece in front of it.

**lamellae (singular, lamella):**

A thin layer. In animals, the many thin, sheetlike structures spread along the length of each gill filament, giving gills a large surface area relative to their size. In plants, the middle lamella is the thin pectin layer between cells.

**lamprey:**

A vertebrate animal with a cranium and vertebral column built of cartilage but no jaws; many lampreys live parasitically, sucking body fluids from fish prey.

**large intestine:**

Part of the hindgut and the site of reabsorption of water and minerals; also known as the *colon*.

**lariat:**

A loop and tail of RNA formed after RNA splicing.

**larynx:**

The structure, above the trachea, that contains the vocal cords.

**lateral inhibition:**

Inhibition of a process in nerve cells adjacent to the cell receiving a signal inducing that process, enhancing the strength of a signal locally but diminishing it peripherally.

**lateral meristem:**

The source of new cells that allows plants to grow in diameter.

**latex:**

A white sticky liquid produced in some plants.

**latitudinal diversity gradient:**

The increase in species diversity from the poles to the equator.

**leading strand:**

A daughter strand that has its 3' end pointed toward the replication fork, so as the parental double helix unwinds, this daughter strand can be synthesized as one long, continuous polymer.

**learned:**

Describes a behavior that depends on an individual's experience.

**learning:**

The process in which experience leads to changes in behavior.

**lengthening contraction:**

The contraction of a muscle against a load greater than the muscle's force output, leading to a lengthening of the muscle.

**lenticel:**

A region of less tightly packed cells in the outer bark that allows oxygen to diffuse into the stem.

**leptosporangium:**

A distinctive sporangium, found in some ferns, whose outer wall is only a single cell thick and in which drying produces a catapult-like mechanism to release spores.

**Leydig cell:**

A type of cell in the testes that secretes testosterone.

**Liebig's Law of the Minimum:**

The principle that primary production is limited by the nutrient that is least available relative to its use by primary producers.

**lichens:**

Stable associations between a fungus and a photosynthetic microorganism, usually a green alga but sometimes a cyanobacterium.

**life history:**

The typical pattern of resource investment in each stage of a given species' lifetime.

**ligand:**

Alternative term for a signaling molecule that binds with a receptor, usually a protein.

**ligand-binding site:**

The specific location on the receptor protein where a signaling molecule binds.

**ligand-gated ion channel:**

A receptor that alters the flow of ions across the plasma membrane when bound by its ligand.

**light (L) chains:**

Two of the four polypeptide chains that make up the simplest antibody molecule.

**limbic system:**

Inner components of the vertebrate forebrain that control physiological drives, instincts, emotions, motivation, spatial memory, and the sense of reward.

**linked:**

Describes genes that are sufficiently close together in the same chromosome that they do not assort independently.

**lipase:**

A type of enzyme produced by the pancreas that breaks apart lipids, thus enabling their more effective digestion.

**lipid:**

A hydrocarbon molecule that is soluble in non-polar solvents but not water; lipids store energy, act as signaling molecules, and are a component of cell membranes.

**lipid raft:**

Lipids assembled in a defined patch in the cell membrane.

**liposome:**

An enclosed bilayer structure spontaneously formed by phospholipids in environments with neutral pH, like water.

**liver:**

A vertebrate organ that aids in the digestion of proteins, carbohydrates, and fats in the duodenum by producing bile, which breaks down fat.

**lobe-finned fish:**

Species of fish with paired pectoral and pelvic fins that have a bone structure similar to that of tetrapod limbs.

**logistic growth:**

The pattern of population growth that results as growth potential slows down as the population size approaches  $K$ , its maximum sustainable size.

**long-day plant:**

A plant that flowers only when the light period exceeds a critical value.

**longitudinal muscle:**

Smooth muscle that runs lengthwise along a body or organ; in the digestive tract, a longitudinal muscle layer contracts to shorten small sections of the gut.

**loop of Henle:**

The middle portion of the vertebrate renal tubule, which creates a concentration gradient that allows water passing through the collecting duct to be reabsorbed.

**Lophotrochozoa:**

A group of bilaterians that includes mollusks and annelid worms.

**loss-of-function mutation:**

A genetic change that inactivates the normal function of a gene.

**Lucy:**

An unusually complete specimen of an early hominin fossil, *Australopithecus afarensis*, found in 1974 in Ethiopia and dating to 3.2 million years ago.

**lumen:**

In eukaryotes, the continuous interior of the endoplasmic reticulum; in plants, a fluid-filled

compartment enclosed by the thylakoid membrane; generally, the interior of any tubelike structure.

**lunar clock:**

A moon-based biological clock that times activities in some species, especially those living in habitats where tides are important.

**lungfish:**

Several species of lobe-finned fish that use a simple lung to survive periods when their watery habitat dries by burying themselves in moist mud and breathing air; along with coelacanths, the closest relatives of tetrapods.

**lungs:**

The internal organs for gas exchange in many terrestrial animals.

**luteal phase:**

The phase of the menstrual cycle of mammals beginning with ovulation.

**luteinizing hormone (LH):**

A hormone secreted by the anterior pituitary gland of vertebrates that stimulates the gonads to secrete testosterone in males and estrogen and progesterone in females.

**lycophytes:**

A monophyletic group of spore-dispersing vascular plants that are the sister group to all other vascular plants.

**lymph:**

The fluid in the vertebrate lymphatic system in which T and B cells circulate.

**lymphatic system:**

A network of vessels distributed through the vertebrate body with important functions in the immune system.

**lysis:**

The breakage, or bursting, of a cell.

**lysogeny:**

The integration of viral DNA into a host cell's DNA, which is then transmitted to offspring cells.

**lysosome:**

A vesicle derived from the Golgi apparatus that contains enzymes that break down

macromolecules such as proteins, nucleic acids, lipids, and complex carbohydrates.

**lytic pathway:**

The alternative to the lysogenic pathway; in the lytic pathway, a virus bursts, or lyses, the cell it infects, releasing new virus particles.

**M phase:**

The stage of the cell cycle consisting of mitosis and cytokinesis, in which the parent cell divides into two daughter cells.

**macrophage:**

A type of large phagocytic cell that is able to engulf other cells.

**mainland population:**

The central and largest population of a species.

**major groove:**

The larger of two uneven grooves on the outside of a DNA duplex.

**major histocompatibility complex (MHC):**

A group of genes and the proteins they encode that appear on the surface of most mammalian cells; only antigens associated with MHC proteins are recognized by T cell receptors.

**malleus:**

A small bone in the vertebrate middle ear that helps amplify the waves that strike the tympanic membrane.

**Malpighian tubule:**

One of the tubes in the main body cavity of insects and other terrestrial arthropods through which fluid passes and which empties into the hindgut.

**mammals:**

A class of vertebrates distinguished by body hair and mammary glands from which they feed their young.

**mandibles:**

Paired mouthparts found in some arthropods.

**map information:**

The knowledge of where an individual is with respect to its goal.

**map unit:**

A unit of distance in a genetic map equal to the distance between genes resulting in 1% recombination.

**mark-and-recapture:**

A method in which individuals are captured, marked in way that doesn't affect their function or behavior, and then released. The percentage of marked individuals captured later enables ecologists to estimate population size.

**marsupials:**

A group of mammals that includes kangaroos, koalas, and opossums; their young are born at an early stage of development and must crawl to abdominal mammary glands that provide them with milk.

**mass extinction:**

A catastrophic drop in recorded diversity, which has occurred five or more times in the past 541 million years.

**mast cell:**

An immune cell that releases histamine.

**maternal-effect gene:**

A gene that is expressed by the mother that affects the phenotype of the offspring, typically through the composition or organization of the oocyte.

**maternal inheritance:**

A type of inheritance in which the organelles in the offspring cells derive from those in the mother.

**mating types:**

Genetically distinct forms of individuals of a fungus species that, by enabling fertilization only between different types, prevent self-fertilization and promote out-crossing.

**mean:**

The average value of a set of numbers.

**mechanical incompatibility:**

Structural configuration of the genitalia that prevents mating with another individual (typically of another species).

**mechanoreceptor:**

A sensory receptor that responds to physical deformations of its membrane produced by touch, stretch, pressure, motion, or sound.

**mediator complex:**

A complex of proteins that interacts with the Pol II complex and allows transcription to begin.

**medulla:**

A part of the brainstem; also, the inner layer of the mammalian kidney and adrenal gland.

**meiosis I:**

Reductional division; the first stage of meiotic cell division, in which the number of chromosomes is halved.

**meiosis II:**

Equational division; the second stage of meiotic cell division, in which the number of chromosomes is unchanged.

**meiotic cell division:**

A form of cell division that includes only one round of DNA replication but two rounds of nuclear division; meiotic cell division makes sexual reproduction possible.

**membrane attack complex (MAC):**

A complex of complement proteins that makes holes in bacterial cells, leading to cell lysis.

**membrane potential:**

A difference in electrical charge across the plasma membrane.

**memory cell:**

A type of long-lived immune cell produced after exposure to a pathogen that contains membrane-bound antibodies having the same specificity as the parent cell.

**menopause:**

The cessation of menstrual cycles resulting from decreased production of estradiol and progesterone by the mammalian ovaries.

**menstrual cycle:**

A monthly cycle in females of some mammals in which oocytes mature and are released from the ovary under the influence of hormones.

**menstruation:**

The monthly shedding of the uterine lining in some mammals.

**meristem:**

A discrete population of actively dividing, totipotent plant cells; apical meristems are located

at the tip of stems and roots and produce cells that allow plants to grow in length, while lateral meristems surround stems and roots and produce cells that allow growth in diameter.

**meristem identity gene:**

A gene that contributes to meristem stability and function.

**mesentery:**

A membrane in the vertebrate abdominal cavity through which blood vessels, nerves, and lymph travel to supply the gut.

**mesoderm:**

In animals, the intermediate germ layer, which differentiates into cells that make up connective tissue, muscle cells, red blood cells, bone cells, kidney cells, and gonad cells.

**mesoglea:**

In cnidarians, a gelatinous mass enclosed by the epidermis and endodermis.

**mesohyl:**

A gelatinous mass that lies between the interior and exterior cell layers of a sponge that contains some amoeba-like cells that function in skeleton formation and the dispersal of nutrients.

**mesophyll:**

A leaf tissue of loosely packed photosynthetic cells.

**messenger RNA (mRNA):**

The RNA molecule that combines with a ribosome to direct protein synthesis; it carries the genetic “message” from the DNA to the ribosome.

**metabolic rate:**

An animal’s overall rate of energy use.

**metabolism:**

The chemical reactions occurring within cells that convert one molecule into another and transfer energy in living organisms.

**metamorphosis:**

The process in some animals in which the body changes dramatically at key stages in development.

**metanephridia:**

A pair of excretory organs in each body segment of annelid worms that filters the body fluid.

**metaphase:**

The stage of mitosis in which the chromosomes are aligned in the middle of the dividing cell.

**metaphase I:**

The stage of meiosis I in which the meiotic spindle is completed and the bivalents move to lie on an imaginary plane cutting transversely across the spindle.

**metaphase II:**

The stage of meiosis II in which the chromosomes line up so that their centromeres lie on an imaginary plane cutting across the spindle.

**metapopulation:**

A large population made up of smaller populations linked by migration.

**methanogens:**

Archaea that generate natural gas (methane, CH<sub>4</sub>) as a by-product of anaerobic energy metabolism.

**MHC class I (genes and proteins):**

MHC genes and proteins in vertebrates that are expressed on the surface of all nucleated cells.

**MHC class II (genes and proteins):**

MHC genes and proteins in vertebrates that are expressed on the surface of macrophages, dendritic cells, and B cells.

**MHC class III (genes and proteins):**

MHC genes and proteins in vertebrates that encode several proteins of the complement system and proteins involved in inflammation.

**micelle:**

A spherical structure in which lipids with bulky heads and a single hydrophobic tail are packed.

**microfilament:**

A helical polymer of actin monomers, present in various locations in the cytoplasm, that helps make up the cytoskeleton.

**microfossil:**

A microscopic fossil, including fossils of bacteria and protists.

**microRNA (miRNA):**

Small, regulatory RNA molecules that can cleave or destabilize RNA or inhibit its translation.

**microtubule:**

A hollow, tubelike polymer of tubulin dimers that helps make up the cytoskeleton.

**microvilli:**

Highly folded surfaces of villi, formed by fingerlike projections on the surfaces of epithelial cells.

**midbrain:**

Along with the hindbrain, the region of the vertebrate brain that controls basic body functions and behaviors; it is a part of the brainstem.

**midgut:**

The middle part of an animal's digestive tract, including the small intestine.

**migration:**

The movement of organisms from one place to another, including the movement of individuals from one population to another.

**minor groove:**

The smaller of two unequal grooves on the outside of a DNA duplex.

**mismatch repair:**

A mechanism for repairing nucleotide mismatches in newly replicated DNA.

**mitochondria (singular, mitochondrion):**

Specialized organelles that are the site of respiration in eukaryotic cells, oxidizing chemical compounds such as sugars to carbon dioxide and transferring their chemical energy to ATP.

**mitochondrial DNA (mtDNA):**

A small circle of DNA, about 17,000 base pairs long in humans, found in every mitochondrion.

**mitochondrial genome:**

In eukaryotic cells, the DNA in the mitochondria.

**mitochondrial matrix:**

The space enclosed by the inner membrane of the mitochondria.

**mitosis:**

In eukaryotic cells, the division of the nucleus, in which the chromosomes are separated into

two nuclei.

**mitotic spindle:**

A structure in the cytosol made up predominantly of microtubules that pull the chromosomes into separate daughter cells.

**Modern Synthesis:**

The current theory of evolution, which combines Darwin's theory of natural selection and Mendelian genetics.

**molar:**

One of the teeth in the back of the mouth of mammals specialized for crushing and shredding tough foods such as meat and fibrous plant material.

**molecular clock:**

The observation of rate constancy in molecular evolution. The extent of genetic divergence at a gene in two taxa is thus a reflection of the time since the taxa last shared a common ancestor.

**molecular evolution:**

Evolution at the level of DNA, which in time results in the genetic divergence of populations.

**molecular fossils:**

Sterols, bacterial lipids, and some pigment molecules, which are relatively resistant to decomposition, that can be preserved in sedimentary rocks, documenting organisms that rarely form conventional fossils.

**molecular orbital:**

A merged orbital traversed by a pair of shared electrons.

**molecular self-assembly:**

The process by which, when conditions and relative amounts are suitable, viral components spontaneously interact and assemble into mature virus particles.

**molecule:**

A substance made up of two or more atoms.

**mollusks:**

A monophyletic invertebrate group distinguished by a mantle, which plays a major role in movement, skeleton-building, breathing, and excretion; includes clams, snails, and squid.

**molting:**

Periodic shedding, as of an exoskeleton.

**monophyletic:**

Describes groupings in which all members share a single common ancestor not shared with any other species or group of species.

**monosaccharide:**

A simple sugar.

**monozygotic (MZ):**

Describes twins that arise from a single fertilized egg, which after several rounds of cell division separates into two distinct, but genetically identical, embryos.

**morphospecies concept:**

The idea that members of the same species usually look like each other more than like other species.

**morula:**

In animals, the solid ball of cells resulting from early cell divisions of the fertilized egg.

**motor endplate:**

The post-synaptic region on a muscle cell where acetylcholine binds with receptors.

**motor neuron:**

A neuron that signals a muscle or gland to cause a response in the body.

**motor protein:**

Any of various proteins that are involved in intracellular transport or cause muscle contraction by moving the actin microfilaments inside muscle cells.

**motor unit:**

A vertebrate motor neuron and the population of muscle fibers that it innervates.

**mouth:**

The first part of the foregut, which receives food.

**mucosa:**

An inner tissue layer with secretory and absorptive functions surrounding the lumen of the digestive tract.

**multiple alleles:**

Two or more different alleles of the same gene, occurring in a population of organisms.

**multiplication rule:**

The principle that the probability of two independent events occurring together is the product of their respective probabilities.

**multipotent:**

Describes cells that can form a limited number of types of specialized cell.

**multiregional hypothesis:**

The idea that modern humans derive from the *Homo ergaster* populations that spread around the world starting 2 million years ago.

**muscle tissue:**

A type of animal tissue made up of cells (fibers) that are able to shorten or contract, resulting in movement.

**mutagen:**

An agent that increases the probability of mutation.

**mutation:**

Any heritable change in the genetic material, usually a change in the nucleotide sequence of a gene.

**mutualism:**

An interaction between two or more species that benefits all.

**mycelium (plural, mycelia):**

A network of branching hyphae.

**mycorrhizae:**

Fungi that live symbiotically among roots, enhancing nutrient uptake by the plants.

**myelin:**

Fatty insulating layers surrounding the axons of vertebrate neurons, produced by glial cells, that speed up the propagation of action potentials.

**myofibril:**

A long rodlike structure in muscle fibers that contains parallel arrays of actin and myosin filaments.

**myoglobin:**

An oxygen-binding protein in the cells of vertebrate muscles, related to hemoglobin, that facilitates oxygen delivery to mitochondria.

**myosin:**

A motor protein found in cells that carries cargo to the plus ends of microfilaments and is also used by both striated and smooth muscles to contract and generate force.

**myotome:**

In chordates, any one of a series of segments that organizes the body musculature.

**myriapods:**

One of the four main groups of arthropods, including centipedes and millipedes; distinguished by their many pairs of legs.

**natural killer cell:**

A cell type of the innate immune system that recognizes and kills host cells that are infected by a virus or have become cancerous or otherwise abnormal.

**natural selection:**

The process in which, when there is genetic variation in a population of organisms, the variants best suited for growth and reproduction in a given environment contribute disproportionately to future generations. Of all the evolutionary mechanisms, natural selection is the only one that leads to adaptations.

**Neanderthal:**

*Homo neanderthalensis*, a species similar to humans, but with thicker bones and flatter heads; present in the fossil record 600,000–30,000 years ago.

**necrotrophic pathogen:**

A plant pathogen that kills cells before drawing resources from them.

**negative feedback:**

The effect in which the final product of a biochemical pathway inhibits the first step; the process in which a stimulus acts on a sensor that communicates with an effector, producing a response that opposes the initial stimulus. Negative feedback is used to maintain steady conditions, or homeostasis.

**negative regulation:**

The process in which a regulatory molecule must bind to the DNA at a site near the gene to prevent transcription.

**negative selection:**

Natural selection that reduces the frequency of a deleterious allele.

**negatively selected:**

In immunology, describes B and T cells that react too strongly to self antigens in association with MHC and are eliminated through cell death.

**nematodes:**

Roundworms, the most numerous of all animals; a phylum of the Ecdysozoa.

**neoteny:**

The process in which the timing of development is altered so that a sexually mature organism retains the physical characteristics of the juvenile form.

**nephron:**

The functional unit of the vertebrate kidney, consisting of the glomerulus, Bowman's capsule, renal tubules, and collecting ducts.

**neritic zone:**

Within the oceans, environments that are near the shore, with a shallow seafloor, relatively high availability of nutrients, and persistent sunlight. Distinct biomes within the neritic zone include intertidal and coral reef biomes.

**nerve:**

A bundle of long fiberlike extensions (axons) from multiple nerve cells.

**nerve cord:**

A bundle of long fiberlike extensions from multiple nerve cells that serves as the central nervous system of invertebrates, such as flatworms and earthworms, and, together with the brain, as the central nervous system of vertebrates.

**nervous system:**

A network of many interconnected nerve cells.

**nervous tissue:**

A type of animal tissue found in the nerve nets of cnidarians and in the brain, spinal cord, and peripheral nerves of vertebrates; it takes in sensory information from the environment, processes information, and sends signals to target organs to elicit a response.

**neural tube:**

In chordates, a cylinder of embryological tissue that develops into a dorsal nerve cord.

**neuron:**

Nerve cell; the basic fundamental unit of nervous systems.

**neurosecretory cell:**

A neuron in the vertebrate hypothalamus and the posterior pituitary gland that secretes hormones into the bloodstream.

**neurotransmitter:**

A molecule that conveys a signal from the end of an axon to the postsynaptic target cell, such as another neuron or a muscle fiber.

**neutral mutations:**

Genetic changes that have no effect or negligible effects on the organism, or whose effects are not associated with differences in survival or reproduction.

**neutron:**

An electrically neutral particle in the atomic nucleus.

**neutrophil:**

A type of phagocytic cell that is very abundant in the blood and is often one of the first cells to respond to infection.

**niche:**

A complete description of the role a species plays in its environment, and of its requirements, both abiotic and biotic.

**nicotinamide adenine dinucleotide phosphate (NADPH):**

An important cofactor in many biosynthetic reactions; the reducing agent used in the Calvin cycle.

**nitrification:**

The process by which chemoautotrophic bacteria oxidize ammonia ( $\text{NH}_3$ ) to nitrite ( $\text{NO}_2^-$ ) and then nitrate ( $\text{NO}_3^-$ ).

**nitrogen fixation:**

The process by which some Bacteria and Archaea convert nitrogen gas ( $\text{N}_2$ ) into ammonia ( $\text{NH}_3$ ), a form biologically useful to primary producers.

**nitrogenous waste:**

Waste in the form of ammonia, urea, and uric acid, which are toxic to organisms in varying degrees.

**node:**

In phylogenetic trees, the point where a branch splits, representing the common ancestor from which the descendant species diverged. In plants, the point on a shoot where one or more leaves are attached.

**nodes of Ranvier:**

Sites on an axon of vertebrate nerve cells that lie between adjacent myelin-wrapped segments, where the axon membrane is exposed.

**non-associative learning:**

Learning that occurs in the absence of any particular outcome, such as a reward or punishment.

**nondisjunction:**

The failure of a pair of chromosomes to separate normally during anaphase of cell division.

**nonpolar:**

Describes compounds that do not have regions of positive and negative charge.

**nonpolar covalent bond:**

A covalent bond between atoms that have the same, or nearly the same, electronegativity.

**nonrandom mating:**

Mate selection biased by genotype or relatedness.

**nonrecombinants:**

Progeny in which the alleles are present in the same combination as that present in a parent.

**nonself:**

From the point of view of a given organism, describes molecules and cells that are foreign.

**nonsense mutation:**

A mutation that creates a stop codon, terminating translation.

**non-sister chromatids:**

Chromatids of different members of a pair of homologous chromosomes; although they carry the same complement of genes, they are not genetically identical.

**nonsynonymous (missense) mutation:**

A point mutation (nucleotide substitution) that causes an amino acid replacement.

**norm of reaction:**

A graphical depiction of the change in phenotype across a range of environments.

**normal distribution:**

A distribution whose plot is a bell-shaped curve.

**notochord:**

In chordates, a stiff rod of cartilage-like tissue that runs along the back and provides support for the axis of the body.

**nuclear envelope:**

The cell structure, composed of two membranes, inner and outer, that defines the boundary of the nucleus.

**nuclear genome:**

In eukaryotic cells, the DNA in the chromosomes.

**nuclear localization signal:**

The signal sequence for the nucleus that enables proteins to move through pores in the nuclear envelope.

**nuclear pore:**

One of many protein channels in the nuclear envelope that act as gateways that allow molecules to move into and out of the nucleus and are thus essential for the nucleus to communicate with the rest of the cell.

**nuclear transfer:**

A procedure in which a hollow glass needle is used to insert the nucleus of a cell into the cytoplasm of an egg whose own nucleus has been destroyed or removed.

**nucleic acid:**

A polymer of nucleotides that encodes and transmits genetic information.

**nucleoid:**

In prokaryotes, a cell structure with multiple loops formed from supercoils of DNA.

**nucleolus:**

A distinct, dense, non-membrane-bound spherical structure within the nucleus that contains the genes and transcripts for ribosomal RNA.

**nucleoside:**

A molecule consisting of a 5-carbon sugar and a base.

**nucleosome:**

A beadlike repeating unit of histone proteins wrapped with DNA making up the 10-nm chromatin fiber.

**nucleotide:**

A constituent of nucleic acids, consisting of a 5-carbon sugar, a nitrogen-containing base, and

one or more phosphate groups.

**nucleotide excision repair:**

The repair of multiple mismatched or damaged bases across a region; a process similar to mismatch repair, but over a much longer piece of DNA, sometimes thousands of nucleotides.

**nucleus (of an atom):**

The dense central part of an atom containing protons and neutrons.

**nucleus (of a cell):**

The compartment of the cell that houses the DNA in chromosomes.

**obligate:**

In ecology, a type of mutualism in which one participant requires the other to survive. In metabolism, a means of gaining energy or carbon that is required by the organism; that is, it has no other options, as in an obligate photoautroph.

**observation:**

The act of viewing the world around us.

**occipital lobe:**

The region of the brain that processes visual information from the eyes.

**ocean acidification:**

A decrease in the pH of seawater caused by an increase in the amount of carbon dioxide in the oceans.

**oceanic zone:**

Deeper waters beyond the continental shelf; it includes the pelagic biome in open ocean water and the deep sea biome on the deep seafloor.

**Okazaki fragment:**

In DNA replication, any of the many short DNA pieces in the lagging strand.

**olfaction:**

The sense of smell.

**oligonucleotides:**

Short stretches of nucleic acids; in the polymerase chain reaction (PCR), the primer sequences produced by chemical synthesis, which are typically 20–30 nucleotides long.

**omasum:**

The third chamber in the stomach of ruminants, into which the mixture of food and bacteria passes and where water is reabsorbed.

**ommatidia (singular, ommatidium):**

Individual light-focusing elements that make up the compound eyes of insects and other arthropods; the number of ommatidia determines the resolution of the image.

**oncogene:**

A cancer-causing gene.

**oocyte:**

An unfertilized egg cell in animals produced by the mother; a developing female gamete.

**oogenesis:**

The formation of ova or eggs.

**open circulatory system:**

A circulatory system found in many invertebrate animals in which most of the circulating fluid is contained within the animal's body cavity.

**open reading frame (ORF):**

A stretch of DNA or RNA consisting of codons for amino acids uninterrupted by a stop codon. In genome annotation, this sequence motif identifies the region as potentially protein coding.

**operant conditioning:**

Associative learning in which a behavior that was initially undirected has become paired with a particular stimulus through reward/punishment reinforcement.

**operator:**

The binding site for a repressor protein.

**operon:**

A group of functionally related genes located in tandem along the DNA and transcribed as a single unit from one promoter; the region of DNA consisting of the promoter, the operator, and the coding sequence for the structural genes.

**Opisthokonta:**

A superkingdom that encompasses animals, fungi, and related protists.

**opsin:**

A photosensitive protein that converts the energy of light photons into electrical signals in the

receptor cell.

**opsonization:**

The binding of a molecule to a pathogen to facilitate uptake by a phagocyte.

**orbital:**

A region in space where an electron is present most of the time.

**organ:**

Two or more tissues that combine and function together.

**organ system:**

A group of organs that have related functions. For example, the intestine is one organ of the digestive system, which also includes the stomach, liver, pancreas, and other organs.

**organelle:**

Any one of several compartments in eukaryotes that divide the cell contents into smaller spaces specialized for different functions.

**organic molecule:**

A molecule containing carbon atoms, usually in chains or rings.

**organogenesis:**

The transformation of the three germ layers into all the organ systems of the body in animals.

**origin of replication:**

Any point on a DNA molecule at which DNA synthesis is initiated.

**osmoconformer:**

An animal that matches its internal osmotic pressure to that of its external environment.

**osmoregulation:**

The regulation of water and solute levels to control osmotic pressure.

**osmoregulator:**

An animal that maintains internal solute concentrations that differ from that of its environment.

**osmosis:**

The net movement of a solvent, such as water, across a selectively permeable membrane toward the side of higher solute concentration.

**osmotic pressure:**

The pressure needed to prevent water from moving from one solution into another by osmosis.

**osteoblast:**

A type of cell that forms bone tissue.

**osteoclast:**

A type of cell that digests and removes bone tissue.

**out-of-Africa hypothesis:**

The idea that modern humans arose from *Homo heidelbergensis* descendants in Africa before dispersing beyond Africa around 60,000 years ago.

**ovary:**

In angiosperms, a hollow structure at the base of the carpel in which the ovules develop and which protects the ovules from being eaten or damaged by animals; in animals, the female gonad where eggs are produced.

**oviduct:**

A tube from each ovary, through one of which a released oocyte passes; also called *fallopian tube*.

**oviparity:**

Laying eggs.

**ovoviviparity:**

Giving birth to live young, with nutritional support of the embryo from the yolk.

**ovulate cone:**

A reproductive shoot in gymnosperms that produces ovules.

**ovule:**

A reproductive structure in seed plants consisting of the female gametophyte developing within a sporangium and surrounded by outer protective layers. Ovules, when fertilized, develop into seeds.

**ovum (plural, ova):**

The larger, female gamete; also called an *egg*.

**oxidation:**

A reaction in which a molecule loses electrons.

**oxidation–reduction reaction:**

A reaction involving the loss and gain of electrons between reactants. In biological systems these reactions are often used to store or release chemical energy.

**oxidative phosphorylation:**

A set of metabolic reactions that occurs by passing electrons along an electron transport chain to the final electron acceptor, oxygen, pumping protons across a membrane, and using the proton electrochemical gradient to drive synthesis of ATP.

**oxygen dissociation curve:**

The curve that results when blood  $pO_2$  is plotted against the percentage of  $O_2$  bound to hemoglobin.

**oxygenic:**

Producing oxygen.

**oxytocin:**

A hormone released by the posterior pituitary gland that causes uterine contraction during labor and stimulates the release of milk during breastfeeding.

**P<sub>1</sub> generation:**

The parental generation in a series of crosses.

**pacemaker:**

Describes cardiac muscle cells that function as a regulator of heart rhythm.

**palindromic:**

Reading the same in both directions; describes sequence identity along the paired strands of a duplex DNA molecule; a symmetry typical of restriction sites.

**pancreas:**

A secretory gland that has both endocrine function, secreting hormones, including insulin, directly into the blood, and exocrine function, aiding the digestion of proteins, carbohydrates, and fats by secreting digestive enzymes into ducts that connect to the duodenum.

**paracrine signaling:**

Signaling by a molecule that travels a short distance to the nearest neighboring cell to bind its receptor and deliver its message.

**paraphyletic:**

Describes groupings that include some, but not all, the descendants of a common ancestor.

**parasexual:**

Describes asexual species that generate genetic diversity by the crossing over of DNA during mitosis.

**parasites:**

Organisms that live in close association with another species, consuming or gaining nutrition from their hosts' tissues, generally without killing them.

**parasympathetic division:**

The division of the vertebrate autonomic nervous system that slows the heart and stimulates digestion and metabolic processes that store energy, enabling the body to "rest and digest."

**parathyroid gland:**

A gland adjacent to the thyroid gland that secretes parathyroid hormone (PTH), which, with calcitonin, regulates the actions of bone cells and levels of calcium in the blood.

**parenchyma:**

In plants, describes thin-walled cells that carry out a variety of functions, including photosynthesis and storage; capable of further cell division if stimulated.

**parietal lobe:**

The vertebrate brain region, posterior to the frontal lobe, that controls body awareness and the ability to perform complex tasks.

**parsimony:**

Choosing the simplest hypothesis to account for a given set of observations. In phylogenetic reconstruction, opting for the tree requiring the fewest evolutionary steps.

**parthenogenesis:**

A form of asexual reproduction in which females produce eggs that are not fertilized by males but divide by mitosis and develop into new individuals.

**partial pressure ( $p$ ):**

The fractional concentration of a gas relative to other gases present multiplied by the atmospheric pressure exerted on the gases.

**partially reproductively isolated:**

Describes populations that have not yet diverged into separate species but whose genetic differences are extensive enough for the hybrid offspring they produce to have reduced fertility or viability compared with offspring produced by crosses between individuals within each population.

**paternal inheritance:**

A type of inheritance in which the organelles in the offspring cells derive from those in the father.

**pathogens:**

Organisms and other agents, such as viruses, that cause disease.

**peat bog:**

Wetland in which dead organic matter accumulates.

**pedigree:**

A diagram of family history that summarizes the record of the ancestor–descendant relationships among individuals.

**penis:**

The male copulatory organ.

**pepsin:**

An enzyme produced in the stomach that breaks down proteins.

**peptide bond:**

A covalent bond that links the carbon atom in the carboxyl group of one amino acid to the nitrogen atom in the amino group of another amino acid.

**peptide hormone:**

A hormone that is a short chain of linked amino acids.

**peptidoglycan:**

A complex polymer of sugars and amino acids that makes up the cell wall in bacteria.

**peptidyl (P) site:**

One of three binding sites for tRNA on the large subunit of a ribosome.

**per capita growth rate ( $r$ ):**

The rate of population growth per individual; it is the change in population size  $\Delta N$  in a given period of time  $\Delta t$ , divided by the size of the population  $N$ .

**pericycle:**

In roots, a single layer of cells just to the inside of the endodermis from which new root apical meristems are formed, allowing roots to branch.

**periodic selection:**

The episodic loss of diversity as a successful variant outcompetes others.

**periodic table of the elements:**

The arrangement of the chemical elements in tabular form, organized by their chemical properties.

**peripatric speciation:**

A specific kind of allopatric speciation in which a few individuals from a mainland population disperse to a new location remote from the original population and evolve separately.

**peripheral nervous system (PNS):**

Collectively, the sensory and motor nerves, including the cranial and spinal nerves, neurons of the autonomic nervous system, and ganglia.

**peripheral membrane protein:**

A protein that is temporarily associated with the lipid bilayer or with integral membrane proteins through weak noncovalent interactions.

**peristalsis:**

Waves of muscular contraction that move food toward the base of the stomach.

**personalized medicine:**

An approach in which the treatment is matched to the patient, not the disease; examination of an individual's genome sequence, by revealing his or her disease susceptibilities and drug sensitivities, allows treatments to be tailored to that individual; also called *precision medicine*.

**petal:**

A structure, often brightly colored and distinctively shaped, occurring in the next-to-outermost whorl of a flower; petals attract and orient animal pollinators.

**phagocyte:**

A type of immune cell that engulfs and destroys foreign cells or particles.

**phagocytosis:**

The engulfing of a cell or particle by another cell.

**pharyngeal slit:**

A vertical opening separated from other slits by stiff rods of protein in the pharynx of chordates.

**pharynx:**

In chordates, the region of the throat that connects the mouth and nasal cavities to the digestive system and, in vertebrates, to the lungs.

**phenol:**

Any one of a class of chemical compounds, produced by some plants as a defensive mechanism.

**phenotype:**

The expressed physical, behavioral, and biochemical traits of an individual, including height, weight, eye color, and so forth.

**pheromone:**

A water- or airborne chemical compound released by animals into the environment that signals and influences the behavior of other members of their species.

**phloem:**

The vascular tissue that transports carbohydrates from leaves to the rest of the plant body.

**phloem sap:**

The sugar-rich solution that flows through both the lumen of the sieve tubes and the sieve plate pores.

**phosphatase:**

An enzyme that removes a phosphate group from another molecule.

**phosphate group:**

A chemical group consisting of a phosphorus atom bonded to four oxygen atoms.

**phosphodiester bond:**

A bond that forms when a phosphate group in one nucleotide is covalently joined to the sugar unit in another nucleotide. Phosphodiester bonds are relatively stable and form the backbone of a DNA strand.

**phospholipid:**

A type of lipid and a major component of the cell membrane.

**photic zone:**

The surface layer of the ocean through which enough sunlight penetrates to enable photosynthesis.

**photoheterotroph:**

An organism that uses the energy from sunlight to make ATP and relies on organic molecules obtained from the environment as the source of carbon for growth and other vital functions.

**photoperiod:**

Day length.

**photoperiodism:**

The effect of the photoperiod, or day length, on physiological or developmental processes; in plants, the effect of day length on flowering.

**photoreceptor:**

A molecule whose chemical properties are altered when it absorbs light; also, photoreceptors are the sensory receptors in the eye.

**photorespiration:**

A process in which rubisco acts as an oxygenase, resulting in release of carbon dioxide and a net loss of energy.

**photosynthesis:**

The biochemical process in which carbohydrates are built from carbon dioxide and water using the energy of sunlight. In anoxygenic photosynthesis, electrons are donated by compounds other than water, especially H<sub>2</sub>S.

**photosynthetic electron transport chain:**

A series of redox reactions in which light energy absorbed by chlorophyll is used to power the movement of electrons; in oxygenic photosynthesis, the electrons ultimately come from water and the terminal electron acceptor is NADP<sup>+</sup>.

**photosystem:**

A protein–pigment complex that absorbs light energy to drive redox reactions and thereby sets the photosynthetic electron transport chain in motion.

**phototroph:**

An organism that captures energy from sunlight.

**phototropic:**

Bending in response to light. A positive phototropic response, as in stems, is toward light; a negative phototropic response, as in roots, is away from light.

**phragmoplast:**

In dividing plant cells, a structure formed by overlapping microtubules that guide vesicles containing cell wall components to the middle of the cell.

**phylogenetic niche conservatism:**

The observed similarity in closely related species of some aspect of their niches, indicating its presence in their common ancestor.

**phylogenetic species concept (PSC):**

The idea that members of a species all share a common ancestry and a common fate.

**phylogenetic tree:**

A tree-like diagram representing a hypothesis about the evolutionary relationships among populations or species.

**phylogeny:**

The history of descent with modification and the accumulation of change over time.

**phylum (plural, phyla):**

A group of closely related classes, defined by having a distinct body plan.

**phytochrome:**

A photoreceptor for red and far-red light that switches back and forth between two stable forms, active and inactive, depending on its exposure to light.

**pilus (plural, pili):**

A hollow, threadlike structure that connects bacteria, drawing two cells together so that plasmids can be transferred between them in the process of conjugation.

**pineal gland:**

A gland located in the thalamic region of the brain that responds to autonomic nervous system input by secreting melatonin, which controls wakefulness.

**pinna (plural, pinnae):**

Small unit of the photosynthetic surface on fern leaves; also, the external structure of mammalian ears that enhance the reception of sound waves contacting the ear.

**pith:**

In a stem, the region inside the ring of vascular bundles.

**pituitary gland:**

An endocrine gland located at the base of the vertebrate brain that produces a number of different hormones and controls many of the other organs of the endocrine system.

**placenta:**

In placental mammals, an organ formed by the fusion of the chorion and allantois that allows

the embryo to obtain nutrients directly from the mother.

**placental mammal:**

A mammal that provides nutrition to the embryo through the placenta, a temporary organ that develops in the uterus.

**placozoans:**

Possibly the simplest of all animals; each contains only a few thousand cells arranged into upper and lower epithelia that sandwich an interior fluid crisscrossed by a network of multinucleate fiber cells.

**plasma (effector) cell:**

An immune cell that secretes antibodies.

**plasma membrane:**

The membrane that surrounds the cytoplasm of the cell, separating the inside of the cell from the outside of the cell; also called the cell membrane.

**plasmid:**

In bacteria, a small circular molecule of DNA carrying a small number of genes that replicate independently of the DNA in the bacterium's circular chromosome.

**plasmodesmata (singular, plasmodesma):**

Connections between the plasma membranes of adjacent plant cells that permit molecules to pass directly from the cytoplasm of one cell to the cytoplasm of another.

**plasmogamy:**

The cytoplasmic union of two cells.

**pleiotropy:**

The phenomenon in which a single gene has multiple effects on seemingly unrelated traits.

**pluripotent:**

A cell that can give rise to any type of cell in an organism. In animals, it describes embryonic stem cells (cells of the inner mass), which can give rise to any of the three germ layers and therefore to any cell of the body.

**podocytes:**

Cells with footlike processes that make up one of the three layers of the filtration barrier of the vertebrate kidney glomerulus.

**point mutation:**

A mutation in which a base pair is replaced by a different base pair; this is the most frequent type of mutation; also known as a *nucleotide substitution*.

**Pol II:**

The RNA polymerase complex responsible for transcription of protein-coding genes.

**polar (molecule):**

A molecule that has regions of positive and negative charge.

**polar body:**

A small cell produced by the asymmetric first meiotic division of a primary oocyte.

**polar covalent bond:**

Bonds that do not share electrons equally.

**polar transport:**

The coordinated movement of auxin across many cells.

**polarity:**

An asymmetry such that one end of a structure differs from the other.

**polarized:**

Having opposite properties in opposite parts; describes a resting membrane potential in which there is a buildup of negatively charged ions on the inside surface of the cell's plasma membrane and positively charged ions on its outer surface.

**pollen:**

In seed plants, the multicellular male gametophyte surrounded by a sporopollenin-containing outer wall.

**pollen cone:**

A reproductive shoot in gymnosperms that produces pollen.

**pollination:**

The process in which pollen is carried to an ovule.

**poly(A) tail:**

The nucleotides added to the 3' end of the primary transcript by polyadenylation.

**polyadenylation:**

The addition of a long string of consecutive A-bearing ribonucleotides to the 3' end of the primary transcript.

**polycistronic mRNA:**

A single molecule of messenger RNA that is formed by the transcription of a group of functionally related genes located next to one another along bacterial DNA.

**polymer:**

A complex organic molecule made up of repeated simpler units connected by covalent bonds.

**polymerase chain reaction (PCR):**

A selective and highly sensitive method for making copies of a piece of DNA, which allows a targeted region of a DNA molecule to be replicated into as many copies as desired.

**polymorphism:**

Any genetic difference among individuals that is present in multiple individuals in a population.

**polypeptide:**

A polymer of amino acids connected by peptide bonds.

**polyphyletic:**

Describes groupings that do not include the last common ancestor of all members.

**polyploidy:**

The condition of having more than two complete sets of chromosomes in the genome.

**polysaccharide:**

A polymer of simple sugars. Polysaccharides provide long-term energy storage or structural support.

**polyspermy:**

In animals, fertilization by more than one sperm.

**pons:**

A part of the brainstem.

**population:**

All the individuals of a given species that live and reproduce in a particular place; one of several interbreeding groups of organisms of the same species living in the same geographical area.

**population density:**

The size of a population divided by its range.

**population size:**

The number of individuals of all ages alive at a particular time in a particular place.

**Porifera:**

Sponges; an animal phylum characterized by few cell types, no well-defined tissues, and no clearly defined plane of symmetry.

**positive feedback:**

In the nervous and endocrine systems, a type of feedback in which a stimulus causes a response that leads to an enhancement of the original stimulus that leads to a larger response in the same direction. The process reinforces itself until interrupted.

**positive regulation:**

The process in which a regulatory molecule must bind to the DNA at a site near the gene in order for transcription to take place.

**positive selection:**

Natural selection that increases the frequency of a favorable allele.

**positively selected:**

In immunology, describes B and T cells that recognize self MHC molecules on epithelium cells and continue to mature.

**posterior pituitary gland:**

An endocrine organ that forms the posterior lobe of the pituitary gland; it develops from neural tissue at the base of the brain and contains axons of neurosecretory cells from the hypothalamus that secrete releasing hormones.

**posttranslational modification:**

The modification, after translation, of proteins in ways that regulate their structure and function.

**post-zygotic isolation:**

Describes factors that cause the failure of the fertilized egg to develop into a fertile individual.

**potential energy:**

Stored energy that is released by a change in an object's structure or position.

**power stroke:**

The stage in the muscle cross-bridge cycle in which the myosin head pivots and generates a force, causing the myosin and actin filaments to slide relative to each other.

**precision medicine:**

An approach in which the treatment is matched to the patient, not the disease; examination of an individual's genome sequence, by revealing his or her disease susceptibilities and drug sensitivities, allows treatments to be tailored to that individual; also called *personalized medicine*.

**predation:**

An interaction between organisms in which one (the predator) consumes the other (the prey).

**pregnancy:**

The carrying of one or more embryos in the mammalian uterus.

**premolar:**

One of the teeth of mammals between the canines and molars that are specialized for shearing tough foods.

**pre-zygotic isolation:**

Describes factors that prevent the fertilization of an egg.

**primary active transport:**

Active transport that uses the energy of ATP directly.

**primary bronchi:**

The two divided airways from the vertebrate tetrapod trachea, supported by cartilage rings, each airway leading to a lung.

**primary consumers:**

Herbivores, which consume primary (plant, algae, or cyanobacterial) producers. Sometimes called grazers.

**primary growth:**

In plants, growth originating in the apical meristems of shoots and roots; resulting in the production of new leaves and an increase in length.

**primary motor cortex:**

The part of the frontal lobe of the vertebrate brain that produces complex coordinated behaviors by controlling skeletal muscle movements.

**primary oocyte:**

A diploid cell formed by mitotic division of oogonia during fetal development.

**primary producer:**

An organism that takes up inorganic carbon, nitrogen, phosphorus, and other compounds from the environment and converts them into organic compounds; a source of food for heterotrophic organisms in the local environment.

**primary response:**

The response to the first encounter with an antigen, during which there is a short lag before antibody is produced.

**primary somatosensory cortex:**

The part of the vertebrate parietal lobe that integrates tactile information from specific body regions and relays it to the motor cortex.

**primary spermatocyte:**

A diploid cell formed by mitotic division of spermatogonia at the beginning of spermatogenesis.

**primary structure:**

The sequence of amino acids in a protein.

**primary transcript:**

The initial RNA transcript that comes off the template DNA strand.

**primate:**

A member of the order of mammals that includes humans, distinguished by a number of molecular and morphological features, including relatively large brains, nails rather than claws, front-facing eyes, and, in some species, an opposable thumb.

**primer:**

A short stretch of RNA at the beginning of each new DNA strand that serves as a starter for DNA synthesis; an oligonucleotide that serves as a starter in the polymerase chain reaction.

**primordia (singular, primordium):**

An organ in its earliest stage of development; in plants, leaf primordia form near the tips of shoot apical meristems and develop into leaves.

**principle of independent assortment:**

The principle that segregation of one set of alleles of a gene pair is independent of the segregation of another set of alleles of a different gene pair.

**principle of segregation:**

The principle by which half the gametes receive one allele of a gene and half receive the other allele.

**probability:**

Among a very large number of observations, the expected proportion of observations that are of a specified type.

**probe:**

A labeled DNA fragment that can be tracked in a procedure such as a Southern blot.

**procambial cell:**

A plant cell that retains the capacity for cell division and gives rise to both xylem and phloem.

**product:**

Any one of the transformed molecules that result from a chemical reaction.

**progesterone:**

A hormone secreted by the vertebrate ovaries that maintains the thickened and vascularized uterine lining.

**prokaryote:**

An organism whose cell or cells do not have a membrane-bound nucleus; sometimes used to refer collectively to archaeons and bacteria.

**prometaphase:**

The stage of mitosis in which the nuclear envelope breaks down and the microtubules of the mitotic spindle attach to chromosomes.

**prometaphase I:**

The stage of meiosis I in which the nuclear envelope breaks down and the meiotic spindles attach to kinetochores on chromosomes.

**prometaphase II:**

The stage of meiosis II in which the meiotic spindles attach to kinetochores on chromosomes.

**promoter:**

A regulatory region where RNA polymerase and associated proteins bind to the DNA duplex.

**proofreading:**

The process in which DNA polymerases can immediately correct their own errors by excising and replacing a mismatched base.

**prophase:**

The stage of mitosis characterized by the appearance of visible chromosomes.

**prophase I:**

The beginning of meiosis I, marked by the visible manifestation of chromosome condensation.

**prophase II:**

The stage of meiosis II in which the chromosomes in the now-haploid nuclei recondense to their maximum extent.

**prostate gland:**

A vertebrate exocrine gland that produces a thin, slightly alkaline fluid that helps maintain sperm motility and counteracts the acidity of the female reproductive tract.

**protease inhibitor:**

A molecule that blocks the action of enzymes that break down proteins. Manufactured by some plants as a defense against herbivores.

**protein family:**

A group of proteins that are structurally and functionally related.

**protein sorting:**

The process by which proteins end up where they need to be in the cell to perform their function.

**proteins:**

The key structural and functional molecules that do the work of the cell, providing structural support and catalyzing chemical reactions. The term “protein” is often used as a synonym for “polypeptide.”

**proteobacteria:**

The most diverse bacterial group, defined largely by similarities in rRNA gene sequences; it includes many of the organisms that populate the expanded carbon cycle and other biogeochemical cycles.

**protist:**

An organism with cells having a nucleus but lacking other features specific to plants, animals, or fungi.

**proton:**

A positively charged particle in the atomic nucleus.

**protonephridia:**

Excretory organs in flatworms that isolate waste from the body cavity.

**proto-oncogene:**

The normal cellular gene counterpart to an oncogene, which is similar to a viral oncogene but can cause cancer only when mutated.

**protostome:**

A bilaterian in which the blastopore, the first opening to the internal cavity of the developing embryo, becomes the mouth. The taxonomic name is Protostomia, and the group includes mollusks and arthropods.

**Protostomia:**

Bilaterians in which the blastopore—the first opening into the embryo interior that is formed during gastrulation—usually develops into the organism's mouth.

**protozoan (plural, protozoa):**

A heterotrophic protist.

**proximal convoluted tubule:**

The first portion of the vertebrate renal tubule from which electrolytes and other nutrients are reabsorbed into the blood.

**pseudogene:**

A gene that is no longer functional.

**pulmonary artery:**

One of two arteries, left and right, that carries deoxygenated blood from the right ventricle of the vertebrate heart to the lungs.

**pulmonary capillary:**

A small blood vessel that supplies the alveolar wall of tetrapod lungs.

**pulmonary circulation:**

Circulation of the blood to the lungs of amphibians, reptiles, birds, and mammals.

**pulmonary valve:**

A valve between the common ventricle of the heart of amphibians and reptiles, or the left ventricle of mammals, and the pulmonary trunk.

**pulmonary vein:**

A vein that returns oxygenated blood from the lungs of amphibians, reptiles and mammals to the heart, or to the left atrium of reptiles and mammals.

**Punnett square:**

A worksheet in the form of a checkerboard used to predict the consequences of a random union of gametes.

**purine:**

In nucleic acids, either of the bases adenine and guanine, which have a double-ring structure.

**pyloric sphincter:**

A band of muscle at the base of the vertebrate stomach that opens to allow small amounts of digested food to enter the small intestine.

**pyrimidine:**

In nucleic acids, any of the bases thymine, cytosine, and uracil, which have a single-ring structure.

**quantitative trait:**

A complex trait that is influenced by many genes and the environment and that is measurable along a continuum, such as height and weight.

**quaternary structure:**

The structure that results from the interactions of several polypeptide chains.

**R gene:**

Any one of the group of genes that express the R proteins in plants.

**R group:**

A chemical group attached to the central carbon atom of an amino acid, whose structure and composition determine the identity of the amino acid; also known as a *side chain*.

**R protein:**

Any one of a group of receptors in plant cells, each expressed by a different gene, that function as part of the plant's immune system by each binding to a specific pathogen-derived protein.

**radiometric dating:**

Dating ancient materials using the decay of radioisotopes as a yardstick, including the decay of radioactive  $^{14}\text{C}$  to nitrogen for time intervals up to a few tens of thousands of years, and the decay of radioactive uranium to lead for most of Earth history.

**reabsorption:**

In renal systems, an active or passive process in which substances that are important for an animal to retain are taken up by cells of the excretory tubule and returned to the bloodstream.

**reactant:**

Any of the starting molecules in a chemical reaction.

**reaction center:**

Specially configured chlorophyll molecules where light energy is converted into electron transport.

**reactive oxygen species:**

Highly reactive forms of oxygen.

**reading frame:**

Following a start codon, a consecutive sequence of codons for amino acids.

**realized niche:**

The actual resources and habitats used by a species.

**receiver:**

The individual who, during communication, receives from the sender a signal designed to elicit a response.

**receptor:**

A molecule on cell membranes that detects critical features of the environment. Receptors detecting signals that easily cross the cell membrane are sometimes found in the cytoplasm.

**receptor activation:**

The “turning on” of a receptor, which often occurs when a signaling molecule binds to a receptor on a responding cell.

**receptor kinase:**

A receptor that is an enzyme that adds a phosphate group to another molecule.

**receptor protein:**

The molecule on the responding cell that binds to the signaling molecule.

**recessive:**

Describes an allele or trait that is only expressed in homozygotes, and not expressed in heterozygotes. Two recessive alleles are needed to express the phenotype.

**reciprocal altruism:**

The exchange of favors between individuals.

**reciprocal cross:**

A cross in which the female and male parents are interchanged.

**reciprocal inhibition:**

The activation of opposing sets of muscles so that one set is inhibited as the other is activated, allowing the movement of joints such as the knee.

**reciprocal translocation:**

Interchange of parts between nonhomologous chromosomes.

**recombinant:**

An offspring with a different combination of alleles from that of either parent, resulting from one or more crossovers in prophase I of meiosis.

**recombinant DNA:**

DNA molecules from two (or more) different sources combined into a single molecule.

**recovery metabolism:**

An animal's elevated consumption of oxygen following activity.

**rectum:**

The part of the hindgut where feces are stored until elimination.

**reduction:**

A reaction in which a molecule gains electrons.

**reductional division:**

An alternative name for meiosis I because this division reduces the number of chromosomes by half.

**refractory period:**

The period following an action potential during which the inner membrane voltage falls below and then returns to the resting potential.

**regeneration:**

In the context of the Calvin cycle, the reactions that produce the 5-carbon molecule needed for carboxylation.

**regenerative medicine:**

A discipline that aims to use the natural processes of cell growth and development to replace diseased or damaged tissues.

**regression toward the mean:**

With regard to complex traits, the principle that offspring exhibit an average phenotype that is intermediate between that of the parents and that of the population as a whole.

**regulatory transcription factor:**

A protein that recruits the components of the transcription complex to the gene.

**release factor:**

A protein that causes a finished polypeptide chain to be freed from the ribosome.

**renal tubules:**

Tubes in the vertebrate kidney that process the filtrate from the glomerulus by reabsorption and secretion.

**releasing hormone:**

A peptide hormone that binds to receptors on cells in the anterior pituitary gland, leading that organ to release a much larger amount of the associated hormones.

**renaturation:**

The base pairing of complementary single-stranded nucleic acids to form a duplex; also known as *hybridization*, it is the opposite of denaturation.

**repetitive DNA:**

The collective term for repeated sequences of various types in eukaryotic genomes.

**replication:**

The process of copying DNA so genetic information can be passed from cell to cell or from an organism to its progeny.

**replication bubble:**

A region formed by the opening of a DNA duplex at an origin of replication, which has a replication fork at each end.

**replication fork:**

The site where the parental DNA strands separate as the DNA duplex unwinds.

**repressor:**

A protein that, when bound with a sequence in DNA, can inhibit transcription.

**reservoir:**

A supply or source of a substance. Reservoirs of carbon, for example, include organisms, the atmosphere, soil, the oceans, and sedimentary rocks.

**residue:**

In the context of protein synthesis, any of the amino acids that is incorporated into a protein.

**resource partitioning:**

A pattern in which species whose niches overlap may diverge to minimize the overlap.

**responding cell:**

The cell that receives information from the signaling molecule.

**response:**

A change in cellular behavior, such as activation of enzymes or genes, following a signal.

**resting membrane potential:**

The negative voltage across a cell membrane at rest.

**restriction enzyme:**

Any one of a class of enzymes that recognizes specific, short nucleotide sequences in double-stranded DNA and cleaves DNA at or near these sites.

**restriction site:**

A recognition sequence in DNA cutting, which is typically four or six base pairs long; most restriction enzymes cleave double-stranded DNA at or near these restriction sites.

**reticulum:**

The second chamber in the stomach of ruminants, which, along with the rumen, harbors large populations of anaerobic bacteria that break down cellulose.

**retina:**

A thin tissue in the posterior of the vertebrate eye that contains the photoreceptors and other nerve cells that sense and initially process light stimuli.

**retinal:**

A derivative of vitamin A that absorbs light and binds to rhodopsin, a transmembrane protein in the photosensitive cells of vertebrates.

**retrotransposons:**

Transposable elements in DNA sequences in which RNA is used as a template to synthesize complementary strands of DNA, a reversal of the usual flow of genetic information from DNA into RNA.

**reverse transcriptase:**

An RNA-dependent DNA polymerase that uses a single-stranded RNA as a template to

synthesize a DNA strand that is complementary in sequence to the RNA.

**rhizosphere:**

The soil layer that surrounds actively growing roots.

**ribonucleic acid (RNA):**

A molecule chemically related to DNA that is synthesized by proteins from a DNA template.

**ribose:**

The sugar in RNA.

**ribosomal RNA (rRNA):**

Noncoding RNA found in all ribosomes that aid in translation.

**ribosome:**

A complex structure of RNA and protein, bound to the cytosolic face of the rough endoplasmic reticulum in the cytoplasm, on which proteins are synthesized.

**ribulose biphosphate carboxylase oxygenase (rubisco):**

The enzyme that catalyzes the carboxylation reaction in the Calvin cycle.

**ribulose 1,5-bisphosphate (RuBP):**

The 5-carbon sugar to which carbon dioxide is added by the enzyme rubisco.

**RISC (RNA-induced silencing complex):**

A protein complex that is targeted to specific mRNA molecules by base pairing with short regions on the target mRNA, inhibiting translation or degrading the RNA.

**ritualization:**

The process of co-opting and modifying behaviors used in another context by increasing the conspicuousness of the behavior, reducing the amount of variation in the behavior so that it can be immediately recognized, and increasing its separation from the original function.

**RNA editing:**

The process in which some RNA molecules become a substrate for enzymes that modify particular bases in the RNA, thereby changing its sequence and sometimes what it codes for.

**RNA polymerase:**

The enzyme that carries out polymerization of ribonucleoside triphosphates from a DNA template to produce an RNA transcript.

**RNA polymerase complex:**

An aggregate of proteins that synthesizes the RNA transcript complementary to the template strand of DNA.

**RNA primase:**

An RNA polymerase that synthesizes a short piece of RNA complementary to the DNA template and does not require a primer.

**RNA processing:**

Chemical modification that converts the primary transcript into finished mRNA, enabling the RNA molecule to be transported to the cytoplasm and recognized by the translational machinery.

**RNA splicing:**

The process of intron removal from the primary transcript.

**RNA transcript:**

The RNA sequence synthesized from a DNA template.

**RNA world hypothesis:**

The hypothesis that the earliest organisms relied on RNA for both catalysis and information storage.

**rod cell:**

A type of photoreceptor cell on the vertebrate retina that detects light and shades ranging from white to shades of gray and black, but not color.

**root apical meristem:**

A group of totipotent cells near the tip of a root that is the source of new root cells.

**root cap:**

A structure that covers and protects the root apical meristem as it grows through the soil.

**root hair:**

A slender outgrowth produced by epidermal cells that greatly increases the surface area of the root.

**root nodule:**

A structure, formed by dividing root cells, in which nitrogen-fixing bacteria live.

**rough endoplasmic reticulum (RER):**

The part of the endoplasmic reticulum with attached ribosomes.

**r-strategist:**

A species that produces large numbers of offspring but provides few resources for their support.

**rumen:**

The first chamber in the stomach of ruminants, which, along with the reticulum, harbors large populations of anaerobic bacteria that break down cellulose.

**S phase:**

The phase of interphase in which the entire DNA content of the nucleus is replicated.

**saccharide:**

The simplest carbohydrate molecule; also called a *sugar*.

**saltatory propagation:**

The movement of an action potential along a vertebrate myelinated axon, “jumping” from node to node.

**Sanger sequencing:**

A procedure in which chemical termination of daughter strands help in determining the DNA sequence.

**sapwood:**

In long-lived trees, the layer adjacent to the vascular cambium that contains the functional xylem.

**sarcomere:**

The region of myofilaments located within muscle myofibrils that span from one Z disc to the next; the basic contractile unit of a muscle.

**sarcoplasmic reticulum (SR):**

A modified form of the endoplasmic reticulum surrounding the myofibrils of muscle cells.

**saturated:**

Describes fatty acids that do not contain double bonds; the maximum number of hydrogen atoms is attached to each carbon atom, “saturating” the carbons with hydrogen atoms.

**scaffold:**

A supporting protein structure in a metaphase chromosome.

**scientific inquiry:**

A deliberate, systematic, careful, and unbiased way of learning about the natural world.

**scrotum:**

A sac outside the abdominal cavity of the male that holds the testes.

**second-division nondisjunction:**

Disjunction in the second meiotic division.

**second law of thermodynamics:**

The principle that the transformation of energy is associated with an increase in the degree of disorder in the universe.

**second messenger:**

An intermediate cytosolic signaling molecule that transmits signals from a receptor to a target within the cell. (First messengers transmit signals from outside the cell to a receptor.)

**secondary active transport:**

Active transport that uses the energy of an electrochemical gradient to drive the movement of molecules.

**secondary consumers:**

Predators or scavengers that feed on primary consumers.

**secondary growth:**

In plants, growth originating in lateral meristems; resulting in larger diameter stems and roots.

**secondary oocyte:**

A large cell produced by the asymmetric first meiotic division of the primary oocyte.

**secondary phloem:**

New phloem cells produced by the vascular cambium, which are located to the outside of the vascular cambium.

**secondary response:**

The response to re-exposure to an antigen, which is quicker, stronger, and longer than the primary response.

**secondary sexual characteristic:**

A trait that characterizes and differentiates the two sexes but that does not relate directly to reproduction.

**secondary spermatocyte:**

A diploid cell formed during the first meiotic division of the primary spermatocyte.

**secondary structure:**

The structure formed by interactions between stretches of amino acids in a protein.

**secondary xylem:**

New xylem cells produced by vascular cambium, which are located to the inside of the vascular cambium.

**secretin:**

A hormone released by cells lining the duodenum in response to the acidic pH of the stomach contents entering the small intestine and that stimulates the pancreas to secrete bicarbonate ions.

**secretion:**

In renal systems, an active process that eliminates substances that were not previously filtered from the blood.

**seed:**

A mature fertilized ovule consisting of a seed coat, a nutritive tissue, and the embryo; seeds are multicellular structures that allow offspring to disperse away from the parent plant.

**seed coat:**

A protective outer structure surrounding the seed.

**segmentation:**

The formation of discrete repeating parts or segments in the developing body of many animals.

**segregate:**

Separate; applies to chromosomes or members of a gene pair moving into different gametes.

**selection:**

The retention or elimination of mutations in a population of organisms.

**selectively permeable:**

Describes the properties of some membranes, including the plasma membrane, which lets some molecules in and out freely, lets others in and out only under certain conditions, and prevents other molecules from passing through at all.

**self:**

Describes an organism's own molecules and cells.

**self-compatible:**

Describes species in which pollen and ovules produced by flowers on the same plant can produce viable offspring.

**self-incompatible:**

Describes species in which pollination by the same or a closely related individual does not lead to fertilization.

**self-propagating:**

Continuing without input from an outside source; action potentials are self-propagating in that they move along axons by sequentially opening and closing adjacent ion channels.

**semen:**

A fluid that nourishes and sustains sperm as they travel in the male and then the female reproductive tracts.

**semicircular canal:**

One of three connected fluid-filled tubes in the mammalian inner ear that contains hair cells that sense angular motions of the head in three perpendicular planes.

**semiconservative replication:**

The mechanism of DNA replication in which each strand of a parental DNA duplex serves as a template for the synthesis of a new daughter strand.

**seminal vesicles:**

Two glands at the junction of the vas deferens and the prostate gland that secrete a protein- and sugar-rich fluid that makes up most of the semen and provides energy for sperm motility.

**seminiferous tubules:**

A series of tubes in the testes where sperm are produced.

**sender:**

The individual who, during communication, supplies a signal designed to elicit a response from the receiver.

**sensitization:**

The enhancement of a response to a stimulus that is achieved by first presenting a strong or novel stimulus.

**sensory neuron:**

A neuron that receives and transmits information about an animal's environment or its internal physiological state.

**sensory organ:**

A group of sensory receptors that converts particular physical and chemical stimuli into nerve impulses that are processed by a nervous system and sent to a brain.

**sensory receptor cell:**

A sensory neuron with specialized membranes in which receptor proteins are embedded.

**sensory transduction:**

The conversion of physical or chemical stimuli into nerve impulses.

**sepal:**

A structure, often green, that forms the outermost whorl of a flower and, with other sepals, encases and protects the flower during its development.

**septum (plural, septa):**

In fungal hyphae, a wall that partially divides the cytoplasm into separate cells.

**sequence assembly:**

The process in which short nucleotide sequences of a long DNA molecule are arranged in the correct order to generate the complete sequence.

**sequence motif:**

Any of a number of sequences or sequence arrangements that indicate the likely function of a segment of DNA.

**serosa:**

An outer layer of cells and connective tissue that covers and protects the gut.

**Sertoli cell:**

A type of cell in the seminiferous tubules of vertebrate testes that supports sperm production.

**set point:**

A steady-state value in homeostatic regulation.

**sex chromosome:**

Any of the chromosomes associated with sex determination.

**sexual reproduction:**

The process of producing offspring that receive genetic material from two parents; in eukaryotes, the process occurs through meiosis and fertilization.

**sexual selection:**

A form of selection that promotes traits that increase an individual's access to reproductive opportunities.

**shell (of an atom):**

One or more orbital zones within an atom where electrons occur. Different shells have distinct energy levels.

**shoot:**

The collective name for the leaves, stems, and reproductive organs; the major aboveground organ systems of vascular plants.

**shoot apical meristem:**

A group of totipotent cells at the tip of a stem or branch that gives rise to new shoot tissues in plants.

**short-day plant:**

A plant that flowers only when the day length is less than a critical value.

**shotgun sequencing:**

DNA sequencing method in which the sequenced fragments do not originate from a particular gene or region, but from sites scattered randomly across the molecule.

**side chain:**

A chemical group attached to the central carbon atom of an amino acid, whose structure and composition determine the identity of the amino acid; also known as an *R group*.

**sieve plate:**

In angiosperm phloem, a modified end wall with large pores that links sieve elements.

**sieve tube:**

A multicellular unit composed of sieve elements that are connected end to end, through which phloem transport takes place.

**sigma factor:**

A protein that associates with RNA polymerase that facilitates its binding to specific promoters.

**signal sequence:**

An amino acid sequence that directs a protein to its proper cellular compartment.

**signal transduction:**

The process in which an extracellular molecule acts as a signal to activate a receptor, which

transmits information through the cytoplasm.

**signal-anchor sequence:**

In protein sorting, an amino acid sequence in a polypeptide chain that embeds the chain in the membrane.

**signaling cell:**

The source of a signaling molecule.

**signaling molecule:**

The carrier of information transmitted when the signaling molecule binds to a receptor; also referred to as a *ligand*.

**signal-recognition particle (SRP):**

An RNA–protein complex that binds with part of a polypeptide chain and marks the molecule for incorporation into the endoplasmic reticulum (eukaryotes) or the plasma membrane (prokaryotes).

**silencers:**

DNA sequences that bind with regulatory transcription factors and repress transcription.

**single-gene trait:**

A trait determined by Mendelian alleles of a single gene with little influence from the environment.

**single-lens eye:**

An eye structure found in vertebrates and cephalopod mollusks that works like a camera to produce a sharply defined image of the animal's visual field.

**single-nucleotide polymorphism (SNP):**

A site in the genome where the base pair that is present differs among individuals in a population.

**single-strand binding protein:**

A protein that binds single-stranded nucleic acids.

**sink:**

In plants, any portion of the plant that imports carbohydrates to fuel growth and respiration, such as a root, young leaf, or developing fruit.

**sinoatrial (SA) node:**

A specialized region of the vertebrate heart containing pacemaker cells where the heartbeat is

initiated.

**sister chromatids:**

The two copies of a chromosome produced by DNA replication.

**sister groups:**

Groups that are more closely related to each other than either of them is to any other group.

**skeletal muscle:**

Striated muscle that connects to the body skeleton to move an animal's limbs and torso.

**sliding filament model:**

The hypothesis that striated muscles produce force and change length by the sliding of actin filaments relative to myosin filaments.

**slow-twitch:**

Describes muscle fibers that contract slowly, resist fatigue, and consume less ATP than do fast-twitch fibers to produce force.

**small interfering RNA (siRNA):**

A type of small double-stranded regulatory RNA that becomes part of a complex able to cleave and destroy single-stranded RNA with a complementary sequence.

**small intestine:**

Part of the midgut; the site of the last part of digestion and most nutrient absorption.

**small nuclear RNA (snRNA):**

Noncoding RNA found in eukaryotes and involved in splicing, polyadenylation, and other processes in the nucleus.

**small regulatory RNA:**

A short RNA molecule that can block transcription, cleave or destabilize RNA, or inhibit mRNA translation.

**smooth endoplasmic reticulum (SER):**

The portion of the endoplasmic reticulum that lacks ribosomes.

**smooth muscle:**

The muscle in the walls of arteries, the respiratory system, and the digestive and excretory systems; smooth muscle appears uniform under the light microscope.

**solubility:**

The ability of a substance to dissolve.

**solute:**

A dissolved molecule such as the electrolytes, amino acids, and sugars often found in a solvent such as water.

**solvent:**

A liquid capable of dissolving a substance.

**somatic cell:**

A nonreproductive cell, the most common type of cell in the body of a multicellular organism.

**somatic mutation:**

A mutation that occurs in somatic cells.

**somatic nervous system:**

The voluntary component of the peripheral nervous system, which is made up of sensory neurons that respond to external stimuli and motor neurons that synapse with voluntary muscles.

**source:**

In plants, a region that supplies carbohydrates to other parts of the plant.

**Southern blot:**

A method for determining the size and number of copies of a DNA sequence of interest by means of a labeled probe hybridized to DNA fragments separated by size by means of gel electrophoresis.

**spatial summation:**

The converging of multiple receptors onto a neighboring neuron, increasing its firing rate proportionally to the number of signals received.

**speciation:**

The process whereby new species are produced.

**species:**

A group of individuals that can exchange genetic material through interbreeding to produce fertile offspring.

**species–area relationship:**

A mathematical relationship between the number of species and the size of an island.

**spermatogenesis:**

The formation of sperm.

**spermatozoa (sperm):**

The smaller, male gametes.

**spinal cord:**

In vertebrates, a central tract of neurons that passes through the vertebrae to transmit information between the brain and the periphery of the body.

**spinal nerve:**

In vertebrates, a nerve running from the spinal cord to the periphery containing axons of both sensory and motor neurons.

**spiracle:**

An opening in the exoskeleton on either side of an insect's abdomen through which gases are exchanged.

**spliceosome:**

A complex of RNA and protein that catalyzes RNA splicing.

**sponges:**

Porifera; a phylum characterized by few cell types, no complex tissues or organs, and an irregular form, with no clearly defined plane of symmetry.

**spongy bone:**

Vertebrate bone tissue consisting of trabeculae, and thus lighter than compact bone, found in the ends of limb bones and within vertebrae.

**spontaneous:**

Occurring in the absence of any assignable cause; most mutations are spontaneous.

**sporangium:**

In plants, a multicellular structure in which haploid spores are formed by meiosis.

**spore:**

A reproductive cell capable of growing into a new individual without fusion with another cell.

**sporophyte:**

Describes the diploid multicellular generation in plants that produces spores.

**sporopollenin:**

A complex mixture of polymers that is remarkably resistant to environmental stresses such as ultraviolet radiation and desiccation. In plants, found in the walls of pollen and spores.

**stabilizing selection:**

A form of selection that selects against extremes and therefore maintains the status quo.

**stamen:**

A pollen-producing floral organ.

**stapes:**

A small bone in the vertebrate middle ear that helps amplify the waves that strike the tympanic membrane; the stapes connects to the oval window of the cochlea.

**starch:**

The storage form of carbohydrates in plants.

**Starling's Law:**

The correspondence between change in stroke volume and change in the volume of blood filling the vertebrate heart.

**statocyst:**

A type of gravity-sensing organ found in most invertebrates.

**statolith:**

In plants, a large starch-filled organelle in the root cap that senses gravity; in animals, a dense particle that moves freely within a statocyst, enabling it to sense gravity.

**stem cell:**

An undifferentiated cell that can undergo an unlimited number of mitotic divisions and differentiate into any of a large number of specialized cell types.

**stereocilia:**

Nonmotile cell-surface projections on hair cells whose movement causes a depolarization of the cell's membrane.

**steroid:**

A type of lipid.

**steroid hormone:**

A hormone that is derived from cholesterol.

**stigma:**

The surface at the top of the carpel, to which pollen adheres.

**stomach:**

The last part of the foregut, which serves as a storage and digestive chamber.

**stomata (singular, stoma):**

Pores in the epidermis of a leaf that regulate the diffusion of gases between the interior of the leaf and the atmosphere.

**Stramenopila:**

A eukaryotic superkingdom including unicellular organisms, giant kelps, algae, protozoa, free-living cells, and parasites; distinguished by a flagellum with two rows of stiff hairs and, usually, a second, smooth flagellum.

**striated muscle:**

Skeletal muscle and cardiac muscle, which appear striped under a light microscope due to regular thick (myosin) and thin (actin) myofilament spacing.

**strigolactone:**

A hormone, produced in roots and transported upward in the xylem, that inhibits the outgrowth of axillary buds.

**stroke volume (SV):**

The volume of blood pumped during each heartbeat.

**stroma:**

The region of the chloroplast that surrounds the thylakoid, where the Calvin cycle takes place.

**stromatolite:**

A layered structure that records sediment accumulation by microbial communities.

**structural gene:**

A gene that codes for the sequence of amino acids in a polypeptide chain.

**style:**

A cylindrical stalk between the ovary and the stigma, through which the pollen tube grows.

**suberin:**

In plants, a waxy compound found in the walls of cork cells that protects against mechanical damage, the entry of pathogens, and water loss.

**submucosa:**

A tissue layer surrounding the mucosa that contains blood vessels, lymph vessels, and nerves.

**subspecies:**

Allopatric populations that have yet to evolve even partial reproductive isolation but which have acquired population-specific traits.

**substrate (S):**

A molecule acted upon by an enzyme.

**substrate-level phosphorylation:**

A way of generating ATP in which a phosphate group is transferred to ADP from an organic molecule, which acts as a phosphate donor or substrate.

**succession:**

In ecology, the process of species replacing one another in time in a predictable sequence; each species modifies the habitat by affecting the environment or changing the community structure, creating opportunities for other species.

**sugar:**

The simplest carbohydrate molecule; also called a *saccharide*.

**sulci (singular, sulcus):**

Deep crevices in the brain that separate the lobes of the cerebral hemispheres.

**supercoil:**

A coil of coils; a circular molecule of DNA can coil upon itself to form a supercoil.

**superkingdom:**

One of seven major groups of eukaryotic organisms, classified by molecular sequence comparisons.

**supernormal stimulus:**

An exaggerated stimulus that elicits a response more strongly than the normal stimulus.

**surfactant:**

A compound that reduces the surface tension of a fluid film.

**suspension filter feeding:**

The most common form of food capture by animals, in which water with food suspended in it passes through a sievelike structure.

**sustainable development:**

Use of natural resources at rates no higher than the rate at which they can be replenished.

**symbiont:**

An organism that lives in closely evolved association with another species.

**symbiosis (plural, symbioses):**

A close interaction that has evolved between species that live together, often interdependently.

**sympathetic division:**

The division of the vertebrate autonomic nervous system that generally produces arousal and increased activity; active in the fight-or-flight response.

**sympatric:**

Describes populations that are in the same geographic location.

**synapomorphy:**

A shared derived character; the basis of cladistic phylogenetic reconstruction.

**synapse:**

A junction through which the axon terminal of a nerve cell communicates with a neighboring cell.

**synapsis:**

The gene-for-gene pairing of homologous chromosomes in prophase I of meiosis.

**synaptic cleft:**

The space between the axon of the presynaptic nerve cell and the neighboring postsynaptic cell.

**synonymous (silent) mutation:**

A mutation resulting in a codon that does not alter the corresponding amino acid in the polypeptide.

**systemic acquired resistance (SAR):**

The ability of a plant to resist future infections, occurring in response to a wide range of pathogens.

**systemic circulation:**

Circulation of the blood to the body, excluding the lungs.

**systole:**

The phase of the vertebrate cardiac cycle when the ventricles contract to eject blood from the heart.

**T cell receptor (TCR):**

A protein receptor on a T cell that recognizes and binds to an antigen.

**T lymphocyte (T cell):**

A cell of the immune system that matures in the thymus and includes helper and cytotoxic cells.

**tandem repeat:**

A region along a DNA molecule in which many duplicated copies of a short sequence of nucleotides are adjacent to one another.

**tannin:**

Any one of a group of phenols found widely in plant tissues that bind with proteins and reduce their digestibility.

**taste bud:**

One of the sensory organs for taste.

**TATA box:**

A DNA sequence present in many promoters in eukaryotes and archaeons that serves as a protein-binding site for a key general transcription factor.

**taxis (plural, taxes):**

Movement in a specific direction in response to a stimulus.

**taxon (plural, taxa):**

A named taxonomic group at any rank, such as a species, a genus, or a family.

**telomerase:**

An enzyme containing an RNA template from which complementary telomere repeats are synthesized.

**telomere:**

A repeating sequence at each end of a eukaryotic chromosome.

**telophase:**

The stage of mitosis in which the nuclei of the daughter cells are formed and the chromosomes uncoil to their original state.

**telophase I:**

The stage of meiosis I in which the chromosomes uncoil slightly, a nuclear envelope briefly reappears, and in many species the cytoplasm divides, producing two separate cells.

**telophase II:**

The stage of meiosis II in which the chromosomes uncoil and become diffuse, a nuclear envelope forms around each set of chromosomes, and the cytoplasm divides by cytokinesis.

**template strand:**

In DNA replication, the parental strand whose sequence is used to synthesize a complementary daughter strand.

**temporal isolation:**

Pre-zygotic isolation between individuals that are reproductively active at different times.

**temporal lobe:**

The region of the brain involved in the processing of sound, language and reading, and object identification and naming.

**temporal summation:**

The summation of postsynaptic potentials over time, which determines whether the postsynaptic cell fires an action potential.

**temporomandibular joint:**

A specialized jaw joint in mammals that allows the teeth of the lower and upper jaws to fit together precisely.

**tendon:**

A collagen structure that attaches vertebrate muscles to the skeleton and transmits muscle forces over a wide range of joint motion.

**termination:**

In protein translation, the time at which the addition of amino acids stops and the completed polypeptide chain is released from the ribosome. In cell communication, the stopping of a signal.

**terminator:**

A DNA sequence at which transcription stops and the transcript is released.

**terpene:**

Any one of a group of compounds that do not contain nitrogen and are produced by some plants as a defensive mechanism.

**tertiary structure:**

The overall three-dimensional shape of a protein, formed by interactions between secondary structures.

**test (of a protist):**

A “house” constructed of organic molecules with or without precipitated minerals or adhering sediment grains that shelters a protist.

**test group:**

The experimental group that is exposed to the variable in an experiment.

**testcross:**

Any cross of an unknown genotype with a homozygous recessive genotype.

**testis (plural, testes):**

The male gonad, where sperm are produced.

**testosterone:**

A steroid hormone, secreted by the vertebrate testes, that plays key roles in male growth, development, and reproduction.

**tetanus:**

A muscle contraction of sustained force resulting from multiple action potentials.

**Tetrapoda:**

A monophyletic group of animals whose last common ancestor had four limbs; this group includes amphibians, lizards, turtles, crocodilians, birds, and mammals; some tetrapods, like snakes, have lost their legs in the course of evolution.

**tetrapods:**

Four-legged vertebrate animals.

**thalamus:**

The inner brain region of the forebrain, which acts as a relay station for sensory information sent to the cerebrum.

**thallus:**

A flattened, often photosynthetic structure lacking differentiated vegetative organs; produced by the body of the gametophyte generation in hornworts and some liverworts.

**theory:**

A general explanation of a natural phenomenon supported by a large body of experiments and

observations.

**theory of island biogeography:**

A theory that states that the number of species that can occupy a habitat island depends on two factors: the size of the island and the distance of the island from a source of colonists.

**thick filament:**

A parallel grouping of myosin molecules that form the myosin filament within muscle sarcomeres.

**thin filament:**

Two helically arranged actin polymers twisted together that form the actin filament within muscle sarcomeres.

**threshold potential:**

The critical depolarization voltage of  $-55$  mV required for an action potential.

**thylakoid membrane:**

A highly folded membrane in the center of the chloroplast that contains light-collecting pigments and that is the site of the photosynthetic electron transport chain.

**thymine (T):**

A pyrimidine base.

**thyroid gland:**

A gland located in the front of the vertebrate neck that leads to the release of two peptide hormones, thyroxine and triiodothyronine.

**Ti plasmid:**

A small circular DNA molecule in virulent strains of *R. radiobacter* containing genes that can be integrated into the host cell's genome, as well as the genes needed to make this transfer.

**tidal ventilation:**

A breathing technique in most land vertebrates in which air is drawn into the lungs during inhalation and moved out during exhalation.

**tidal volume:**

The amount of air inhaled and exhaled in a cycle; in humans, tidal volume is 0.5 liter when breathing at rest.

**tight junction:**

A junctional complex that establishes a seal between animal cells so that the only way a

substance can travel from one side of a sheet of epithelial cells to the other is by moving through the cells by a cellular transport mechanism.

**tissue:**

A collection of cells that work together to perform a specific function.

**tolerance:**

In immunology, the ability of B and T cells not to respond to self antigens even though the immune system functions normally otherwise.

**toll-like receptors (TLRs):**

A family of transmembrane receptors on phagocytes that recognize and bind to molecules on the surface of microorganisms, providing an early signal that an infection is present.

**topography:**

The physical features of Earth.

**topoisomerase II:**

An enzyme that breaks a DNA double helix, rotates the ends, and seals the break.

**totipotent:**

Describes cells that have the potential to give rise to a complete organism; a fertilized egg is a totipotent cell.

**trabeculae:**

Small plates and rods with spaces between them, found in spongy bone.

**trace fossil:**

A track or trail, such as a dinosaur track or the feeding trails of snails and trilobites, left by an animal as it moves about or burrows into sediments.

**trachea:**

The central airway leading to the lungs of air-breathing animals, supported by cartilage rings.

**tracheae:**

An internal system of tubes in insects that branch from openings along the abdominal surface into smaller airways, directing oxygen to and removing carbon dioxide from respiring tissues.

**tracheid:**

A unicellular xylem conduit.

**trade-off:**

An exchange in which something is gained at the expense of something lost.

**trait:**

A characteristic of an individual.

**transcription:**

The synthesis of RNA from a DNA template.

**transcriptional activator protein:**

A protein that binds to a sequence in DNA to enable transcription to begin.

**transcriptional regulation:**

The mechanisms that collectively regulate whether transcription occurs.

**transduction:**

Horizontal gene transfer by means of viruses.

**transfer RNA (tRNA):**

Noncoding RNA that carries individual amino acids for use in translation.

**transformation:**

The conversion of cells from one state to another, as from nonvirulent to virulent, when DNA released to the environment by cell breakdown is taken up by recipient cells. In recombinant DNA technology, the introduction of recombinant DNA into a recipient cell.

**transgenic organisms:**

An alternative term for genetically modified organisms.

**transition state:**

The brief time in a chemical reaction in which chemical bonds in the reactants are broken and new bonds in the product are formed.

**translation:**

Synthesis of a polypeptide chain corresponding to the coding sequence present in a molecule of messenger RNA.

**transmembrane proteins:**

Proteins that span the entire lipid bilayer; most integral membrane proteins are transmembrane proteins.

**transmission genetics:**

The discipline that deals with the manner in which genetic material is passed from generation

to generation.

**transpiration:**

The loss of water vapor from leaves.

**transporters:**

Membrane proteins that move ions or other molecules across the cell membrane.

**transposable element (TE):**

A DNA sequence that can replicate and move from one location to another in a DNA molecule; also known as a *transposon*.

**transposon:**

A DNA sequence that can replicate and move from one location to another in a DNA molecule; also known as a *transposable element (TE)*.

**triacylglycerol:**

A lipid composed of a glycerol backbone and three fatty acids.

**trimesters:**

The three periods of pregnancy, each lasting about 3 months.

**triose phosphate:**

A 3-carbon carbohydrate molecule, produced by the Calvin cycle and exported from the chloroplast.

**triploblastic:**

Describes animals in which the embryo has three germ layers, with the mesoderm between the endoderm and ectoderm.

**trisomy 21:**

A condition resulting from the presence of three, rather than two, copies of chromosome 21; also known as *Down syndrome*.

**trophic level:**

An organism's typical place in a food web as a producer or consumer.

**trophic pyramid:**

A diagram that traces the flow of energy through communities, showing the amount of energy available at each level to feed the next. The pyramid shape results because biomass and the energy it represents generally decrease from one trophic level to the next.

**tropic hormone:**

A hormone that controls the release of other hormones.

**tropism:**

The bending or turning of an organism in response to an external signal such as light or gravity.

**tropomyosin:**

A protein that runs in the grooves formed by the actin helices and blocks the myosin-binding sites on the actin filament.

**troponin:**

A protein that moves tropomyosin away from myosin-binding sites, allowing cross-bridges between actin and myosin to form and the muscle to contract.

**true breeding:**

Describes a trait whose physical appearance in each successive generation is identical to that in the previous one.

**trypsin:**

A digestive enzyme produced by the vertebrate pancreas that breaks down proteins.

**tube feet:**

In echinoderms, small projections of the water vascular system that extend outward from the body surface and facilitate locomotion, sensory perception, food capture, and gas exchange.

**tubulin:**

Dimers (composed of an  $\alpha$  tubulin and a  $\beta$  tubulin) that assemble into microfilaments.

**tumor suppressor:**

One of a family of genes that encode proteins whose normal activities inhibit cell division.

**tunicates:**

A subphylum of Chordata that includes about 3000 species of filter-feeding marine animals, such as sea squirts and salps.

**turgor pressure:**

Pressure within a cell resulting from the movement of water into the cell by osmosis and the tendency of the cell wall to resist deformation.

**Turner syndrome:**

A sex-chromosomal abnormality in which an individual has 45 chromosomes, including only

one X chromosome.

**twitch:**

A muscle contraction that results from a single action potential.

**twofold cost of sex:**

The observation that population size can increase more rapidly in asexually reproducing organisms than in sexually reproducing organisms because only females produce offspring in sexually reproducing organisms.

**unsaturated:**

Describes fatty acids that contain carbon–carbon double bonds.

**uracil (U):**

A pyrimidine base in RNA, where it replaces the thymine found in DNA.

**ureter:**

A large tube in the vertebrate kidney that brings urine from the kidneys to the bladder.

**urethra:**

A tube from the mammalian urinary bladder that in males carries semen as well as urine from the body.

**uterus:**

A hollow organ within the reproductive tract of female mammals with thick, muscular walls that is adapted to support the developing embryo if fertilization occurs and to deliver the baby during birth.

**vacuole:**

A membrane-bound organelle present in some cells, including plant and fungal cells, that contains fluid, ions, and other molecules; in some cases, it absorbs water and contributes to turgor pressure.

**vagina:**

A tubular channel connecting the mammalian uterus to the exterior of the body; also known as the birth canal.

**valence electrons:**

The electrons farthest from the nucleus, which are at the highest energy level.

**van der Waals interactions:**

The binding of temporarily polarized molecules because of the attraction of opposite charges.

**variable (in experimentation):**

The feature of an experiment that is changed by the experimenter from one treatment to the next.

**variable expressivity:**

The phenomenon in which a particular phenotype is expressed with a different degree of severity in different individuals.

**variable (V) region:**

A region of the heavy (H) and light (L) chains of an antibody; the variable region distinguishes a given antibody from all others.

**vas deferens:**

A long, muscular tube that carries sperm from the testes to the ejaculatory duct of amniote vertebrates.

**vasa recta:**

The blood vessels in the vertebrate kidneys.

**vascular cambium (plural, cambia):**

Lateral meristem that is the source of new xylem and phloem.

**vascular tissues:**

A plant tissue that extends from leaves to roots and allows water and nutrients to move by bulk flow.

**vasoconstriction:**

The narrowing of a vessel by the contraction of smooth muscle, which in turn increases resistance and decreases blood flow.

**vasodilation:**

The widening of a vessel by the relaxation of smooth muscle, which in turn decreases resistance and increases blood flow.

**vasopressin:**

In vertebrates, a posterior pituitary gland hormone that acts on the kidneys and controls the water permeability of the collecting ducts, thus regulating the concentration of urine that an animal excretes; also known as *antidiuretic hormone (ADH)*.

**vector:**

In recombinant DNA, a carrier of the donor fragment, usually a plasmid.

**vegetative reproduction:**

Asexual reproduction by growth and fragmentation.

**veins:**

In plants, the system of vascular conduits within the leaf; in animals, the large, low-pressure vessels that return blood to the heart.

**vena cava (plural, venae cavae):**

One of two large veins in the vertebrate body that drain blood from the head and body into the heart.

**ventilation:**

The movement of an animal's respiratory medium—water or air—past a specialized respiratory surface.

**ventricle:**

In vertebrates and some invertebrates, a heart chamber that pumps blood to the lungs or the rest of the body.

**venule:**

A blood vessel into which capillaries drain as blood is returned to the heart.

**vernalization:**

A prolonged period of exposure to cold temperatures necessary to induce flowering in some plants.

**vertebrae (singular, vertebra):**

The series of hard bony segments making up the jointed skeleton that runs along the main axis of the body in vertebrates.

**vertebral column:**

A skeletal structure in vertebrates that functionally replaces the embryonic notochord that supports the body.

**vertebrates:**

A subphylum of Chordata, distinguished by a bony cranium that protects the brain and (unless lost through evolution), a vertebral column; also known as *craniates*.

**vesicle:**

A small membrane-enclosed sac that transports substances within the cell.

**vessel:**

A multicellular xylem conduit.

**vessel element:**

An individual cell that is part of a xylem vessel for water transport in plants.

**vestibular system:**

A system in the vertebrate inner ear made up of two statocyst chambers and three semicircular canals.

**vestigial structure:**

A structure that has lost its original function over time and is now much reduced in size.

**vicariance:**

The process in which a geographic barrier arises within a single population, separating it into two or more isolated populations that are isolated from each other.

**villi:**

Highly folded inner surfaces of the jejunum and ileum of the small intestine.

**virulent:**

Describes pathogens that are able to overcome a host's defenses and lead to disease.

**virus:**

A small infectious agent that contains a nucleic acid genome packaged inside a protein coat called a capsid.

**visible light:**

The portion of the electromagnetic spectrum apparent to our eyes.

**vitamin:**

An organic molecule that is required in very small amounts in the diet.

**viviparity:**

Giving birth to live young, with nutritional support of the embryo from the mother.

**vocal cords:**

Twin organs in the vertebrate (amniote) larynx that vibrate as air passes over them, enabling sound production.

**voltage-gated channels:**

Ion membrane channels that open and close in response to changes in membrane potential.

**voluntary component:**

The part of the peripheral nervous system that controls conscious reactions.

**vulva:**

The external genitalia of the female.

**water potential:**

A parameter that combines all of the factors that influence the movement of water, such as pressure, osmosis, and gravity.

**water vascular system:**

A series of fluid-filled canals that permit bulk transport of oxygen and nutrients in echinoderms.

**white blood cell (leukocyte):**

A type of cell in the immune system that arises by differentiation from stem cells in the bone marrow.

**white matter:**

Collectively, the axons of cortical neurons in the interior of the vertebrate brain and spinal cord; it is the fatty myelin produced by glial cells surrounding the axons that makes these regions white.

**wild type:**

The most common allele, genotype, or phenotype present in a population; nonmutant.

**X chromosome:**

One of the sex chromosomes; a normal human female has two copies of the X chromosome; a normal male has one X chromosome and one Y chromosome.

**xanthophyll:**

Any one of several yellow-orange pigments that slow the formation of reactive oxygen species by reducing excess light energy; these pigments accept absorbed light energy directly from chlorophyll and convert this energy to heat.

**X-inactivation:**

The process in female mammals in which dosage compensation occurs through the inactivation of one X chromosome in each cell.

**X-linked genes:**

A gene in the X chromosome.

**xylem:**

Vascular tissue consisting of lignified conduits that transports water and nutrients from the roots to the leaves.

**Y chromosome:**

One of the sex chromosomes; a normal human male has one X chromosome and one Y chromosome.

**yeast:**

A single-celled fungus found in moist, nutrient-rich environments. Many yeasts can metabolize sugar by means of fermentation.

**Y-linked gene:**

A gene that is present in the region of the Y chromosome that shares no homology with the X chromosome.

**yolk:**

A substance in the eggs of animals with external fertilization that provides all the nutrients that the developing embryo needs until it hatches.

**Z disc:**

A protein backbone found regularly spaced along the length of a myofibril.

**Z scheme:**

Another name for the photosynthetic electron transport chain, so called because the overall energy trajectory resembles a “Z.”

**zygomycetes:**

Fungi that produce hyphae undivided by septa and do not form multicellular fruiting bodies; they make up less than 1% of known fungal diversity.

**zygote:**

The diploid cell formed by the fusion of two gametes.

An aerial photograph of a savanna landscape. In the lower center, a large elephant is visible, with a smaller elephant partially visible behind it. The landscape is a mosaic of green grass and dark, winding paths or water channels. The sky is a pale, hazy blue.

## About the Cover

A stunning photograph by George Steinmetz graces our cover. We were drawn to this aerial imagery of elephants because it provides a different perspective on an otherwise familiar subject, not unlike what we aim to do in *How Life Works*. The elephants are majestic and increasingly endangered, while the intense greenery through which they amble bursts with life. The photograph tells a story and invites the reader to ask questions—What are those paths? Where are the elephants headed? What is the social structure of this group? How do the elephants affect the plants that surround them, and what are those birds doing among the pachyderms? There is a touch of mystery in the image, encouraging the reader to open the book and explore how life works.

All of our covers show multiple organisms set in a richly colored and thought-provoking context with a bold, contrasting spine. This consistent visual language echoes our consistent vision across editions: a book and set of resources that are selective, thematic, and integrated. Just as the organisms are in motion, we too continue to innovate in each edition.

George Steinmetz is an American photographer who uses a lightweight, motorized paraglider to take photographs from the air and reach places that might otherwise be inaccessible. He has given us new views of such diverse subjects as the world's deserts, 21st-century farming, New York City, and a warming planet. He is the recipient of numerous awards, has published several books of photography, and is a regular contributor to *National Geographic Magazine*.

| Chapter 2 The Molecules of Life                                                                | 266 |
| 2.1 Properties of Atoms                                                                        | 269 |
| Atoms consist of protons, neutrons, and electrons                                              | 269 |

|                                                                                                        |     |
|--------------------------------------------------------------------------------------------------------|-----|
| Electrons occupy regions of space called orbitals                                                      | 271 |
| Elements have recurring, or periodic, chemical properties                                              | 273 |
| 2.2 Molecules and Chemical Bonds                                                                       | 276 |
| A covalent bond results when two atoms share electrons                                                 | 276 |
| A polar covalent bond is characterized by unequal sharing of electrons                                 | 279 |
| An ionic bond forms between oppositely charged ions                                                    | 280 |
| A chemical reaction involves breaking and forming chemical bonds                                       | 282 |
| 2.3 Water                                                                                              | 284 |
| Water is a polar molecule                                                                              | 284 |
| A hydrogen bond is an interaction between a hydrogen atom and an electronegative atom                  | 285 |
| Hydrogen bonds give water many unusual properties                                                      | 286 |
| pH is a measure of the concentration of protons in solution                                            | 289 |
| 2.4 Carbon                                                                                             | 291 |
| Carbon atoms form four covalent bonds                                                                  | 292 |
| Carbon-based molecules are structurally and functionally diverse                                       | 293 |
| 2.5 Organic Molecules                                                                                  | 298 |
| Functional groups add chemical character to carbon chains                                              | 299 |
| Proteins are composed of amino acids                                                                   | 300 |
| Nucleic acids encode genetic information in their nucleotide sequence                                  | 302 |
| Complex carbohydrates are made up of simple sugars                                                     | 307 |
| Lipids are hydrophobic molecules                                                                       | 311 |
| 2.6 Life's Origins                                                                                     | 317 |
| How did the molecules of life form?                                                                    | 317 |
| The building blocks of life can be generated in the laboratory                                         | 318 |
| Experiments show how life's building blocks can form macromolecules                                    | 320 |
| How do we know? Could the building blocks of organic molecules have been generated on the early Earth? | 318 |

|                                                                                                                |     |
|----------------------------------------------------------------------------------------------------------------|-----|
| Core Concepts Summary                                                                                          | 323 |
| Chapter 3 Nucleic Acids and Transcription                                                                      | 327 |
| 3.1 Chemical Composition and Structure of DNA                                                                  | 331 |
| How do we know? Can genetic information be transmitted between two strains of bacteria?                        | 332 |
| How do we know? Which molecule carries genetic information?                                                    | 334 |
| A DNA strand consists of subunits called nucleotides                                                           | 336 |
| DNA is a linear polymer of nucleotides linked by phosphodiester bonds                                          | 339 |
| Cellular DNA molecules take the form of a double helix                                                         | 342 |
| 3.2 DNA Structure And Function                                                                                 | 351 |
| DNA molecules are copied in the process of replication, which relies on base pairing                           | 352 |
| RNA is an intermediary between DNA and protein                                                                 | 354 |
| 3.3 Transcription                                                                                              | 358 |
| RNA is a polymer of nucleotides in which the 5-carbon sugar is ribose                                          | 359 |
| What kinds of nucleic acids were present in the earliest cells?                                                | 361 |
| In transcription, DNA is used as a template to make complementary RNA                                          | 363 |
| Transcription starts at a promoter and ends at a terminator                                                    | 364 |
| RNA polymerase adds successive nucleotides to the 3' end of the transcript                                     | 369 |
| The RNA polymerase complex is a molecular machine that opens, transcribes, and closes duplex DNA               | 371 |
| 3.4 RNA Processing                                                                                             | 374 |
| Primary transcripts in prokaryotes are translated immediately                                                  | 374 |
| Primary transcripts in eukaryotes undergo several types of chemical modification                               | 376 |
| Some RNA transcripts are processed differently from protein-coding transcripts and have functions of their own | 381 |
| Core Concepts Summary                                                                                          | 383 |
| Chapter 4 Translation and Protein Structure                                                                    | 386 |

|                                                                                 |     |
|---------------------------------------------------------------------------------|-----|
| 4.1 Molecular Structure of Proteins                                             | 389 |
| Amino acids differ in their side chains                                         | 389 |
| Successive amino acids in proteins are connected by peptide bonds               | 395 |
| The sequence of amino acids dictates protein folding, which determines function | 397 |
| Secondary structures result from hydrogen bonding in the polypeptide backbone   | 400 |
| Tertiary structures result from interactions between amino acid side chains     | 403 |
| Polypeptide subunits can come together to form quaternary structures            | 409 |
| Chaperones help some proteins fold properly                                     | 410 |
| How do we know? What determines secondary and tertiary structure of proteins?   | 406 |
| 4.2 Protein Synthesis                                                           | 412 |
| Translation uses many molecules found in all cells                              | 413 |
| The genetic code shows the correspondence between codons and amino acids        | 419 |
| How do we know? How was the genetic code deciphered?                            | 420 |
| Translation consists of initiation, elongation, and termination                 | 424 |
| How did the genetic code originate?                                             | 429 |
| 4.3 Protein Origins and Evolution                                               | 431 |
| Most proteins are composed of modular folding domains                           | 431 |
| Amino acid sequences evolve through mutation and selection                      | 433 |
| Visual Synthesis: Gene Expression                                               | 437 |
| Core Concepts Summary                                                           | 439 |
| Chapter 5 Organizing Principles: Lipids, Membranes, and Cell Compartments       | 442 |
| 5.1 Structure of Cell Membranes                                                 | 446 |
| Cell membranes are composed of two layers of lipids                             | 446 |
| How did the first cell membranes form?                                          | 449 |
| Cell membranes are dynamic                                                      | 450 |

|                                                                                 |     |
|---------------------------------------------------------------------------------|-----|
| Proteins associate with cell membranes in different ways                        | 453 |
| How do we know? Do proteins move in the plane of the membrane?                  | 456 |
| 5.2 Movement in and out of Cells                                                | 459 |
| The plasma membrane maintains homeostasis                                       | 459 |
| Passive transport involves diffusion                                            | 460 |
| Primary active transport uses the energy of ATP                                 | 465 |
| Secondary active transport is driven by an electrochemical gradient             | 467 |
| Many cells maintain size and composition using active transport                 | 469 |
| The cell wall provides another means of maintaining cell shape                  | 471 |
| 5.3 Internal Organization of Cells                                              | 475 |
| Eukaryotes and prokaryotes differ in internal organization                      | 475 |
| Prokaryotic cells lack a nucleus and extensive internal compartmentalization    | 477 |
| Eukaryotic cells have a nucleus and specialized internal structures             | 478 |
| 5.4 The Endomembrane System                                                     | 482 |
| The endomembrane system compartmentalizes the cell                              | 483 |
| The nucleus houses the genome and is the site of RNA synthesis                  | 485 |
| The endoplasmic reticulum is involved in protein and lipid synthesis            | 486 |
| The Golgi apparatus modifies and sorts proteins and lipids                      | 488 |
| Lysosomes degrade macromolecules                                                | 491 |
| Protein sorting directs proteins to their proper location in or out of the cell | 492 |
| 5.5 Mitochondria and Chloroplasts                                               | 499 |
| Mitochondria provide the eukaryotic cell with most of its usable energy         | 499 |
| Chloroplasts capture energy from sunlight                                       | 501 |
| Core Concepts Summary                                                           | 503 |
| Chapter 6 Making Life Work: Capturing and Using Energy                          | 507 |

|                                                                                                                   |     |
|-------------------------------------------------------------------------------------------------------------------|-----|
| 6.1 An Overview of Metabolism                                                                                     | 510 |
| Organisms can be classified according to their energy and carbon sources                                          | 511 |
| Metabolism is the set of chemical reactions that sustain life                                                     | 513 |
| 6.2 Kinetic and Potential Energy                                                                                  | 515 |
| Kinetic energy and potential energy are two forms of energy                                                       | 516 |
| Chemical energy is a form of potential energy                                                                     | 517 |
| ATP is a readily accessible form of cellular energy                                                               | 518 |
| 6.3 Laws of Thermodynamics                                                                                        | 521 |
| The first law of thermodynamics: energy is conserved                                                              | 521 |
| The second law of thermodynamics: energy transformations always result in an increase in disorder in the universe | 522 |
| 6.4 Chemical Reactions                                                                                            | 526 |
| A chemical reaction occurs when molecules interact                                                                | 526 |
| The laws of thermodynamics determine whether a chemical reaction requires or releases energy available to do work | 528 |
| The hydrolysis of ATP is an exergonic reaction                                                                    | 531 |
| Non-spontaneous reactions are often coupled to spontaneous reactions                                              | 533 |
| 6.5 Enzymes and the Rate of Chemical Reactions                                                                    | 537 |
| Enzymes reduce the activation energy of a chemical reaction                                                       | 537 |
| Enzymes form a complex with reactants and products                                                                | 540 |
| Enzymes are highly specific                                                                                       | 546 |
| How do we know? Do enzymes form complexes with substrates?                                                        | 543 |
| Enzyme activity can be influenced by inhibitors and activators                                                    | 547 |
| Allosteric enzymes regulate key metabolic pathways                                                                | 548 |
| What naturally occurring elements might have spurred the first reactions that led to life?                        | 551 |
| Core Concepts Summary                                                                                             | 553 |

|                                                                                                               |     |
|---------------------------------------------------------------------------------------------------------------|-----|
| Chapter 7 Cellular Respiration: Harvesting Energy from Carbohydrates and Other Fuel Molecules                 | 557 |
| 7.1 An Overview of Cellular Respiration                                                                       | 561 |
| Cellular respiration uses chemical energy stored in molecules such as carbohydrates and lipids to produce ATP | 561 |
| ATP is generated by substrate-level phosphorylation and oxidative phosphorylation                             | 564 |
| Redox reactions play a central role in cellular respiration                                                   | 565 |
| Cellular respiration occurs in four stages                                                                    | 569 |
| 7.2 Glycolysis                                                                                                | 574 |
| Glycolysis is the partial breakdown of glucose                                                                | 574 |
| 7.3 Pyruvate Oxidation                                                                                        | 578 |
| The oxidation of pyruvate connects glycolysis to the citric acid cycle                                        | 578 |
| 7.4 The Citric Acid Cycle                                                                                     | 581 |
| The citric acid cycle produces ATP and reduced electron carriers                                              | 581 |
| What were the earliest energy-harnessing reactions?                                                           | 584 |
| 7.5 The Electron Transport Chain and Oxidative Phosphorylation                                                | 587 |
| The electron transport chain transfers electrons and pumps protons                                            | 587 |
| The proton gradient is a source of potential energy                                                           | 590 |
| ATP synthase converts the energy of the proton gradient into the energy of ATP                                | 591 |
| How do we know? Can a proton gradient drive the synthesis of ATP?                                             | 593 |
| 7.6 Anaerobic Metabolism                                                                                      | 599 |
| Fermentation extracts energy from glucose in the absence of oxygen                                            | 599 |
| How did early cells meet their energy requirements?                                                           | 603 |
| 7.7 Metabolic Integration                                                                                     | 607 |
| Excess glucose is stored as glycogen in animals and starch in plants                                          | 607 |
| Sugars other than glucose contribute to glycolysis                                                            | 608 |

|                                                                                                            |     |
|------------------------------------------------------------------------------------------------------------|-----|
| Fatty acids and proteins are useful sources of energy                                                      | 610 |
| The intracellular level of ATP is a key regulator of cellular respiration                                  | 612 |
| Exercise requires several types of fuel molecules and the coordination of metabolic pathways               | 616 |
| Core Concepts Summary                                                                                      | 618 |
| Chapter 8 Photosynthesis: Using Sunlight to Build Carbohydrates                                            | 623 |
| 8.1 An Overview of Photosynthesis                                                                          | 626 |
| Photosynthesis is widely distributed                                                                       | 626 |
| Photosynthesis is a redox reaction                                                                         | 628 |
| How do we know? Does the oxygen released by photosynthesis come from H <sub>2</sub> O or C <sub>2</sub> O? | 631 |
| The photosynthetic electron transport chain takes place in specialized membranes                           | 634 |
| 8.2 The Calvin Cycle                                                                                       | 637 |
| The incorporation of CO <sub>2</sub> is catalyzed by the enzyme rubisco                                    | 638 |
| NADPH is the reducing agent of the Calvin cycle                                                            | 638 |
| The regeneration of RuBP requires ATP                                                                      | 640 |
| The steps of the Calvin cycle were determined using radioactive CO <sub>2</sub>                            | 640 |
| How do we know? How is CO <sub>2</sub> incorporated into carbohydrates?                                    | 641 |
| Carbohydrates are stored in the form of starch                                                             | 642 |
| 8.3 Capturing Sunlight Into Chemical Forms                                                                 | 645 |
| Chlorophyll is the major entry point for light energy in photosynthesis                                    | 645 |
| Antenna chlorophyll passes light energy to reaction centers                                                | 648 |
| How do we know? Do chlorophyll molecules operate on their own or in groups?                                | 650 |
| The photosynthetic electron transport chain connects two photosystems                                      | 652 |
| The accumulation of protons in the thylakoid lumen drives the synthesis of ATP                             | 656 |

|                                                                                        |     |
|----------------------------------------------------------------------------------------|-----|
| Cyclic electron transport increases the production of ATP                              | 657 |
| 8.4 Photosynthetic Challenges                                                          | 660 |
| Excess light energy can cause damage                                                   | 660 |
| Photorespiration leads to a net loss of energy and carbon                              | 663 |
| Photosynthesis captures just a small percentage of incoming solar energy               | 666 |
| 8.5 The Evolution of Photosynthesis                                                    | 670 |
| How did early cells use sunlight to meet their energy requirements?                    | 670 |
| Visual Synthesis: Harnessing Energy: Photosynthesis and Cellular Respiration           | 676 |
| Core Concepts Summary                                                                  | 678 |
| Case 2: Cancer: Cell Signaling, Form, and Division                                     | 682 |
| Chapter 9 Cell Signaling                                                               | 689 |
| 9.1 Principles of Cell Signaling                                                       | 692 |
| Cells communicate using chemical signals that bind to receptors                        | 692 |
| Signaling involves receptor activation, signal transduction, response, and termination | 697 |
| The response of a cell to a signaling molecule depends on the cell type                | 699 |
| 9.2 Distance Between Cells                                                             | 701 |
| Endocrine signaling acts over long distances                                           | 701 |
| Signaling can occur over short distances                                               | 702 |
| How do we know? Where do growth factors come from?                                     | 703 |
| Signaling can occur by direct cell–cell contact                                        | 708 |
| 9.3 Signaling Receptors                                                                | 710 |
| Receptors for polar signaling molecules are located on the cell surface                | 711 |
| Receptors for nonpolar signaling molecules are located in the interior of the cell     | 712 |
| Cell-surface receptors act like molecular switches                                     | 713 |
| 9.4 G Protein-Coupled Receptors                                                        | 717 |
| The first step in cell signaling is receptor activation                                | 718 |
| Signals are often amplified in the cytosol                                             | 720 |

|                                                                                                                              |     |
|------------------------------------------------------------------------------------------------------------------------------|-----|
| Signals lead to a cellular response                                                                                          | 722 |
| Signaling pathways are eventually terminated                                                                                 | 723 |
| 9.5 Receptor Kinases                                                                                                         | 725 |
| Receptor kinases phosphorylate each other, activate intracellular signaling pathways, lead to a response, and are terminated | 726 |
| How do cell signaling errors lead to cancer?                                                                                 | 730 |
| Signaling pathways are integrated to produce a response in a cell                                                            | 731 |
| Core Concepts Summary                                                                                                        | 734 |
| Chapter 10 Cell and Tissue Architecture: Cytoskeleton, Cell Junctions, and Extracellular Matrix                              | 738 |
| 10.1 Tissues and Organs                                                                                                      | 743 |
| Tissues and organs are communities of cells                                                                                  | 743 |
| The structure of skin relates to its function                                                                                | 744 |
| 10.2 The Cytoskeleton                                                                                                        | 748 |
| Microtubules and microfilaments are polymers of protein subunits                                                             | 749 |
| Microtubules and microfilaments are dynamic structures                                                                       | 750 |
| Motor proteins associate with microtubules and microfilaments to cause movement                                              | 752 |
| Intermediate filaments are polymers of proteins that vary according to cell type                                             | 759 |
| The cytoskeleton is an ancient feature of cells                                                                              | 762 |
| 10.3 Cell Junctions                                                                                                          | 765 |
| Cell adhesion molecules allow cells to attach to other cells and to the extracellular matrix                                 | 765 |
| Anchoring junctions connect adjacent cells and are reinforced by the cytoskeleton                                            | 768 |
| Tight junctions prevent the movement of substances through the space between cells                                           | 771 |
| Molecules pass between cells through communicating junctions                                                                 | 772 |
| 10.4 The Extracellular Matrix                                                                                                | 775 |
| The extracellular matrix of plants is the cell wall                                                                          | 775 |
| The extracellular matrix is abundant in connective tissues                                                                   |     |

|                                                                                    |     |
|------------------------------------------------------------------------------------|-----|
| of animals                                                                         |     |
| How do cancer cells spread throughout the body?                                    | 783 |
| Extracellular matrix proteins influence cell shape and gene expression             | 785 |
| How do we know? Can extracellular matrix proteins influence gene expression?       | 786 |
| Core Concepts Summary                                                              | 791 |
| Chapter 11 Cell Division: Variation, Regulation, and Cancer                        | 795 |
| 11.1 Cell Division                                                                 | 798 |
| Prokaryotic cells divide by binary fission                                         | 798 |
| Eukaryotic cells divide by mitotic cell division                                   | 801 |
| The cell cycle describes the life cycle of a eukaryotic cell                       | 802 |
| 11.2 Mitotic Cell Division                                                         | 806 |
| The DNA of eukaryotic cells is organized as chromosomes                            | 806 |
| Prophase: Chromosomes condense and become visible                                  | 809 |
| Prometaphase: Chromosomes attach to the mitotic spindle                            | 811 |
| Metaphase: Chromosomes align as a result of dynamic changes in the mitotic spindle | 813 |
| Anaphase: Sister chromatids fully separate                                         | 813 |
| Telophase: Nuclear envelopes re-form around newly segregated chromosomes           | 814 |
| The parent cell divides into two daughter cells by cytokinesis                     | 814 |
| 11.3 Meiotic Cell Division                                                         | 817 |
| Pairing of homologous chromosomes is unique to meiosis                             | 818 |
| Crossing over between DNA molecules results in exchange of genetic material        | 820 |
| The first meiotic division reduces the chromosome number                           | 822 |
| The second meiotic division resembles mitosis                                      | 825 |
| Division of the cytoplasm often differs between the sexes                          | 830 |
| Meiosis is the basis of sexual reproduction                                        | 831 |
| 11.4 Nondisjunction                                                                | 834 |

|                                                                                 |     |
|---------------------------------------------------------------------------------|-----|
| Nondisjunction in meiosis results in extra or missing chromosomes               | 834 |
| Some human disorders result from nondisjunction                                 | 836 |
| Extra or missing sex chromosomes have fewer effects than extra autosomes        | 838 |
| 11.5 Cell Cycle Regulation                                                      | 843 |
| Protein phosphorylation controls passage through the cell cycle                 | 844 |
| How do we know? How is progression through the cell cycle controlled?           | 846 |
| Different cyclin–CDK complexes regulate each stage of the cell cycle            | 849 |
| Cell cycle progression requires successful passage through multiple checkpoints | 850 |
| 11.6 Cancer                                                                     | 854 |
| What genes are involved in cancer?                                              | 854 |
| Oncogenes promote cancer                                                        | 854 |
| Proto-oncogenes are genes that when mutated may cause cancer                    | 858 |
| Tumor suppressors block specific steps in the development of cancer             | 859 |
| How do we know? Can a virus cause cancer?                                       | 855 |
| Most cancers require the accumulation of multiple mutations                     | 860 |
| Visual Synthesis: Cellular Communities                                          | 863 |
| Core Concepts Summary                                                           | 864 |
| Case 3: Your Personal Genome You, from A to T                                   | 870 |
| Chapter 12 DNA Replication and Manipulation                                     | 878 |
| 12.1 DNA Replication                                                            | 881 |
| During DNA replication, the parental strands separate and new partners are made | 881 |
| How do we know? How is DNA replicated?                                          | 883 |
| New DNA strands grow by the addition of nucleotides to the 3' end               | 887 |
| In replicating DNA, one daughter strand is synthesized                          | 890 |

|                                                                                 |     |
|---------------------------------------------------------------------------------|-----|
| A small stretch of RNA is needed to begin synthesis of a new DNA strand         | 892 |
| Synthesis of the leading and lagging strands is coordinated                     | 893 |
| DNA polymerase is self-correcting because of its proofreading function          | 896 |
| 12.2 Replication of Chromosomes                                                 | 900 |
| Replication of DNA in chromosomes starts at many places almost simultaneously   | 900 |
| Telomerase restores tips of linear chromosomes shortened during DNA replication | 902 |
| 12.3 DNA Techniques                                                             | 909 |
| The polymerase chain reaction selectively amplifies regions of DNA              | 909 |
| Electrophoresis separates DNA fragments by size                                 | 913 |
| Restriction enzymes cleave DNA at particular short sequences                    | 916 |
| DNA strands can be separated and brought back together again                    | 919 |
| DNA sequencing makes use of the principles of DNA replication                   | 922 |
| What new technologies are used to sequence your personal genome?                | 928 |
| 12.4 Genetic Engineering                                                        | 931 |
| Recombinant DNA combines DNA molecules from two or more sources                 | 932 |
| Recombinant DNA is the basis of genetically modified organisms                  | 935 |
| DNA editing can be used to alter gene sequences almost at will                  | 937 |
| Core Concepts Summary                                                           | 942 |
| Chapter 13 Genomes                                                              | 945 |
| 13.1 Genome Sequencing                                                          | 948 |
| Complete genome sequences are assembled from smaller pieces                     | 949 |
| How do we know? How are whole genomes sequenced?                                | 950 |

|                                                                                                                   |     |
|-------------------------------------------------------------------------------------------------------------------|-----|
| How do we know? How are whole genomes sequenced?                                                                  | 950 |
| Sequences that are repeated complicate sequence assembly                                                          | 952 |
| Why sequence your personal genome?                                                                                | 955 |
| 13.2 Genome Annotation                                                                                            | 957 |
| Genome annotation identifies various types of sequence                                                            | 957 |
| Genome annotation includes searching for sequence motifs                                                          | 960 |
| Comparison of genomic DNA with messenger RNA reveals the intron–exon structure of genes                           | 963 |
| An annotated genome summarizes knowledge, guides research, and reveals evolutionary relationships among organisms | 964 |
| The HIV genome illustrates the utility of genome annotation and comparison                                        | 966 |
| 13.3 Genes, Genomes, and Organismal Complexity                                                                    | 970 |
| Gene number is not a good predictor of biological complexity                                                      | 970 |
| Viruses, bacteria, and archaeons have small, compact genomes                                                      | 972 |
| Among eukaryotes, no relationship exists between genome size and organismal complexity                            | 973 |
| About half of the human genome consists of transposable elements and other types of repetitive DNA                | 977 |
| 13.4 Organization of Genomes                                                                                      | 981 |
| Bacterial cells package their DNA as a nucleoid composed of many loops                                            | 981 |
| Eukaryotic cells package their DNA as one molecule per chromosome                                                 | 983 |
| The human genome consists of 22 pairs of chromosomes and two sex chromosomes                                      | 987 |
| Organelle DNA forms nucleoids that differ from those in bacteria                                                  | 992 |
| 13.5 Viruses and Viral Genomes                                                                                    | 994 |
| Viruses can be classified by their genomes                                                                        | 995 |
| The host range of a virus is determined by viral and host                                                         | 998 |

|                                                                                                            |      |
|------------------------------------------------------------------------------------------------------------|------|
| Viruses have diverse sizes and shapes                                                                      | 1000 |
| Core Concepts Summary                                                                                      | 1004 |
| Chapter 14 Mutation and Genetic Variation                                                                  | 1007 |
| 14.1 Genotype and Phenotype                                                                                | 1011 |
| Genotype is the genetic makeup of a cell or organism,<br>and the phenotype is its observed characteristics | 1012 |
| Some genetic differences are harmful                                                                       | 1013 |
| Some genetic differences are neutral                                                                       | 1015 |
| A few genetic differences are beneficial                                                                   | 1016 |
| The effect of a mutation may depend on the genotype and<br>environment                                     | 1018 |
| 14.2 The Nature of Mutations                                                                               | 1022 |
| Mutation of individual nucleotides is rare, but mutation<br>across the genome is common                    | 1022 |
| Only germ-line mutations are transmitted to progeny                                                        | 1025 |
| What can your personal genome tell you about your<br>genetic risk factors for cancer?                      | 1029 |
| Mutations are random with regard to an organism's needs                                                    | 1030 |
| How do we know? Do mutations occur randomly, or are<br>they directed by the environment?                   | 1031 |
| 14.3 Small-Scale Mutations                                                                                 | 1036 |
| Point mutations are changes in a single nucleotide                                                         | 1036 |
| The effect of a point mutation depends in part on where<br>in the genome it occurs                         | 1038 |
| Small insertions and deletions involve several nucleotides                                                 | 1041 |
| Some mutations are due to the insertion of a transposable<br>element                                       | 1045 |
| How do we know? What causes sectoring in corn<br>kernels?                                                  | 1046 |
| 14.4 Chromosomal Mutations                                                                                 | 1050 |
| Duplications and deletions result in gain or loss of DNA                                                   | 1050 |
| Gene families arise from gene duplication and divergence                                                   | 1052 |
| Copy-number variation constitutes a significant<br>proportion of genetic variation                         | 1053 |
| Tandem repeats are useful in DNA typing                                                                    | 1055 |

|                                                                                                  |      |
|--------------------------------------------------------------------------------------------------|------|
| Tandem repeats are useful in DNA typing                                                          | 1055 |
| An inversion has a chromosomal region reversed in orientation                                    | 1058 |
| A reciprocal translocation joins segments from nonhomologous chromosomes                         | 1059 |
| 14.5 DNA Damage and Repair                                                                       | 1061 |
| DNA damage can affect both DNA backbone and bases                                                | 1061 |
| Most DNA damage is corrected by specialized repair enzymes                                       | 1063 |
| Core Concepts Summary                                                                            | 1069 |
| Chapter 15 Mendelian Inheritance                                                                 | 1074 |
| 15.1 Early Theories of Inheritance                                                               | 1077 |
| Early theories of heredity predicted the transmission of acquired characteristics                | 1077 |
| Belief in blending inheritance discouraged studies of hereditary transmission                    | 1079 |
| 15.2 Foundations of Modern Transmission Genetics                                                 | 1082 |
| Mendel's experimental organism was the garden pea                                                | 1082 |
| In crosses, one of the traits was dominant in the offspring                                      | 1085 |
| 15.3 Segregation                                                                                 | 1090 |
| Genes come in pairs that segregate in the formation of reproductive cells                        | 1092 |
| The principle of segregation was tested by predicting the outcome of crosses                     | 1095 |
| A testcross is a mating to an individual with the homozygous recessive genotype                  | 1097 |
| Segregation of alleles reflects the separation of chromosomes in meiosis                         | 1099 |
| Dominance is not universally observed                                                            | 1100 |
| The principles of transmission genetics are statistical and are stated in terms of probabilities | 1102 |
| Mendelian segregation preserves genetic variation                                                | 1105 |
| 15.4 Independent Assortment                                                                      | 1107 |
| Independent assortment is observed when genes segregate independently of one another             | 1107 |
| How do we know? How are single-gene traits inherited?                                            | 1112 |

|                                                                                            |      |
|--------------------------------------------------------------------------------------------|------|
| Independent assortment reflects the random alignment of chromosomes in meiosis             | 1115 |
| Phenotypic ratios can be modified by interactions between genes                            | 1117 |
| 15.5 Human Genetics                                                                        | 1121 |
| Dominant traits appear in every generation                                                 | 1122 |
| Recessive traits skip generations                                                          | 1124 |
| Many genes have multiple alleles                                                           | 1126 |
| Incomplete penetrance and variable expression can obscure inheritance patterns             | 1128 |
| Core Concepts Summary                                                                      | 1133 |
| Chapter 16 Inheritance of Sex Chromosomes, Linked Genes, and Organelles                    | 1137 |
| 16.1 The X and Y Chromosomes                                                               | 1140 |
| In many animals, sex is genetically determined and associated with chromosomal differences | 1140 |
| Segregation of the sex chromosomes predicts a 1 : 1 ratio of females to males              | 1143 |
| 16.2 Inheritance of Genes in the X Chromosome                                              | 1146 |
| X-linked inheritance was discovered through studies of male fruit flies with white eyes    | 1146 |
| Genes in the X chromosome exhibit a crisscross inheritance pattern                         | 1147 |
| X-linkage provided the first experimental evidence that genes are in chromosomes           | 1153 |
| Genes in the X chromosome show characteristic patterns in human pedigrees                  | 1157 |
| 16.3 Genetic Linkage                                                                       | 1162 |
| Nearby genes in the same chromosome show linkage                                           | 1162 |
| The frequency of recombination is a measure of the genetic distance between linked genes   | 1168 |
| Genetic mapping assigns a location to each gene along a chromosome                         | 1171 |
| Genetic risk factors for disease can be localized by genetic mapping                       | 1174 |
| How do we know? Can recombination be used to                                               | 1172 |

|                                                                                                        |      |
|--------------------------------------------------------------------------------------------------------|------|
| construct a genetic map of a chromosome?                                                               | 1172 |
| 16.4 Inheritance of Genes in the Y Chromosome                                                          | 1178 |
| Y-linked genes are transmitted from father to son                                                      | 1178 |
| How can the Y chromosome be used to trace ancestry?                                                    | 1180 |
| 16.5 Inheritance of Mitochondrial and Chloroplast DNA                                                  | 1184 |
| Mitochondrial and chloroplast genomes often show uniparental inheritance                               | 1184 |
| Maternal inheritance is characteristic of mitochondrial diseases                                       | 1186 |
| How can mitochondrial DNA be used to trace ancestry?                                                   | 1188 |
| Core Concepts Summary                                                                                  | 1190 |
| Chapter 17 The Genetic and Environmental Basis of Complex Traits                                       | 1194 |
| 17.1 Heredity and Environment                                                                          | 1198 |
| Complex traits are affected by the environment                                                         | 1199 |
| Complex traits are affected by multiple genes                                                          | 1202 |
| The relative importance of genes and environment can be determined by differences among individuals    | 1207 |
| Genetic and environmental effects can interact in unpredictable ways                                   | 1207 |
| 17.2 Resemblance Among Relatives                                                                       | 1212 |
| For complex traits, offspring resemble parents but show regression toward the mean                     | 1212 |
| Heritability is the proportion of the total variation due to genetic differences among individuals     | 1216 |
| 17.3 Twin Studies                                                                                      | 1222 |
| Twin studies help separate the effects of genes and environment in differences among individuals       | 1223 |
| How do we know? What is the relative importance of genes and of the environment for complex traits?    | 1225 |
| 17.4 Complex Traits in Health and Disease                                                              | 1230 |
| Most common diseases and birth defects are affected by many genes, each with a relatively small effect | 1231 |
| Human height is affected by hundreds of genes                                                          | 1235 |
| Can personalized medicine lead to effective treatments of                                              | 1236 |

|                                                                                                              |      |
|--------------------------------------------------------------------------------------------------------------|------|
| Core Concepts Summary                                                                                        | 1240 |
| Chapter 18 Genetic and Epigenetic Regulation                                                                 | 1243 |
| 18.1 Chromatin to Messenger RNA in Eukaryotes                                                                | 1247 |
| Gene expression can be influenced by chemical modification of DNA or histones                                | 1247 |
| Gene expression can be regulated at the level of an entire chromosome                                        | 1253 |
| Transcription is a key control point in gene expression                                                      | 1258 |
| RNA processing is also important in gene regulation                                                          | 1260 |
| 18.2 Messenger RNA to Phenotype in Eukaryotes                                                                | 1266 |
| Small regulatory RNAs inhibit translation or promote mRNA degradation                                        | 1266 |
| Translational regulation controls the rate, timing, and location of protein synthesis                        | 1268 |
| Protein structure and chemical modification modulate protein effects on phenotype                            | 1270 |
| How do lifestyle choices affect expression of your personal genome?                                          | 1272 |
| 18.3 Transcriptional Regulation in Prokaryotes                                                               | 1275 |
| Transcriptional regulation can be positive or negative                                                       | 1276 |
| Lactose utilization in <i>E. coli</i> is the pioneering example of transcriptional regulation                | 1280 |
| How do we know? How does lactose lead to the production of active $\beta$ -galactosidase enzyme?             | 1281 |
| The repressor protein binds with the operator and prevents transcription, but not in the presence of lactose | 1285 |
| The function of the lactose operon was revealed by genetic studies                                           | 1287 |
| The lactose operon is also positively regulated by CRP–cAMP                                                  | 1289 |
| Transcriptional regulation determines the outcome of infection by a bacterial virus                          | 1291 |
| Visual Synthesis: Virus: A Genome in Need of a Cell                                                          | 1296 |
| Core Concepts Summary                                                                                        | 1298 |
| Chapter 19 Genes and Development                                                                             | 1302 |
| 19.1 Genetic Basis of Development                                                                            | 1305 |

|                                                                                           |      |
|-------------------------------------------------------------------------------------------|------|
| 19.1 Genetic Basis of Development                                                         | 1305 |
| The fertilized egg is a totipotent cell                                                   | 1305 |
| Cellular differentiation increasingly restricts alternative fates                         | 1308 |
| How do we know? How do stem cells lose their ability to differentiate into any cell type? | 1310 |
| Can cells with your personal genome be reprogrammed for new therapies?                    | 1315 |
| 19.2 Hierarchical Control                                                                 | 1318 |
| Drosophila development proceeds through egg, larval, and adult stages                     | 1318 |
| The egg is a highly polarized cell                                                        | 1320 |
| Development proceeds by progressive regionalization and specification                     | 1325 |
| Homeotic genes determine where different body parts develop in the organism               | 1329 |
| 19.3 Master Regulators                                                                    | 1335 |
| Animals have evolved a wide variety of eyes                                               | 1335 |
| Pax6 is a master regulator of eye development                                             | 1337 |
| 19.4 Combinatorial Control                                                                | 1344 |
| Floral differentiation is a model for plant development                                   | 1344 |
| The identity of the floral organs is determined by combinatorial control                  | 1346 |
| 19.5 Cell Signaling In Development                                                        | 1352 |
| A signaling molecule can cause multiple responses in the cell                             | 1352 |
| Developmental signals are amplified and expanded                                          | 1355 |
| Visual Synthesis: Genetic Variation and Inheritance                                       | 1358 |
| Core Concepts Summary                                                                     | 1360 |
| Case 4 Malaria, Coevolution of Humans and a Parasite                                      | 1364 |
| Chapter 20 Evolution: How Genotypes and Phenotypes Change over Time                       | 1371 |
| 20.1 Genetic Variation                                                                    | 1374 |
| Population genetics is the study of patterns of genetic variation                         | 1374 |
| Mutation and recombination are the two sources of                                         |      |

|                                                                                                                          |      |
|--------------------------------------------------------------------------------------------------------------------------|------|
| genetic variation                                                                                                        |      |
| 20.2 Measuring Genetic Variation                                                                                         | 1379 |
| To understand patterns of genetic variation, we require information about allele frequencies                             | 1379 |
| Early population geneticists relied on observable traits and gel electrophoresis to measure variation                    | 1381 |
| How do we know? How did gel electrophoresis allow us to detect genetic variation?                                        | 1383 |
| DNA sequencing is the gold standard for measuring genetic variation                                                      | 1386 |
| 20.3 Evolution and the Hardy–Weinberg Equilibrium                                                                        | 1388 |
| Evolution is a change in allele or genotype frequency over time                                                          | 1388 |
| The Hardy–Weinberg equilibrium describes situations in which allele and genotype frequencies do not change               | 1389 |
| The Hardy–Weinberg equilibrium relates allele frequencies and genotype frequencies                                       | 1391 |
| The Hardy–Weinberg equilibrium is the starting point for population genetic analysis                                     | 1396 |
| 20.4 Natural Selection                                                                                                   | 1398 |
| Natural selection brings about adaptations                                                                               | 1398 |
| The Modern Synthesis combines Mendelian genetics and Darwinian evolution                                                 | 1403 |
| Natural selection increases the frequency of advantageous mutations and decreases the frequency of deleterious mutations | 1404 |
| Which genetic differences have made some individuals more and some less susceptible to malaria?                          | 1406 |
| Natural selection can be stabilizing, directional, or disruptive                                                         | 1408 |
| How do we know? How far can artificial selection be taken?                                                               | 1411 |
| Sexual selection increases an individual’s reproductive success                                                          | 1413 |
| 20.5 Non-Adaptive Mechanisms of Evolution                                                                                | 1416 |
| Genetic drift is a change in allele frequency due to chance                                                              | 1416 |

|                                                                                                                       |      |
|-----------------------------------------------------------------------------------------------------------------------|------|
| Genetic drift has a large effect in small populations                                                                 | 1418 |
| Migration reduces genetic variation between populations                                                               | 1420 |
| Mutation increases genetic variation                                                                                  | 1421 |
| Nonrandom mating alters genotype frequencies without affecting allele frequencies                                     | 1421 |
| 20.6 Molecular Evolution                                                                                              | 1424 |
| The molecular clock relates the amount of sequence difference between species and the time since the species diverged | 1426 |
| The rate of the molecular clock varies                                                                                | 1427 |
| Core Concepts Summary                                                                                                 | 1431 |
| Chapter 21 Species and Speciation                                                                                     | 1435 |
| 21.1 The Biological Species Concept                                                                                   | 1437 |
| Species are reproductively isolated from other species                                                                | 1437 |
| The BSC is more useful in theory than in practice                                                                     | 1440 |
| The BSC does not apply to asexual or extinct organisms                                                                | 1444 |
| Hybridization complicates the BSC                                                                                     | 1444 |
| Ecology and evolution can extend the BSC                                                                              | 1446 |
| 21.2 Reproductive Isolation                                                                                           | 1450 |
| Pre-zygotic isolating factors occur before egg fertilization                                                          | 1450 |
| Post-zygotic isolating factors occur after egg fertilization                                                          | 1452 |
| 21.3 Speciation                                                                                                       | 1454 |
| Speciation is a by-product of the genetic divergence of separated populations                                         | 1454 |
| Allopatric speciation is speciation that results from the geographical separation of populations                      | 1456 |
| Dispersal and vicariance can isolate populations from each other                                                      | 1457 |
| How do we know? Can vicariance cause speciation?                                                                      | 1458 |
| Co-speciation is speciation that occurs in response to speciation in another species                                  | 1467 |
| How did malaria come to infect humans?                                                                                | 1468 |
| Sympatric populations—those in the same place—may undergo speciation                                                  | 1469 |

|                                                                                               |      |
|-----------------------------------------------------------------------------------------------|------|
| Speciation can occur with or without natural selection                                        | 1479 |
| Visual Synthesis: Speciation                                                                  | 1480 |
| Core Concepts Summary                                                                         | 1482 |
| Chapter 22 Evolutionary Patterns: Phylogeny and Fossils                                       | 1485 |
| 22.1 Reading a Phylogenetic Tree                                                              | 1488 |
| Phylogenetic trees provide hypotheses of evolutionary relationships                           | 1489 |
| The search for sister groups lies at the heart of phylogenetics                               | 1493 |
| A monophyletic group consists of a common ancestor and all its descendants                    | 1495 |
| Taxonomic classifications are information storage and retrieval systems                       | 1497 |
| 22.2 Building a Phylogenetic Tree                                                             | 1501 |
| Homology is similarity by common descent                                                      | 1501 |
| Shared derived characters enable biologists to reconstruct evolutionary history               | 1505 |
| The simplest tree is often favored among multiple possible trees                              | 1507 |
| Molecular data complement comparative morphology in reconstructing phylogenetic history       | 1511 |
| Phylogenetic trees can help solve practical problems                                          | 1517 |
| How do we know? Did an HIV-positive dentist spread the AIDS virus to his patients?            | 1518 |
| 22.3 The Fossil Record                                                                        | 1522 |
| Fossils provide unique information                                                            | 1522 |
| Fossils provide a selective record of past life                                               | 1524 |
| Geologic data indicate the age and environmental setting of fossils                           | 1530 |
| Fossils can contain unique combinations of characters                                         | 1536 |
| How do we know? Do fossils bridge the evolutionary gap between fish and tetrapod vertebrates? | 1538 |
| Rare mass extinctions have altered the course of evolution                                    | 1540 |
| 22.4 Comparing Evolution's Two Great Patterns                                                 | 1545 |
| Phylogeny and fossils complement each other                                                   | 1545 |

|                                                                                                                           |      |
|---------------------------------------------------------------------------------------------------------------------------|------|
| Phylogeny and fossils complement each other                                                                               | 1545 |
| Agreement between phylogenies and the fossil record provides strong evidence of evolution                                 | 1546 |
| Core Concepts Summary                                                                                                     | 1550 |
| Chapter 23 Human Origins and Evolution                                                                                    | 1554 |
| 23.1 The Great Apes                                                                                                       | 1557 |
| Comparative anatomy shows that the human lineage branches off the great apes tree                                         | 1557 |
| Molecular analysis reveals that the human lineage split from the chimpanzee lineage about 5–7 million years ago           | 1559 |
| How do we know? How closely related are humans and chimpanzees?                                                           | 1560 |
| The fossil record gives us direct information about our evolutionary history                                              | 1563 |
| 23.2 African Origins                                                                                                      | 1574 |
| Studies of mitochondrial DNA reveal that modern humans evolved in Africa relatively recently                              | 1574 |
| How do we know? When and where did the most recent common ancestor of all living humans live?                             | 1575 |
| Studies of the Y chromosome provide independent evidence for a recent origin of modern humans                             | 1580 |
| Neanderthals disappear from the fossil record as modern humans appear, but have contributed to the modern human gene pool | 1580 |
| 23.3 Human Traits                                                                                                         | 1584 |
| Bipedalism was a key innovation                                                                                           | 1584 |
| Adult humans share many features with juvenile chimpanzees                                                                | 1587 |
| Humans have large brains relative to body size                                                                            | 1591 |
| The human and chimpanzee genomes help us identify genes that make us human                                                | 1593 |
| 23.4 Human Genetic Variation                                                                                              | 1597 |
| Humans have very little genetic variation                                                                                 | 1597 |
| The prehistory of humans influenced the distribution of genetic variation                                                 | 1598 |
| The recent spread of modern humans means that there are                                                                   | 1600 |

|                                                                                               |      |
|-----------------------------------------------------------------------------------------------|------|
| Some human differences have likely arisen by natural selection                                | 1602 |
| Which human genes are under selection for resistance to malaria?                              | 1604 |
| 23.5 Culture, Language, and Consciousness                                                     | 1607 |
| Culture changes rapidly                                                                       | 1607 |
| Is culture uniquely human?                                                                    | 1610 |
| Is language uniquely human?                                                                   | 1611 |
| Is consciousness uniquely human?                                                              | 1613 |
| Core Concepts Summary                                                                         | 1616 |
| Part 2 From Organisms to the Environment                                                      | 1620 |
| Case 5 The Human Microbiome, Diversity Within                                                 | 1621 |
| Chapter 24 Bacteria and Archaea                                                               | 1630 |
| 24.1 Two Prokaryotic Domains                                                                  | 1633 |
| The bacterial cell is small but powerful                                                      | 1633 |
| Diffusion limits cell size in bacteria                                                        | 1636 |
| Horizontal gene transfer promotes genetic diversity in bacteria                               | 1639 |
| Archaea form a second prokaryotic domain                                                      | 1643 |
| 24.2 An Expanded Carbon Cycle                                                                 | 1648 |
| Many photosynthetic bacteria do not produce oxygen                                            | 1650 |
| Many bacteria respire without oxygen                                                          | 1655 |
| Photoheterotrophs obtain energy from light but obtain carbon from preformed organic molecules | 1657 |
| Chemoautotrophy is a uniquely prokaryotic metabolism                                          | 1658 |
| 24.3 Sulfur and Nitrogen Cycles                                                               | 1661 |
| Bacteria and archaeons dominate Earth's sulfur cycle                                          | 1661 |
| The nitrogen cycle is also driven by bacteria and archaeons                                   | 1664 |
| 24.4 Bacterial Diversity                                                                      | 1669 |
| How do we know? How many kinds of bacterium live in the oceans?                               | 1670 |
| Bacterial phylogeny is a work in progress                                                     | 1673 |
| What, if anything, is a bacterial species?                                                    | 1678 |
| Proteobacteria are the most diverse bacteria                                                  | 1679 |

|                                                                                        |      |
|----------------------------------------------------------------------------------------|------|
| Proteobacteria are the most diverse bacteria                                           | 1679 |
| The gram-positive bacteria include organisms that cause and cure disease               | 1680 |
| Photosynthesis is widely distributed on the bacterial tree                             | 1681 |
| 24.5 Archaeal Diversity                                                                | 1685 |
| The archaeal tree has anaerobic, hyperthermophilic organisms near its base             | 1687 |
| The Archaea include several groups of acid-loving microorganisms                       | 1688 |
| Only Archaea produce methane as a by-product of energy metabolism                      | 1689 |
| One group of the Euryarchaeota thrives in extremely salty environments                 | 1690 |
| Thaumarchaeota may be the most abundant cells in the deep ocean                        | 1690 |
| How do we know? How abundant are archaeons in the oceans?                              | 1691 |
| 24.6 The Evolutionary History of Prokaryotes                                           | 1695 |
| Life originated early in our planet's history                                          | 1697 |
| Prokaryotes have coevolved with eukaryotes                                             | 1698 |
| How do intestinal bacteria influence human health?                                     | 1701 |
| Core Concepts Summary                                                                  | 1706 |
| Chapter 25 Eukaryotic Cells: Origins and Diversity                                     | 1711 |
| 25.1 A Review of the Eukaryotic Cell                                                   | 1714 |
| Internal protein scaffolding and dynamic membranes organize the eukaryotic cell        | 1715 |
| In eukaryotic cells, energy metabolism is localized in mitochondria and chloroplasts   | 1717 |
| The organization of the eukaryotic genome also helps explain eukaryotic diversity      | 1719 |
| Sex promotes genetic diversity in eukaryotes and gives rise to distinctive life cycles | 1720 |
| 25.2 Eukaryotic Origins                                                                | 1725 |
| What role did symbiosis play in the origin of chloroplasts?                            | 1725 |
| How do we know? What is the evolutionary origin of                                     | 1727 |

|                                                                                               |      |
|-----------------------------------------------------------------------------------------------|------|
| What role did symbiosis play in the origin of mitochondria?                                   | 1731 |
| How did the eukaryotic cell originate?                                                        | 1733 |
| In the oceans, many single-celled eukaryotes harbor symbiotic bacteria                        | 1737 |
| 25.3 Eukaryotic Diversity                                                                     | 1741 |
| Our own group, the opisthokonts, is the most diverse eukaryotic superkingdom                  | 1744 |
| Amoebozoans include slime molds that produce multicellular structures                         | 1747 |
| Archaeplastids, which include land plants, are photosynthetic organisms                       | 1751 |
| Stramenopiles, alveolates, and rhizarians dominate eukaryotic diversity in the oceans         | 1755 |
| Photosynthesis spread through eukaryotes by repeated endosymbioses involving eukaryotic algae | 1761 |
| How do we know? How did photosynthesis spread through the Eukarya?                            | 1761 |
| 25.4 The Fossil Record of Protists                                                            | 1768 |
| Fossils show that eukaryotes existed at least 1800 million years ago                          | 1768 |
| Protists have continued to diversify during the age of animals                                | 1771 |
| Core Concepts Summary                                                                         | 1774 |
| Chapter 26 Being Multicellular                                                                | 1778 |
| 26.1 The Phylogenetic Distribution of Multicellular Organisms                                 | 1781 |
| Simple multicellularity is widespread among eukaryotes                                        | 1781 |
| Complex multicellularity evolved several times                                                | 1785 |
| 26.2 Diffusion and Bulk Flow                                                                  | 1790 |
| Diffusion is effective only over short distances                                              | 1790 |
| Animals achieve large size by circumventing limits imposed by diffusion                       | 1791 |
| Complex multicellular organisms have structures specialized for bulk flow                     | 1793 |
| 26.3 How to Build a Multicellular Organism                                                    | 1796 |

|                                                                                                                   |      |
|-------------------------------------------------------------------------------------------------------------------|------|
| 26.3 How to Build a Multicellular Organism                                                                        | 1796 |
| Complex multicellularity requires adhesion between cells                                                          | 1796 |
| How did animal cell adhesion originate?                                                                           | 1797 |
| How do we know? How do bacteria influence the life cycles of choanoflagellates?                                   | 1798 |
| Complex multicellularity requires communication between cells                                                     | 1800 |
| Complex multicellularity requires a genetic program for coordinated growth and cell differentiation               | 1803 |
| 26.4 Plants Versus Animals                                                                                        | 1808 |
| Cell walls shape patterns of growth and development in plants                                                     | 1808 |
| Animal cells can move relative to one another                                                                     | 1811 |
| 26.5 The Evolution of Complex Multicellularity                                                                    | 1814 |
| Fossil evidence of complex multicellular organisms is first observed in rocks deposited 575–555 million years ago | 1815 |
| Oxygen is necessary for complex multicellular life                                                                | 1818 |
| Land plants evolved from green algae that could carry out photosynthesis on land                                  | 1820 |
| Regulatory genes played an important role in the evolution of complex multicellular organisms                     | 1822 |
| How do we know? What controls color pattern in butterfly wings?                                                   | 1824 |
| Core Concepts Summary                                                                                             | 1827 |
| Case 6 Agriculture, Feeding a Growing Population                                                                  | 1831 |
| Chapter 27 Plant Form, Function, and Evolutionary History                                                         | 1839 |
| 27.1 Photosynthesis on Land                                                                                       | 1842 |
| Land plants share many cellular features with green algae                                                         | 1842 |
| Bryophytes rely on surface water for hydration                                                                    | 1845 |
| Water pulled from the soil moves through vascular plants by bulk flow                                             | 1847 |
| Vascular plants produce four major organ types                                                                    | 1848 |
| 27.2 Carbon Dioxide Gain and Water Loss                                                                           | 1852 |
| CO <sub>2</sub> uptake results in water loss                                                                      | 1852 |
| The cuticle restricts water loss from leaves but inhibits                                                         |      |

|                                                                                              |      |
|----------------------------------------------------------------------------------------------|------|
| Stomata allow leaves to regulate water loss and carbon gain                                  | 1857 |
| CAM plants use nocturnal CO <sub>2</sub> storage to avoid water loss during the day          | 1859 |
| C4 plants suppress photorespiration by concentrating CO <sub>2</sub> in bundle-sheath cells  | 1861 |
| How do we know? Does C4 photosynthesis suppress photorespiration?                            | 1865 |
| 27.3 Water Transport                                                                         | 1868 |
| Xylem provides a low-resistance pathway for the movement of water                            | 1869 |
| Water is pulled through xylem by an evaporative pump                                         | 1874 |
| How do we know? Do plants generate negative pressures?                                       | 1875 |
| Xylem transport is at risk of conduit collapse and cavitation                                | 1881 |
| 27.4 Transport of Carbohydrates                                                              | 1885 |
| Phloem transports carbohydrates from sources to sinks                                        | 1885 |
| Carbohydrates are pushed through phloem by an osmotic pump                                   | 1888 |
| Phloem feeds both the plant and the rhizosphere                                              | 1891 |
| 27.5 Uptake of Water and Nutrients                                                           | 1893 |
| Plants obtain nutrients from the soil                                                        | 1894 |
| Nutrient uptake by roots is highly selective                                                 | 1896 |
| Nutrient uptake requires energy                                                              | 1899 |
| Mycorrhizae enhance nutrient uptake                                                          | 1900 |
| Symbiotic nitrogen-fixing bacteria supply nitrogen to both plants and ecosystems             | 1902 |
| How has nitrogen availability influenced agricultural productivity?                          | 1905 |
| Core Concepts Summary                                                                        | 1909 |
| Chapter 28 Plant Reproduction: Finding Mates and Dispersing Young                            | 1913 |
| 28.1 Alternation of Generations                                                              | 1916 |
| The algal sister groups of land plants have one multicellular generation in their life cycle | 1917 |

|                                                                                                                                    |      |
|------------------------------------------------------------------------------------------------------------------------------------|------|
| The algal sister groups of land plants have one multicellular generation in their life cycle                                       | 1917 |
| Land plants have two multicellular generations in their life cycle                                                                 | 1919 |
| Bryophytes illustrate how the alternation of generations allows the dispersal of spores in the air                                 | 1922 |
| Dispersal enhances reproductive fitness in several ways                                                                            | 1924 |
| Spore-dispersing vascular plants have free-living gametophytes and sporophytes                                                     | 1925 |
| 28.2 Seed Plants                                                                                                                   | 1929 |
| The seed plant life cycle is distinguished by four major steps                                                                     | 1930 |
| Pine trees illustrate how the transport of pollen in air allows fertilization to occur in the absence of external sources of water | 1932 |
| Seeds enhance the establishment of the next sporophyte generation                                                                  | 1935 |
| 28.3 Flowering Plants                                                                                                              | 1939 |
| Flowers are reproductive shoots specialized for the transfer and receipt of pollen                                                 | 1939 |
| The diversity of floral morphology is related to modes of pollination                                                              | 1944 |
| How do we know? How do long nectar spurs evolve?                                                                                   | 1947 |
| Angiosperms have mechanisms to increase outcrossing                                                                                | 1951 |
| Angiosperms delay provisioning their ovules until after fertilization                                                              | 1953 |
| Fruits enhance the dispersal of seeds                                                                                              | 1956 |
| How did scientists increase crop yields during the Green Revolution?                                                               | 1960 |
| 28.4 Asexual Reproduction                                                                                                          | 1963 |
| Asexually produced plants disperse with and without seeds                                                                          | 1963 |
| Core Concepts Summary                                                                                                              | 1966 |
| Chapter 29 Plant Growth and Development                                                                                            | 1969 |
| 29.1 Shoot Growth and Development                                                                                                  | 1972 |
| Stems grow by adding new cells at their tips                                                                                       | 1973 |

|                                                                                                                           |      |
|---------------------------------------------------------------------------------------------------------------------------|------|
| Stems branch by producing new apical meristems                                                                            | 1976 |
| The shoot apical meristem controls the production and arrangement of leaves                                               | 1977 |
| Young leaves develop vascular connections to the stem                                                                     | 1983 |
| Flower development terminates the growth of shoot meristems                                                               | 1985 |
| 29.2 Plant Hormones                                                                                                       | 1987 |
| Hormones affect the growth and differentiation of plant cells                                                             | 1987 |
| Polar transport of auxin guides the placement of leaf primordia and the development of vascular connections with the stem | 1991 |
| What is the developmental basis for the shorter stems of high-yielding rice and wheat?                                    | 1995 |
| Cytokinins, in combination with other hormones, control the outgrowth of branches                                         | 1996 |
| 29.3 Secondary Growth                                                                                                     | 2000 |
| Shoots produce two types of lateral meristem                                                                              | 2000 |
| The vascular cambium produces secondary xylem and phloem                                                                  | 2001 |
| The cork cambium produces an outer protective layer                                                                       | 2005 |
| Wood has both support and transport functions                                                                             | 2007 |
| 29.4 Root Growth and Development                                                                                          | 2010 |
| Roots grow by producing new cells at their tips                                                                           | 2010 |
| Root elongation and vascular development are coordinated                                                                  | 2012 |
| The formation of new root apical meristems allows roots to branch                                                         | 2014 |
| The structures and functions of root systems are diverse                                                                  | 2016 |
| 29.5 The Environmental Context of Growth and Development                                                                  | 2019 |
| Plants orient the growth of their stems and roots by light and gravity                                                    | 2019 |
| How do we know? How do plants grow toward light?                                                                          | 2020 |
| Seeds can delay germination if they detect the presence of plants overhead                                                | 2026 |

|                                                                                      |      |
|--------------------------------------------------------------------------------------|------|
| plants overhead                                                                      | 2026 |
| How do we know? How do seeds detect the presence of plants growing overhead?         | 2027 |
| Plants grow taller and branch less when growing in the shade of other plants         | 2031 |
| Roots elongate more and branch less when water is scarce                             | 2033 |
| Exposure to wind results in shorter and stronger stems                               | 2034 |
| 29.6 Timing of Developmental Events                                                  | 2036 |
| Flowering time is affected by day length                                             | 2036 |
| Plants use their internal circadian clock and photoreceptors to determine day length | 2039 |
| Vernalization prevents plants from flowering until winter has passed                 | 2041 |
| Plants use day length as a cue to prepare for winter                                 | 2042 |
| Core Concepts Summary                                                                | 2044 |
| Chapter 30 Plant Defense                                                             | 2049 |
| 30.1 Protection Against Pathogens                                                    | 2052 |
| Plant pathogens infect and exploit host plants by a variety of mechanisms            | 2053 |
| Plants are able to detect and respond to pathogens                                   | 2056 |
| Plants respond to infections by isolating infected regions                           | 2059 |
| Mobile signals trigger defenses in uninfected tissues                                | 2061 |
| How do we know? Can plants develop immunity to specific pathogens?                   | 2062 |
| Plants defend against viral infections by producing siRNA                            | 2064 |
| A pathogenic bacterium provides a way to modify plant genomes                        | 2066 |
| 30.2 Defense Against Herbivores                                                      | 2069 |
| Plants use mechanical and chemical defenses to avoid being eaten                     | 2069 |
| Diverse chemical compounds deter herbivores                                          | 2073 |
| Some plants provide food and shelter for ants, which actively defend them            | 2076 |
| Grasses can regrow quickly following grazing by                                      |      |

|                                                                                                         |      |
|---------------------------------------------------------------------------------------------------------|------|
| 30.3 Allocating Resources to Defense                                                                    | 2082 |
| Some defenses are always present, whereas others are turned on in response to a threat                  | 2082 |
| Plants can sense and respond to herbivores                                                              | 2083 |
| Plants produce volatile signals that attract insects that prey upon herbivores                          | 2086 |
| How do we know? Can plants communicate?                                                                 | 2087 |
| Nutrient-rich environments select for plants that allocate more resources to growth than to defense     | 2088 |
| Exposure to multiple threats can lead to trade-offs                                                     | 2091 |
| 30.4 Defense and Plant Diversity                                                                        | 2093 |
| The evolution of new defenses may allow plants to diversify                                             | 2094 |
| Pathogens, herbivores, and seed predators can increase plant diversity                                  | 2095 |
| Can modifying plants genetically protect crops from herbivores and pathogens?                           | 2097 |
| Core Concepts Summary                                                                                   | 2103 |
| Chapter 31 Plant Diversity                                                                              | 2107 |
| 31.1 Major Themes in the Evolution of Plant Diversity                                                   | 2110 |
| Four major transformations in life cycle and structure characterize the evolutionary history of plants  | 2111 |
| Plant diversity has changed over time                                                                   | 2115 |
| 31.2 Bryophytes                                                                                         | 2119 |
| Bryophytes are small and tough                                                                          | 2119 |
| The small gametophytes and unbranched sporophytes of bryophytes are adaptations for reproducing on land | 2122 |
| Bryophytes exhibit several cases of convergent evolution with the vascular plants                       | 2124 |
| Sphagnum moss plays an important role in the global carbon cycle                                        | 2125 |
| 31.3 Spore-Dispersing Vascular Plants                                                                   | 2129 |
| Rhynie chert fossils provide a window into the early evolution of vascular plants                       | 2130 |
| Lycophytes evolved leaves and roots independently from all other vascular plants                        | 2132 |

|                                                                                                           |      |
|-----------------------------------------------------------------------------------------------------------|------|
| Lycophytes evolved leaves and roots independently from all other vascular plants                          | 2132 |
| Ancient lycophytes included giant trees that dominated coal swamps about 320 million years ago            | 2134 |
| Ferns and horsetails are morphologically and ecologically diverse                                         | 2139 |
| How do we know? Did woody plants evolve more than once?                                                   | 2135 |
| Fern diversity has been strongly affected by the evolution of angiosperms                                 | 2142 |
| 31.4 Gymnosperms                                                                                          | 2144 |
| Seed plants have been the dominant plants on land for more than 200 million years                         | 2145 |
| Cycads and ginkgos were once both diverse and widespread                                                  | 2147 |
| Conifers are woody plants that thrive in dry and cold climates                                            | 2149 |
| Gnetophytes are gymnosperms that have independently evolved xylem vessels and double fertilization        | 2152 |
| 31.5 Angiosperms                                                                                          | 2154 |
| Several innovations increased the efficiency of the angiosperm life cycle and xylem transport             | 2154 |
| Angiosperm diversity may result in part from coevolutionary interactions with animals and other organisms | 2156 |
| Monocots are diverse in shape and size despite not forming a vascular cambium                             | 2160 |
| How do we know? When did grasslands expand over the land surface?                                         | 2164 |
| Eudicots are the most diverse group of angiosperms                                                        | 2166 |
| What can be done to protect the genetic diversity of crop species?                                        | 2170 |
| Visual Synthesis: Angiosperms: Structure and Function                                                     | 2173 |
| Core Concepts Summary                                                                                     | 2175 |
| Chapter 32 Fungi                                                                                          | 2180 |
| 32.1 Growth and Nutrition                                                                                 | 2183 |

|                                                                                                    |      |
|----------------------------------------------------------------------------------------------------|------|
| Fungi transport materials within their hyphae                                                      | 2185 |
| Not all fungi produce hyphae                                                                       | 2187 |
| Fungi are principal decomposers of plant tissues                                                   | 2188 |
| Fungi are important plant and animal pathogens                                                     | 2192 |
| Many fungi form symbiotic associations with plants and animals                                     | 2196 |
| Lichens are symbioses between a fungus and a green alga or a cyanobacterium                        | 2198 |
| 32.2 Reproduction                                                                                  | 2203 |
| Fungi proliferate and disperse using spores                                                        | 2203 |
| Multicellular fruiting bodies facilitate the dispersal of sexually produced spores                 | 2205 |
| Sexual reproduction in fungi often includes a stage in which haploid cells fuse, but nuclei do not | 2208 |
| How do we know? What determines the shape of fungal spores that are ejected into the air?          | 2207 |
| Genetically distinct mating types promote outcrossing                                              | 2212 |
| Parasexual fungi generate genetic diversity by asexual means                                       | 2213 |
| 32.3 Diversity                                                                                     | 2215 |
| Fungi are highly diverse                                                                           | 2215 |
| Chytrids are aquatic fungi that lack hyphae                                                        | 2217 |
| Zygomycetes produce hyphae undivided by septa                                                      | 2219 |
| Glomeromycetes form endomycorrhizae                                                                | 2221 |
| The Dikarya produce regular septa during mitosis                                                   | 2222 |
| Ascomycetes are the most diverse group of fungi                                                    | 2224 |
| Basidiomycetes include smuts, rusts, and mushrooms                                                 | 2230 |
| How do we know? Can a fungus influence the behavior of an ant?                                     | 2227 |
| How do fungi threaten global wheat production?                                                     | 2236 |
| Core Concepts Summary                                                                              | 2240 |
| Case 7: Biology-Inspired Design: Using Nature to Solve Problems                                    | 2243 |
| Chapter 33 Animal Form, Function, and Evolutionary History                                         | 2253 |
| 33.1 Animal Body Plans                                                                             | 2256 |

|                                                                                                         |      |
|---------------------------------------------------------------------------------------------------------|------|
| Chapter 33 Animal Form, Function, and Evolutionary History                                              | 2253 |
| 33.1 Animal Body Plans                                                                                  | 2256 |
| What is an animal?                                                                                      | 2256 |
| Animals can be classified based on type of symmetry                                                     | 2257 |
| Many animals have a brain and specialized sensory organs at the front of the body                       | 2261 |
| Some animals also show segmentation                                                                     | 2263 |
| Animals can be classified based on the number of their germ layers                                      | 2264 |
| Molecular sequence comparisons have confirmed some relationships and raised new questions               | 2268 |
| Can we mimic the form and function of animals to build robots?                                          | 2270 |
| 33.2 Tissues and Organs                                                                                 | 2273 |
| Most animals have four types of tissues                                                                 | 2274 |
| Tissues are organized into organs that carry out specific functions                                     | 2279 |
| 33.3 Homeostasis                                                                                        | 2281 |
| Homeostasis is the active maintenance of stable conditions inside of cells and organisms                | 2281 |
| Homeostasis is often achieved by negative feedback                                                      | 2283 |
| 33.4 Evolutionary History                                                                               | 2286 |
| Fossils and phylogeny show that animal forms were initially simple but rapidly evolved complexity       | 2287 |
| The animal body plans we see today emerged during the Cambrian Period                                   | 2288 |
| Five mass extinctions have changed the trajectory of animal evolution during the past 500 million years | 2290 |
| Animals began to colonize the land 420 million years ago                                                | 2293 |
| Some animals show a trend toward increased body size over time                                          | 2296 |
| How do we know? Do animals tend to get bigger over time?                                                | 2296 |
| Core Concepts Summary                                                                                   | 2301 |
| Chapter 34 Animal Nervous Systems                                                                       | 2304 |
| 34.1 Nervous System Function and Evolution                                                              | 2307 |

|                                                                                                                                                    |      |
|----------------------------------------------------------------------------------------------------------------------------------------------------|------|
| 34.2 Neuron Structure                                                                                                                              | 2314 |
| Neurons share a common organization                                                                                                                | 2314 |
| Neurons differ in size and shape                                                                                                                   | 2317 |
| Neurons are supported by other types of cells                                                                                                      | 2318 |
| 34.3 Signal Transmission                                                                                                                           | 2320 |
| The resting membrane potential is negative and results in part from the movement of potassium and sodium ions                                      | 2320 |
| Neurons are excitable cells that transmit information by action potentials                                                                         | 2323 |
| Neurons propagate action potentials along their axons by sequentially opening and closing adjacent Na <sup>+</sup> and K <sup>+</sup> ion channels | 2328 |
| How do we know? How does electrical activity change during an action potential?                                                                    | 2331 |
| Neurons communicate at synapses                                                                                                                    | 2333 |
| Signals between neurons can be excitatory or inhibitory                                                                                            | 2336 |
| 34.4 Nervous System Organization                                                                                                                   | 2340 |
| Nervous systems are organized into peripheral and central components                                                                               | 2340 |
| Peripheral nervous systems have voluntary and involuntary components                                                                               | 2342 |
| Simple reflex circuits provide rapid responses to stimuli                                                                                          | 2345 |
| 34.5 Sensory Systems                                                                                                                               | 2349 |
| Sensory receptor cells detect diverse stimuli                                                                                                      | 2349 |
| Sensory transduction converts a stimulus into an electrical impulse                                                                                | 2350 |
| Chemoreceptors respond to chemical stimuli                                                                                                         | 2352 |
| Mechanoreceptors detect physical forces                                                                                                            | 2355 |
| How do cochlear implants work?                                                                                                                     | 2360 |
| Electromagnetic receptors sense light                                                                                                              | 2361 |
| 34.6 Brain Organization and Function                                                                                                               | 2368 |
| The brain processes and integrates information received from different sensory systems                                                             | 2368 |
| The brain is divided into lobes with specialized functions                                                                                         | 2370 |
| Information is topographically mapped into the vertebrate                                                                                          |      |

|                                                                                                     |      |
|-----------------------------------------------------------------------------------------------------|------|
| The brain is divided into lobes with specialized functions                                          | 2370 |
| Information is topographically mapped into the vertebrate cerebral cortex                           | 2372 |
| The brain allows for memory, learning, and cognition                                                | 2374 |
| Core Concepts Summary                                                                               | 2377 |
| Chapter 35 Animal Movement: Muscles and Skeletons                                                   | 2382 |
| 35.1 How Muscles Work                                                                               | 2385 |
| Muscles use chemical energy to produce force and movement                                           | 2386 |
| Muscles can be striated or smooth                                                                   | 2387 |
| Skeletal and cardiac muscle fibers are organized into repeating contractile units called sarcomeres | 2388 |
| Muscles contract by the sliding of myosin and actin protein filaments                               | 2392 |
| Calcium regulates actin–myosin interaction through excitation–contraction coupling                  | 2397 |
| Calmodulin regulates calcium activation and relaxation of smooth muscle                             | 2400 |
| 35.2 Muscle Contractile Properties                                                                  | 2403 |
| Antagonist pairs of muscles produce reciprocal motions at a joint                                   | 2403 |
| How do we know? How does actin-myosin filament overlap affect force generation in muscles?          | 2405 |
| Muscle length affects actin–myosin overlap and generation of force                                  | 2405 |
| Muscle force and shortening velocity are inversely related                                          | 2408 |
| Muscle force is summed by an increase in stimulation frequency and the recruitment of motor units   | 2411 |
| Skeletal muscles have slow-twitch and fast-twitch fibers                                            | 2414 |
| How do different types of muscle fibers affect the speed of animals?                                | 2417 |
| 35.3 Animal Skeletons                                                                               | 2420 |
| Hydrostatic skeletons support animals by muscles that act on a fluid-filled cavity                  | 2420 |
| Exoskeletons provide hard external support and protection                                           | 2423 |

|                                                                                                                            |      |
|----------------------------------------------------------------------------------------------------------------------------|------|
| 35.4 Vertebrate Skeletons                                                                                                  | 2431 |
| Vertebrate bones form directly or by forming a cartilage model first                                                       | 2431 |
| The two main types of bone are compact bone and spongy bone                                                                | 2433 |
| Bones grow in length and width, and can be repaired                                                                        | 2434 |
| Can we design smart materials to heal bones that are damaged and improve artificial joints?                                | 2436 |
| Joint shape determines range of motion and skeletal muscle organization                                                    | 2437 |
| Core Concepts Summary                                                                                                      | 2440 |
| Chapter 36 Animal Endocrine Systems                                                                                        | 2444 |
| 36.1 Endocrine Function                                                                                                    | 2447 |
| The endocrine system helps to regulate an organism's response to its environment                                           | 2447 |
| The endocrine system regulates growth and development                                                                      | 2448 |
| How do we know? How are growth and development controlled in insects?                                                      | 2450 |
| The endocrine system underlies homeostasis                                                                                 | 2455 |
| 36.2 Hormones                                                                                                              | 2462 |
| Hormones act specifically on cells that bind the hormone                                                                   | 2462 |
| Two main classes of hormones are peptide and amines, and steroid hormones                                                  | 2463 |
| Hormonal signals are amplified to produce a strong effect                                                                  | 2470 |
| Hormones are evolutionarily conserved molecules with diverse functions                                                     | 2473 |
| 36.3 The Vertebrate Endocrine System                                                                                       | 2475 |
| The pituitary gland integrates diverse bodily functions by secreting hormones in response to signals from the hypothalamus | 2475 |
| Many targets of pituitary hormones are endocrine tissues that also secrete hormones                                        | 2480 |
| Other endocrine organs have diverse functions                                                                              | 2483 |
| The fight-or-flight response represents a change in set point in many different organs                                     | 2485 |

|                                                                                                                  |      |
|------------------------------------------------------------------------------------------------------------------|------|
| point in many different organs                                                                                   |      |
| 36.4 Other Forms of Chemical Communication                                                                       | 2489 |
| Local chemical signals regulate neighboring target cells                                                         | 2489 |
| Pheromones are chemical compounds released into the environment that signal physiological and behavioral changes | 2492 |
| Core Concepts Summary                                                                                            | 2498 |
| Chapter 37 Animal Cardiovascular and Respiratory Systems                                                         | 2502 |
| 37.1 Delivery of Oxygen and Elimination of Carbon Dioxide                                                        | 2505 |
| Diffusion governs gas exchange over short distances                                                              | 2505 |
| Bulk flow moves fluid over long distances                                                                        | 2508 |
| 37.2 Respiratory Gas Exchange                                                                                    | 2512 |
| Many aquatic animals breathe through gills                                                                       | 2514 |
| Insects breathe air through tracheae                                                                             | 2519 |
| Most terrestrial vertebrates breathe by tidal ventilation of internal lungs                                      | 2521 |
| Mammalian lungs are well adapted for gas exchange                                                                | 2523 |
| The structure of bird lungs allows unidirectional airflow for increased oxygen uptake                            | 2526 |
| Voluntary and involuntary mechanisms control breathing                                                           | 2528 |
| 37.3 Oxygen Transport by Hemoglobin                                                                              | 2531 |
| Blood is composed of fluid and several types of cell                                                             | 2531 |
| Hemoglobin is an ancient molecule with diverse roles related to oxygen binding and transport                     | 2533 |
| Hemoglobin reversibly binds oxygen                                                                               | 2534 |
| How do we know? What is the molecular structure of hemoglobin and myoglobin?                                     | 2535 |
| Myoglobin stores oxygen, enhancing oxygen delivery to muscle mitochondria                                        | 2538 |
| Many factors affect hemoglobin–oxygen binding                                                                    | 2540 |
| 37.4 Circulatory Systems                                                                                         | 2543 |
| Circulatory systems have vessels of different sizes                                                              | 2546 |
| Arteries are muscular vessels that carry blood away from the heart under high pressure                           | 2548 |

|                                                                                                    |      |
|----------------------------------------------------------------------------------------------------|------|
| Compounds and fluid move across capillary walls by diffusion, filtration, and osmosis              | 2551 |
| Hormones and nerves provide homeostatic regulation of blood pressure                               | 2553 |
| 37.5 Structure and Function of the Heart                                                           | 2555 |
| Fishes have two-chambered hearts and a single circulatory system                                   | 2556 |
| Amphibians and reptiles have three-chambered hearts and partially divided circulations             | 2557 |
| Mammals and birds have four-chambered hearts and fully divided pulmonary and systemic circulations | 2559 |
| How can we engineer replacement heart valves?                                                      | 2562 |
| Cardiac muscle cells are electrically connected to contract in synchrony                           | 2564 |
| Heart rate and cardiac output are regulated by the autonomic nervous system                        | 2567 |
| Core Concepts Summary                                                                              | 2570 |
| Chapter 38 Animal Metabolism, Nutrition, and Digestion                                             | 2575 |
| 38.1 Patterns of Animal Metabolism                                                                 | 2578 |
| Animals rely on anaerobic and aerobic metabolism                                                   | 2578 |
| Metabolic rate varies with activity level                                                          | 2582 |
| Metabolic rate is affected by body size                                                            | 2585 |
| Metabolic rate is linked to body temperature                                                       | 2589 |
| How do we know? How is metabolic rate affected by running speed and body size?                     | 2587 |
| Visual Synthesis: Homeostasis and Thermoregulation                                                 | 2591 |
| 38.2 Nutrition and Diet                                                                            | 2592 |
| Energy balance is a form of homeostasis                                                            | 2592 |
| An animal's diet must supply nutrients that it cannot synthesize                                   | 2594 |
| 38.3 Adaptations for Feeding                                                                       | 2600 |
| Suspension filter feeding is common in many aquatic animals                                        | 2600 |
| Large aquatic animals apprehend prey by suction feeding and active swimming                        | 2601 |

|                                                                                               |      |
|-----------------------------------------------------------------------------------------------|------|
| and active swimming                                                                           | 2601 |
| Specialized structures allow for capture and mechanical breakdown of food                     | 2603 |
| 38.4 Regional Specialization of the Gut                                                       | 2608 |
| Most animal digestive tracts have three main parts: a foregut, midgut, and hindgut            | 2609 |
| Digestion begins in the mouth                                                                 | 2611 |
| Further digestion and storage of nutrients take place in the stomach                          | 2613 |
| Final digestion and nutrient absorption take place in the small intestine                     | 2616 |
| The large intestine absorbs water and stores waste                                            | 2622 |
| The lining of the digestive tract is composed of distinct layers                              | 2623 |
| Plant-eating animals have specialized digestive tracts adapted to their diets                 | 2625 |
| Core Concepts Summary                                                                         | 2630 |
| Chapter 39 Animal Renal Systems: Water and Waste                                              | 2633 |
| 39.1 Water and Electrolyte Balance                                                            | 2636 |
| Osmosis governs the movement of water across cell membranes                                   | 2636 |
| Osmoregulation is the control of osmotic pressure inside cells and organisms                  | 2639 |
| Osmoconformers match their internal solute concentration to that of the environment           | 2642 |
| Osmoregulators have internal solute concentrations that differ from that of their environment | 2643 |
| 39.2 Excretion of Wastes                                                                      | 2650 |
| The excretion of nitrogenous wastes is linked to an animal's habitat and evolutionary history | 2650 |
| Excretory organs work by filtration, reabsorption and secretion                               | 2654 |
| Animals have diverse excretory organs                                                         | 2658 |
| Vertebrates filter blood under pressure through paired kidneys                                | 2662 |

|                                                                                                                         |      |
|-------------------------------------------------------------------------------------------------------------------------|------|
| medulla                                                                                                                 | 2669 |
| Glomerular filtration isolates wastes carried by the blood along with water and small solutes                           | 2670 |
| The proximal convoluted tubule reabsorbs solutes by active transport                                                    | 2672 |
| The loop of Henle acts as a countercurrent multiplier to create a concentration gradient from the cortex to the medulla | 2673 |
| How do we know? How does the mammalian kidney produce concentrated urine?                                               | 2678 |
| The distal convoluted tubule secretes additional wastes                                                                 | 2680 |
| The final concentration of urine is determined in the collecting ducts and is under hormonal control                    | 2681 |
| The kidneys help regulate blood pressure and blood volume                                                               | 2683 |
| How does dialysis work?                                                                                                 | 2686 |
| Core Concepts Summary                                                                                                   | 2689 |
| Chapter 40 Animal Reproduction and Development                                                                          | 2692 |
| 40.1 The Evolutionary History of Reproduction                                                                           | 2695 |
| Asexual reproduction produces clones                                                                                    | 2695 |
| Sexual reproduction involves the formation and fusion of gametes                                                        | 2698 |
| Many species reproduce both sexually and asexually                                                                      | 2701 |
| Exclusive asexuality is often an evolutionary dead end                                                                  | 2702 |
| How do we know? Do bdelloid rotifers only reproduce asexually?                                                          | 2707 |
| 40.2 Movement onto Land and Reproductive Adaptations                                                                    | 2711 |
| Fertilization can take place externally or internally                                                                   | 2711 |
| r-strategists and K-strategists differ in number of offspring and parental care                                         | 2713 |
| Animals either lay eggs or give birth to live young                                                                     | 2715 |
| 40.3 Human Reproductive Anatomy and Physiology                                                                          | 2719 |
| The male reproductive system is specialized for the production and delivery of sperm                                    | 2719 |
| The female reproductive system produces eggs and                                                                        | 2724 |

|                                                                                   |      |
|-----------------------------------------------------------------------------------|------|
| The female reproductive system produces eggs and supports the developing embryo   | 2724 |
| Hormones regulate the human reproductive system                                   | 2728 |
| 40.4 Gamete Formation to Birth in Humans                                          | 2735 |
| Male and female gametogenesis have both shared and distinct features              | 2735 |
| Fertilization occurs when a sperm fuses with an oocyte                            | 2738 |
| The first trimester includes cleavage, gastrulation, and organogenesis            | 2741 |
| The second and third trimesters are characterized by fetal growth                 | 2748 |
| Childbirth is initiated by hormonal changes                                       | 2749 |
| Visual Synthesis: Reproduction and Development                                    | 2752 |
| Core Concepts Summary                                                             | 2754 |
| Chapter 41 Animal Immune Systems                                                  | 2759 |
| 41.1 An Overview of the Immune System                                             | 2762 |
| Pathogens cause disease                                                           | 2763 |
| The immune system distinguishes self from nonself                                 | 2764 |
| The immune system consists of innate and adaptive immunity                        | 2766 |
| 41.2 Innate Immunity                                                              | 2768 |
| The skin and mucous membranes provide the first line of defense against infection | 2768 |
| White blood cells provide a second line of defense against pathogens              | 2770 |
| Phagocytes recognize foreign molecules and send signals to other cells            | 2773 |
| Inflammation is a coordinated response to tissue injury                           | 2774 |
| The complement system participates in the innate and adaptive immune systems      | 2777 |
| How can we use a protein that circulates in the blood to treat sepsis?            | 2780 |
| 41.3 B Cells and Antibodies                                                       | 2783 |
| B cells produce antibodies                                                        | 2785 |
| Mammals produce five classes of antibodies with                                   | 2787 |

|                                                                                                                                      |      |
|--------------------------------------------------------------------------------------------------------------------------------------|------|
| Clonal selection is the basis for antibody specificity                                                                               | 2788 |
| Clonal selection explains immunological memory                                                                                       | 2791 |
| How do we know? How is antibody diversity generated?                                                                                 | 2794 |
| Genomic rearrangement generates antibody diversity                                                                                   | 2793 |
| 41.4 T Cells and Cell-Mediated Immunity                                                                                              | 2801 |
| T cells include helper and cytotoxic cells                                                                                           | 2802 |
| T cells have T cell receptors on their surface that recognize an antigen in association with MHC proteins                            | 2802 |
| The ability to distinguish between self and nonself is acquired during T cell maturation                                             | 2807 |
| 41.5 Three Pathogens                                                                                                                 | 2811 |
| The flu virus evades the immune system by antigenic drift and shift                                                                  | 2811 |
| Tuberculosis is caused by a slow-growing, intracellular bacterium                                                                    | 2815 |
| The malaria parasite changes surface molecules by antigenic variation                                                                | 2817 |
| Core Concepts Summary                                                                                                                | 2820 |
| Chapter 42 Animal Diversity                                                                                                          | 2824 |
| 42.1 Sponges, Cnidarians, Ctenophores, and Placozoans                                                                                | 2827 |
| Sponges share some features with choanoflagellates but also exhibit adaptations conferred by multicellularity                        | 2830 |
| Cnidarians are the architects of life's largest constructions: coral reefs                                                           | 2834 |
| Ctenophores and placozoans represent the extremes of body organization among phyla that branch from early nodes on the animal tree   | 2840 |
| Branching relationships among early nodes on the animal tree remain uncertain                                                        | 2843 |
| 42.2 Protostome Animals                                                                                                              | 2846 |
| Lophotrochozoans account for nearly half of all animal phyla, including the diverse and ecologically important annelids and mollusks | 2847 |
| Ecdysozoans are animals that episodically molt their external cuticle during growth                                                  | 2856 |
| 42.3 Arthropods                                                                                                                      | 2861 |

|                                                                                                                           |      |
|---------------------------------------------------------------------------------------------------------------------------|------|
| 42.3 Arthropods                                                                                                           | 2861 |
| The Arthropoda is the most diverse animal phylum                                                                          | 2861 |
| How do we know? How did the diverse feeding structures of arthropods arise?                                               | 2861 |
| Insects make up the majority of all known animal species and have adaptations that allow them to live in diverse habitats | 2868 |
| 42.4 Deuterostome Animals                                                                                                 | 2872 |
| Hemichordates include acorn worms and pterobranchs, and echinoderms include sea stars and sea urchins                     | 2873 |
| Chordates include vertebrates, cephalochordates, and tunicates                                                            | 2877 |
| 42.5 Vertebrates                                                                                                          | 2881 |
| Fish are the most diverse vertebrate animals                                                                              | 2882 |
| The common ancestor of tetrapods had four limbs                                                                           | 2887 |
| Amniotes evolved terrestrial eggs                                                                                         | 2891 |
| Visual Synthesis: Diversity Through Time                                                                                  | 2896 |
| Core Concepts Summary                                                                                                     | 2898 |
| Case 8: Conserving Biodiversity: Rainforest and Coral Reef Hotspots                                                       | 2902 |
| Chapter 43 Behavior and Behavioral Ecology                                                                                | 2909 |
| 43.1 Tinbergen's Questions                                                                                                | 2912 |
| Tinbergen asked proximate and ultimate questions about behavior                                                           | 2912 |
| 43.2 Dissecting Behavior                                                                                                  | 2917 |
| The fixed action pattern is a stereotyped behavior                                                                        | 2917 |
| The nervous system processes stimuli and evokes behaviors                                                                 | 2920 |
| Hormones can trigger certain behaviors                                                                                    | 2922 |
| Breeding experiments can help determine the degree to which a behavior is genetic                                         | 2923 |
| Molecular techniques provide new ways of testing the role of genes in behavior                                            | 2926 |
| How do we know? Can the same gene influence behavior differently in different species?                                    | 2928 |

|                                                                                                                                   |      |
|-----------------------------------------------------------------------------------------------------------------------------------|------|
| Non-associative learning occurs without linking two events                                                                        | 2934 |
| Associative learning occurs when two events are linked                                                                            | 2935 |
| How do we know? To what extent are insects capable of learning?                                                                   | 2937 |
| Learning is an adaptation                                                                                                         | 2936 |
| 43.4 Information Processing                                                                                                       | 2942 |
| Orientation involves a directed response to a stimulus                                                                            | 2942 |
| Navigation is demonstrated by the remarkable ability of homing in birds                                                           | 2944 |
| Biological clocks provide important time cues for many behaviors                                                                  | 2944 |
| How do we know? Does a biological clock play a role in birds' ability to orient?                                                  | 2946 |
| 43.5 Communication                                                                                                                | 2950 |
| Communication is the transfer of information between a sender and a receiver                                                      | 2950 |
| Some forms of communication are complex and learned during a sensitive period                                                     | 2953 |
| Various forms of communication can convey specific information                                                                    | 2956 |
| 43.6 Social Behavior                                                                                                              | 2960 |
| Group selection is a weak explanation of altruistic behavior                                                                      | 2962 |
| Reciprocal altruism is one way that altruism can evolve                                                                           | 2963 |
| Kin selection is based on the idea that it is possible to contribute genetically to future generations by helping close relatives | 2964 |
| Core Concepts Summary                                                                                                             | 2971 |
| Chapter 44 Population Ecology                                                                                                     | 2975 |
| 44.1 Populations and Their Properties                                                                                             | 2978 |
| A population includes all the individuals of a species in a particular place                                                      | 2978 |
| Three key features of a population are its size, range, and density                                                               | 2979 |
| Ecologists estimate population size by sampling                                                                                   | 2984 |

|                                                                                                   |      |
|---------------------------------------------------------------------------------------------------|------|
| Three key features of a population are its size, range, and density                               | 2979 |
| Ecologists estimate population size by sampling                                                   | 2984 |
| How do we know? How many butterflies are there in a given population?                             | 2986 |
| 44.2 Population Growth and Decline                                                                | 2990 |
| Population size is affected by birth, death, immigration, and emigration                          | 2990 |
| Population size increases rapidly when the per capita growth rate is constant over time           | 2993 |
| Carrying capacity is the maximum number of individuals a habitat can support                      | 2999 |
| Logistic growth produces an S-shaped curve and describes the growth of many natural populations   | 3000 |
| Factors that influence population growth can be dependent on or independent of population density | 3002 |
| 44.3 Age-Structured Population Growth                                                             | 3006 |
| Birth and death rates vary with age and environment                                               | 3006 |
| Survivorship curves record changes in survival probability over an organism's life-span           | 3009 |
| Patterns of survivorship vary among organisms                                                     | 3012 |
| Reproductive patterns reflect the predictability of a species' environment                        | 3014 |
| The life history of an organism shows trade-offs among physiological functions                    | 3016 |
| 44.4 Metapopulation Dynamics                                                                      | 3020 |
| A metapopulation is a group of populations linked by immigrants                                   | 3020 |
| How do populations colonize islands?                                                              | 3025 |
| Core Concepts Summary                                                                             | 3030 |
| Chapter 45 Species interactions and Communities                                                   | 3033 |
| 45.1 The Niche                                                                                    | 3036 |
| The niche is a species' place in nature                                                           | 3036 |
| The realized niche of a species is more restricted than its fundamental niche                     | 3037 |
| Niches are shaped by evolutionary history                                                         | 3039 |

|                                                                                                               |      |
|---------------------------------------------------------------------------------------------------------------|------|
| Species compete for resources other than food                                                                 | 3043 |
| Competitive exclusion prevents two species from occupying the same niche at the same time                     | 3045 |
| Can competition drive species diversification?                                                                | 3048 |
| Predation, parasitism, and herbivory are interactions in which one species benefits at the expense of another | 3049 |
| How do we know? Can predators and prey coexist stably in certain environments?                                | 3051 |
| 45.3 Mutualistic Interactions                                                                                 | 3056 |
| Mutualisms are interactions between species that benefit both participants                                    | 3056 |
| Mutualisms may evolve increasing interdependence                                                              | 3058 |
| Digestive symbioses recycle plant material                                                                    | 3061 |
| How do we know? Have aphids and their symbiotic bacteria coevolved?                                           | 3059 |
| Mutualisms may be obligate or facultative                                                                     | 3063 |
| In some interactions, one partner is unaffected by the interaction                                            | 3064 |
| The costs and benefits of species interactions can change over time                                           | 3067 |
| 45.4 Communities                                                                                              | 3069 |
| Species that live in the same place make up communities                                                       | 3069 |
| How is biodiversity measured?                                                                                 | 3071 |
| Species influence each other in a complex web of interactions                                                 | 3074 |
| Keystone species have disproportionate effects on communities                                                 | 3075 |
| Disturbance can modify community composition                                                                  | 3079 |
| Succession describes the community response to new habitats or disturbance                                    | 3080 |
| Island biogeography explains species diversity on habitat islands                                             | 3084 |
| Visual Synthesis: Succession: Ecology in Microcosm                                                            | 3089 |
| Core Concepts Summary                                                                                         | 3091 |
| Chapter 46 Ecosystem Ecology                                                                                  | 3095 |
| 46.1 The Short-Term Carbon Cycle                                                                              | 3097 |

|                                                                                                                                         |      |
|-----------------------------------------------------------------------------------------------------------------------------------------|------|
| Chapter 46 Ecosystem Ecology                                                                                                            | 3095 |
| 46.1 The Short-Term Carbon Cycle                                                                                                        | 3097 |
| The Keeling curve records changing levels of carbon dioxide in the atmosphere over time                                                 | 3098 |
| Photosynthesis and respiration are key processes in short-term carbon cycling                                                           | 3101 |
| The regular oscillation of CO <sub>2</sub> reflects the seasonality of photosynthesis in the Northern Hemisphere                        | 3104 |
| Human activities play an important role in the modern carbon cycle                                                                      | 3104 |
| How do we know? How much CO <sub>2</sub> was in the atmosphere 1000 years ago?                                                          | 3105 |
| Carbon isotopes show that much of the CO <sub>2</sub> added to air over the past half century comes from burning fossil fuels           | 3108 |
| How do we know? What is the major source of the CO <sub>2</sub> that has accumulated in Earth's atmosphere over the past two centuries? | 3108 |
| 46.2 The Long-Term Carbon Cycle                                                                                                         | 3115 |
| Records of atmospheric composition over 400,000 years show periodic shifts in CO <sub>2</sub> levels                                    | 3115 |
| Reservoirs and fluxes are key in long-term carbon cycling                                                                               | 3119 |
| 46.3 Food Webs and Trophic Pyramids                                                                                                     | 3125 |
| Food webs trace carbon and other elements through communities and ecosystems                                                            | 3125 |
| Energy as well as carbon is transferred through ecosystems                                                                              | 3128 |
| 46.4 Other Biogeochemical Cycles                                                                                                        | 3134 |
| The nitrogen cycle is closely linked to the carbon cycle                                                                                | 3135 |
| Phosphorus cycles through ecosystems, supporting primary production                                                                     | 3137 |
| 46.5 The Ecological Framework of Biodiversity                                                                                           | 3140 |
| Biological diversity reflects the many ways that organisms participate in biogeochemical cycles                                         | 3140 |
| Biological diversity can influence primary production and therefore the biological carbon cycle                                         | 3142 |
| Biogeochemical cycles weave together biological                                                                                         |      |

|                                                                                                                                    |      |
|------------------------------------------------------------------------------------------------------------------------------------|------|
| How do we know? Does species diversity promote primary productivity?                                                               | 3143 |
| Visual Synthesis: Flow of Matter and Energy Through Ecosystems                                                                     | 3150 |
| Core Concepts Summary                                                                                                              | 3151 |
| Chapter 47 Climate and Biomes                                                                                                      | 3155 |
| 47.1 Climate                                                                                                                       | 3157 |
| The principal control on Earth's surface temperature is the angle at which solar radiation strikes the surface                     | 3157 |
| Heat is transported toward the poles by wind and ocean currents                                                                    | 3161 |
| Global circulation patterns determine patterns of rainfall, but topography also matters                                            | 3166 |
| 47.2 Biomes                                                                                                                        | 3170 |
| Terrestrial biomes reflect the distribution of climate                                                                             | 3171 |
| Aquatic biomes reflect climate, the availability of nutrients and oxygen, and the depth to which sunlight penetrates through water | 3194 |
| Marine biomes cover most of our planet's surface                                                                                   | 3198 |
| 47.3 Global Patterns                                                                                                               | 3207 |
| Global patterns of primary production reflect variations in climate and nutrient availability                                      | 3207 |
| How do we know? Does iron limit primary production in some parts of the oceans?                                                    | 3208 |
| Biodiversity is highest at the equator and lowest toward the poles                                                                 | 3213 |
| How do evolutionary and ecological history explain biodiversity?                                                                   | 3218 |
| Core Concepts Summary                                                                                                              | 3222 |
| Chapter 48 The Anthropocene: Humans as a Planetary Force                                                                           | 3224 |
| 48.1 The Anthropocene Epoch                                                                                                        | 3227 |
| Humans are a major force on the planet                                                                                             | 3227 |
| 48.2 Human Influence on the Carbon Cycle                                                                                           | 3232 |
| As atmospheric carbon dioxide levels have increased, so has mean surface temperature                                               | 3233 |
| Changing environments affect species distribution and                                                                              |      |

|                                                                                                                         |      |
|-------------------------------------------------------------------------------------------------------------------------|------|
| As atmospheric carbon dioxide levels have increased, so has mean surface temperature                                    | 3233 |
| Changing environments affect species distribution and community composition                                             | 3242 |
| How has global environmental change affected coral reefs around the world?                                              | 3249 |
| How do we know? How will rising twenty-first-century CO <sub>2</sub> levels affect coral reefs?                         | 3254 |
| What can be done?                                                                                                       | 3257 |
| 48.3 Human Influence on the Nitrogen and Phosphorus Cycles                                                              | 3262 |
| Nitrogen fertilizer transported to lakes and the sea causes eutrophication                                              | 3262 |
| Phosphate fertilizer is also used in agriculture, but has finite sources                                                | 3265 |
| 48.4 Human Influence on Evolution                                                                                       | 3271 |
| Human activities have reduced the quality and size of many habitats, decreasing the number of species they can support  | 3271 |
| Overexploitation threatens species and disrupts ecological relationships within communities                             | 3274 |
| Humans play an important role in the dispersal of species                                                               | 3276 |
| Humans have altered the selective landscape for many pathogens                                                          | 3279 |
| Are amphibians ecology's "canary in the coal mine"?                                                                     | 3282 |
| 48.5 Conservation Biology                                                                                               | 3286 |
| What are our conservation priorities?                                                                                   | 3287 |
| Conservation biologists have a diverse toolkit for confronting threats to biodiversity                                  | 3288 |
| Climate change provides new challenges for conservation biology in the twenty-first century                             | 3291 |
| Sustainable development provides a strategy for conserving biodiversity while meeting the needs of the human population | 3294 |
| 48.6 Scientists and Citizens in the Twenty-First Century                                                                | 3297 |
| Core Concepts Summary                                                                                                   | 3301 |
